We imagine that this "Old Cologne Gymnasium," thus referred to by v. Pettenkofer, is none other than the "mixed" (*simultan*) school described by Mr. Matthew Arnold under the name of the *Friedrich Wilhelm's Gymnasium* at Cologne, in his "Schools and Universities of the Continent," pp. 218-221; and but that more antagonism and less familiarity subsisted between North and South Germany six months ago than, we are happy to think, subsists now, we apprehend that more would have been made of the history of this institution by the Munich Professor. For Dr. Jaeger, the director of this mixed school, who, as he had been refused a nomination to another school, the Bielefeld Gymnasium, by the Education Minister, on account of his politics, cannot be suspected of reactionary leanings, spoke to Mr. Arnold in the following sense (see p. 221, *l. c.*): "It was the universal conviction with those competent to form an opinion, that the *Realschulen* were not at present successful institutions. He declared that the boys in the corresponding forms of the classical school beat the Realschule boys in matters which both do alike, such as history, geography, the mother tongue, and even French, though to French the Realschule boys devote far more time than their comrades of the classical school. The reason for this, Dr. Jaeger affirms, is that the classical training strengthens a boy's mind so much more. This is what, as I have already said, the chief school authorities everywhere in France and Germany testify. In Switzerland you do no hear the same story."

With regard to Switzerland, we learn from the Owens College Report above mentioned that Professor Zeuner of the Polytechnic School at Zurich, holds that the establishment of "Real Gymnasia," or High Schools of Science, to take equal rank with the old classical gymnasia, and to put pure and applied science on the same footing for educational purposes as that which the classics enjoy in these schools, is a desirable thing, but that he allows that by the introduction of a "bifurcation" system into the older schools they might be made equal to meeting all modern requirements. Helmholtz, on the other hand, may in the

* It may be well here to lay an English programme of school-work alongside of the two above given schedules of German school-work. A scheme to the following effect may be found as suggested by the Public School Commissioners, in their report, vol. i., 1864, pp. 34, 35:—

In an English public school of 39 hours per week—

11	hours	are to be assigned to	Classics, History, and Divinity (lessons)
10	,,	,,	,, ,, (preparation).
3	,,	,,	Arithmetic and Mathematics, *i.e.*, not less.
2	,,	,,	French and German (lessons).
	,,	,,	,, ,, (preparation).
	,,	,,	natural science (lessons).
	,,	,,	,, ,, (preparation).
	,,	,,	music and drawing.
	,,	,,	composition.

same report be found pleading strongly for "the foundation on equal terms of complete academic institutions for science" as a "counteraction of the tendency of classical men to lean on authority alone."

"Philological culture," says the eminent physiologist of Heidelberg, "has an ill effect on those who are to devote themselves to science; the philologist is too much dependent on authority and books, he cannot observe for himself, or rely upon his own conclusions, and having only been accustomed to consider the laws of grammar, all of which have their exceptions, he cannot understand the invariable character of physical laws." Granting with all respect the premises laid down by Professor Helmholtz, we should demur to the conclusion which he would base upon them, and profess ourselves unable to see that, because particular institutions had a tendency to dwarf and stunt particular faculties, they should therefore be left undisturbed to do this evil work uncounteracted. And still leaving the premises unimpugned, we should set up a cross-indictment to the effect that if classical studies left the student of them unacquainted with the invariability of natural laws, physical studies leave the student unacquainted with the variability of men's minds. But, so far as the business of life consists in having to do business and hold intercourse with our fellow-men, this acquaintance with the variability of men's minds is simply the particular kind of knowledge which is not only the most practically useful and marketable of all kinds of knowledge, but is precisely the kind which, by common consent, is allowed to characterise if not to constitute "culture."

Lord Lyttelton, however, and the Endowed Schools Commissioners would appear to be in favour of the establishment of locally distinct schools for the two sets of studies and of students, and herein to be at one with Helmholtz. The Owens College Delegates, on the other hand, are, like ourselves, in favour of a system of bifurcation, which would not necessarily keep apart persons of different mental conformation who might be much benefited by mutual contact. They have come to this conclusion mainly for reasons based on observations and testimony given in Germany. Our peculiar social organisation makes the question more complex for us; but we, too, have our experience as well as the Germans; and time has shown that an Englishman, whose reputation as an educationalist is equal to that of Helmholtz as a physicist, may, in this very matter, be as far wrong as we believe that great physicist to be. In 1864 Dr. Temple told the Public Commissioners (see Report, vol. ii., p. 312) that he should "not consider it wise to follow the Cheltenham and Marlborough examples by attaching to the public schools modern departments. The classical work would lose, the other work would not gain!" In 1867 we find a distinguished Rugby master, the Rev. J. M. Wilson, speaking to the following effect of the results produced by the changes set on foot in accordance with the proposals of the Public Schools Commissioners, and earnestly and honestly carried out. "Lastly, what are the general results of the introduction of scientific teaching in the opinion of the body of the masters? In brief it is this: that the school, as a whole, is better for it, and that the scholarship is not worse. . . . This is the testimony of classical masters, by no means specially favourable to science, who are in a position which enables them to judge. . . . It is believed that no master in Rugby School would wish to give up natural science and recur to the old curriculum."

G. ROLLESTON

PAMPHLETS ON METEOROLOGY AND MAGNETISM

Journal of the Scottish Meteorological Society. (Blackwood and Sons.)

The Normal Winds of Bombay. By C. Chambers, F.R.S

WE have received the *Journals* of the Scottish Meteorological Society from the beginning of 1867 to the end of last year, and we find them, on inspection, to be full of a variety of interesting and valuable matter.

The Scottish Society does not confine its attention to one particular branch of meteorology, but is broad in its sympathies as well as energetic in the development of its objects, and it is no doubt owing to this that so much is done with comparatively small means, and so much ground occupied with advantage. Among the numerous papers which constitute these journals we observe an address by that veteran agriculturist, the Marquis of Tweeddale, "On the effects of solar radiation in relation to crops." Anything on this subject is interesting from one who has himself grown wheat on the fields of India, and baked it into loaves which were duly distributed to his various sceptical friends.

We note with pleasure a proposal by the noble author for two experiments on the physiological branch of meteorology, firstly, What portion of the value of the sun's direct rays is due to heat, and what to light? and secondly, Whether the heat is of value as applied to the roots in the soil, or as regards its stimulating effects on the plant above ground?

The indefatigable secretary of the society, Mr. Alex. Buchan, contributes many interesting papers, and among them a series on the well-known interruptions in the regular rise and fall of temperature in the course of the year. Six cold and three warm periods are discussed and the author arrives at the following conclusion:—

"The unusually cold or warm periods which occur with considerable regularity at certain times of the year have, so far as we have examined them, been proved to depend on the relations of the polar and equatorial currents to each other. And the circumstance that one of these great atmospheric currents and not the other prevails over this portion of the earth's surface at stated seasons, is a valuable fact in meteorology, particularly in the light it seems to cast on the periodicity of weather changes."

In another memoir, Mr. Buchan discusses the cold weather of March 1867, which he attributes to the unprecedentedly high atmospheric pressure which prevailed in the north and north-west of Europe from the beginning to the 24th of the month.

Mr. Thomas Stevenson, in another very valuable and original paper, introduces the method of Barometric gradients as a means of ascertaining the intensity of storms. Very probably it may ultimately be found that we can measure a storm better by the Barometric differences which cause it than by the violence of the wind which constitutes it a storm, but the first step is surely to measure directly and accurately the intensity of storms considered as independent phenomena, and the second to trace the connection which subsists between storms and Barometric differences.

We have also in these journals papers on Ozone, from Dr. Mitchell and Prof. Crum Brown; and in the physiological branch of the science we have observations on crops, trees, birds, &c., besides an interesting paper by Dr. Mitchell, on the cause of some of the pernicious effects of polar winds.

Besides the *Journals* of the Scottish Meteorological Society, we have received two pamphlets written by Mr. Charles Chambers, Director of the Bombay Observatory, which are of much value to men of science as thoroughly scientific discussions of phenomena observed with instruments of precision. In one of these, entitled "The Normal Winds of Bombay," we have a full analysis of the climate of that part of India as far as the element of wind is concerned.

In another pamphlet by the same author, forming part of the *Transactions* of the Royal Society of London, we have the magnetic phenomena of Bombay discussed in a very able manner after the method first introduced by General Sir E. Sabine and followed now by most magneticians. If we have yet made little advance in assigning the causes of magnetic variations, we have at least in such pages as these a solid foundation upon which to build, and our progress in terrestrial magnetism in this respect contrasts favourably with what we have achieved in former years. BALFOUR STEWART

DONKIN'S ACOUSTICS

Acoustics: Theoretical. Part I. By W. F. Donkin, M.A., F.R.S., &c., Savilian Professor of Astronomy, Oxford. Pp. 202. (Clarendon Press, 1870.)

IF the Delegates of the Clarendon Press are able to carry out their programme, it will be possible before long for English students to learn Physics in their native language. Besides Thomson and Tait's "Natural Philosophy," which, if completed in the same way as it has been begun, will be a book for a nation to be proud of, they promise us a series of separate educational treatises on the several branches of Physics. Of these there are already published Dr. Balfour Stewart's excellent treatise on Heat, and the work mentioned at the head of this notice. This, unhappily, is only a fragment, forming part of the general theoretical introduction to a treatise on Sound and the principles of Music which the author did not live to write. But, although its quality is such as to make us keenly sensible of the loss which English science has suffered by the author's removal before he had completed the work, the part that is published treats of subjects of so fundamental a nature, and so little dependent on what would have followed them, that its intrinsic value is probably not much lessened by the absence of the remainder.

The first chapter begins with a general description of the mechanism of the ear; this is followed by an explanation of the mode of representing vibratory movements by periodic curves, and a discussion of the nature of pitch, and of the principle of the superposition of vibrations, as bearing upon the distinction between noises and musical sounds, and upon the general mode of perception of sounds by the ear. The second chapter is headed "Miscellaneous Definitions and Propositions," and is chiefly occupied with the mode of defining musical intervals, and with the statement of their most important relations. The third chapter treats of the analytical representation of simple harmonic vibrations, and of the composition of vibrations at right angles to each other. The fourth chapter treats of the properties of the *harmonic curve*, of the composition of harmonic curves, and of Fourier's Theorem. The fifth, sixth, and seventh chapters are devoted to the vibrations of elastic strings, the greater part of the sixth being occupied with the description and experimental treatment of the important subject of *forced oscillations*, and an appendix to the same chapter with the mathematical theory of them. The eighth chapter treats of the longitudinal vibrations; and the ninth and last, of the transverse vibrations of elastic rods. The greater part of the book is addressed to mathematical readers, but much of it may be read with profit by students whose mathematical acquirements are very moderate. The evidence throughout the work of the author's mastery of his subject gives to it a freshness and individuality which are in strong contrast to the characteristics of the undigested compilations which form so large a part of the literature of physics. C. FOSTER

OUR BOOK-SHELF

Daily Readings in Natural Science. By Rev. J. Robertson. (London: C. Bean. 1870.)

THIS book has been prepared for beginners in the study of Natural Science; it is clearly and pleasantly written; each day in the week during a term has its subject allotted to it, either on Natural History, Physics, Botany, Astronomy, Natural Phenomena, Chemistry, Geology, Manufactures, Animal Physiology, or Applied Chemistry. The chapters are short, with questions at the end of each for the use of teachers. Mr. Robertson has written several other similar books, which he uses in his own school, and his success as a teacher lends great weight to the following extract from the preface:—"It is hardly necessary to descant lengthily upon the advantage of introducing science teaching into schools. The author, however, may be pardoned for giving his experience of adding science to the usual course of studies among his own boys. The science classes in his school had not long been established before he found that those boys who took no interest in their ordinary work soon manifested a quickness and brightness in dealing with natural objects that was quite remarkable, so much so, that after the first three months he doubled the time devoted to science by the upper form, and commenced new classes for the benefit of the middle and lower forms. Speaking generally, the study of Natural Science quickens a boy's powers of observation and comparison; he learns to express his thoughts in proper logical order, his judgment is developed, and the tendency that all boys have to form hasty conclusions is checked and tempered." To these we may join the following practical hints on conveying scientific instruction to schoolboys, in a notice to teachers at the end of the book:—"To be of real use science must be taught practically. Experiment and deduction should go hand in hand, and a boy ought never to be called upon to commit a fact to memory the truth of which he has not previously seen demonstrated. This of course presupposes perfection in the way of apparatus and specimens, a state of things that may possibly exist some day at such magnificent centres of learning as Eton, Harrow, or Rugby, but the boy who by circumstances is obliged to pass his days at smaller establishments, must take for granted a large number of the facts with which he stores his memory. But the ingenious teacher will see a thousand ways of demonstrating facts to his pupils with the outlay of very little money or time. The short course of

Natural History given here should be supplemented by visits to the Zoological Gardens and the British Museum. Having gone through the first three lessons, the cleverest boy in the class, or the teacher himself, should note down the names of the different animals described, with their peculiarities; the notes might then be copied by each boy, or at any rate read out to them. The visit to the Gardens or Museum should next be paid, not with the idea of wandering about in a desultory manner, but with the object of testing the truth of the statements contained in the lessons. Half an hour with a rabbit's or sheep's head, the examination of the teeth of the cat or dog, will help wonderfully to develop a boy's love for Natural History. The lessons should if possible be illustrated by the skulls or skeletons of some of the smaller members of each order or class. Such specimens may be obtained at a cheap rate from Mr. Cutter, 35, Great Russell Street, Bloomsbury. The same principle may be followed with Astronomy." These extracts show that the book is the work of a practical man, and as such we commend it.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

Spontaneous Generation

PROF. WANKLYN says the opponents of spontaneous generation are placed in a dilemma by some new facts and arguments recently advanced in favour of the theory by Dr. C. Bastian, whose observations were only concluded in NATURE for July 14, 1870.

Prof. Wanklyn might have allowed the "opponents" a little more breathing time, and if his cause is really so strong, why so soon call attention to "other difficulties" under which they labour? These tactics compel me to remark that the spontaneous generation theory will gain nothing by being forced upon the attention. Like other doctrines it must stand or fall according as the facts on which it is based are confirmed or refuted. It matters not whether A or B is an advocate for or against. The question can be determined by observation and experiment only. It is of little importance though the theory be supported by the press or be believed in by a large section of the public. If it can be proved to be true it will be accepted, but the utmost notoriety it may be possible to gain for it cannot create conviction of its truth.

I confess to being an "opponent" of the doctrine but simply because I cannot admit that the evidence yet adduced is at all convincing; while it seems to me the very way in which the doctrine has been thrust forward is calculated to excite undeserved distrust. The attempts made to prepare our minds, as it were, for its reception, the frequent announcements that the proof is *coming*, the bolstering up, if I may use such a term, this doctrine appears to require—instead of promoting its reception, is only calculated to excite suspicion, which may be entirely undeserved. I, for one, am quite prepared to receive the facts adduced in favour of the doctrine, but am by no means disposed to accept immediately or unconditionally the inferences drawn therefrom.

Before I proceed to discuss the "dilemma" in which, according to Prof. Wanklyn, as an opponent of the doctrine, I am placed, I would suggest that figures of the different forms of organisms, supposed to be *spontaneously generated*, be published in NATURE, side by side, with a short description, reference to authority, and magnifying power. In this way we should see at a glance the different kinds of organisms which had been formed *de novo*, according to different authorities.

Some of the figures of Dr. Bastian, I confess, astonished me. To judge from the drawings and statements it would appear that a solution of tartrate of ammonia and phosphate of soda *in vacuo*, was a much more potent generator of life than a solution of boiled turnip or boiled hay. I was certainly very much surprised when I saw Figs. 11, 12, 13, 14, and 15. If the organisms represented in those drawings have been produced, as Dr. Bastian states, in saline solutions destitute of living germs *in vacuo*, the fact is, indeed, so very important and of such very great interest, that it would have been better, in my opinion, to have directed attention to it alone without mixing up the question of fact with Mr. Herbert Spencer's probabilities. The experiments are either sound or not. If the former they do not require the support or assistance of any *à priori* reasoning; if the latter, all the philosophical arguments that can be adduced will not procure their acceptance. Dr. Bastian could not have published his drawings without feeling that those at all familiar with such inquiries would be surprised—and those who support him must therefore not feel hurt at the reserve of "opponents," and because they do not write to the very next number of NATURE to declare themselves *convinced*, and ready to subscribe to the spontaneous generation doctrine and give it all the support in their power.

But indisposition on the part of many of us to accept immediately the inferences does not detract in the slightest degree from the acknowledgment of their importance. I for one, as I said before, am ready to accept them, but not yet, because, as far as I know, Dr. Bastian's results are exceptional, and the experiments may require repetition. Nor could I thus early make the inquiries that would be necessary concerning the details and the many little precautionary measures that are requisite, and which, for aught that appears, have been taken, without seeming to be offensive. But I cannot help saying here that many of the preliminary remarks, and many observations in the notes, and much of the argument, are calculated rather to prejudice the mind against the conclusions sought to be established by experiment.

All the arguments hitherto adduced in favour of spontaneous generation fail to convince. Neither Mr. Herbert Spencer nor Mr. J. S. Mill himself could convince any man acquainted with the facts of the case, that heterogenesis really occurs in these days. At the same time a very strong case—nay, a case certain to convince anyone who was not practically acquainted with the matter—might be made. Such a case has indeed many times been made, and has produced a vast number of converts, some of whom have afterwards fallen away from the faith, and have been led to believe in another view. Many things *seem* to be proved by irrefragable reasoning which are *not proved*, and cannot be proved in the present state of our knowledge. Dr. Bastian of course admits all this, or he would never have tried *new experiments*. It is therefore only these new experiments which, by adding to our knowledge, can alter the question as it stands. All the arguments concerning invisible germs of crystals, the mode of "building together the molecules of corn," "collocations," "*à priori* presumptions in favour of new modes of evolution," &c., &c., merely increase the difficulty experienced by ordinary mortals of grasping the real question at issue and discussing the theory within any reasonable limits. The introduction of these preliminary *à priori* considerations is calculated to confuse. They certainly interfere with the due concentration of the attention upon the results of the experiments. They will not excite persons who are at all conversant with the inquiry to put more trust in the new experimental results than they would be inclined to do without them. On me, I regret to say, they have a contrary effect. The fact of *à priori* arguments having been so very much dwelt upon, makes me think that the mind of the experimenter may have been to some extent prejudiced (prepossessed) in favour of the doctrine he seeks to support by new facts, and in this way they are calculated to excite in my mind, however much I may resist, a doubt whether the inferences which have been arrived at really have been deduced from facts of observation and experiment *only*.

Prof. Wanklyn, whose observations have called forth these remarks, is rather damaging the cause he hopes to serve in another way. He states that "rather more than one pint of average atmospheric air does not contain so much organic nitrogenous matter as corresponds to a cube of dry albumen of the $\frac{1}{250}$th part of an inch in diameter," and affirms that this quantity is altogether inadequate to account for the "immense multitudes of germs, the existence of which in atmospheric air is assumed by the vitalists." Now these "vitalists" hardly require "immense" multitudes, and instead of being "assumed," the presence of quite a sufficient number has been *proved*, and moreover, they can be seen by anyone who chooses to take the trouble to look for them.

But I thank Prof. Wanklyn for his fact and calculation. The evidence he adduces is very interesting, and conclusively in favour of the presence of living germs in the air; for those who accept the views he objects to, do not require a tithe or even a hundredth part of the albuminous matter he finds actually exists. The space occupied by a moist blood corpuscle $\frac{1}{3000}$ of an inch in diameter, which only contained even less than a *tenth of its weight* of dry albuminous matter, would be large enough to hold so many living germs that if uniformly diffused through the pint of air, not a thimbleful could be taken without containing several. These germs, placed under favourable circumstances, would soon grow large enough to be detected without any difficulty.

LIONEL S. BEALE

The Source of Solar Energy

IT is, I think, rather unfortunate that Mr. Proctor, in his recent work entitled "More Worlds than One," should have re-advocated the earlier and now discarded views of Sir W. Thomson concerning the source of solar heat or energy by *meteoric percussion*. That theory, however ingenious as advanced by the physicist, is surely hardly one to be admitted by the astronomer. Nothing less than an intense desire or necessity for finding some solution to the problem, whence or how the solar heat is maintained, could have encouraged scientific men seriously to advance or support so plausible and unsatisfactory a doctrine, or one, when examined, so little supported by what we really know either of meteors or of nature's laws. Having given much attention to *meteoric* astronomy, may I be permitted briefly to state what I hold are serious and practical objections to the validity of the meteoric or dynamical theory as applied to the conservation of solar heat and energy.

1. Because meteors and aërolites are known to impinge and strike the earth in her orbit, *ergo*, as I understand Mr. Proctor, numbers infinitely greater must no doubt be constantly rushing into the sun, as a body at once far larger, and much nearer to myriads of such bodies than the earth herself; but which, at a much smaller distance, are more likely to be drawn into the sun. Now, all that we really do know about meteors amounts to this, that by far the greater number of shooting stars visible in our atmosphere, in size no larger than a bean, and really separated from each other by thousands of miles, belong to fixed and definite systems or rings, having fixed radiant points for certain epochs or periods, showing clearly that these bodies are revolving round the sun, in courses as true and regular as the planets themselves, and are no more eddying or rushing into the sun, merely because they are so insignificant, than is the earth herself. Having projected upon celestial charts the apparent courses or tracks of nearly 5,000 meteors, observed during every part of the year, I feel I am justified in stating that not more than seven or eight per cent. of the shooting stars observed on any clear night throughout the year, are *sporadic*, or do not belong to meteor systems at present known to us. More than one hundred meteor systems are now recognised, several of which appear most certainly to be connected with known comets; and from a paper I have just received from Professor Schiaparelli, of Milan, it would appear that the approximate average *perihelion* distance for 44 of these meteor systems is not less than 0·7, the earth's distance from the sun being 1·0; whilst of these 44 systems, only 4, or about 10 per cent. have their *perihelion* distance under 0·1, that is, approach the sun nearer than nine millions of miles! Now, it is pretty well admitted that meteors are intimately connected with comet systems, yet out of some 200 comets, the elements of whose orbits have been calculated with tolerable precision, only 5 per cent. have their *perihelion* distance under 0·1. The same argument holds good also for planets, whose numbers also diminish after a certain considerable mean distance from the sun. Are these facts, then, in accordance with the notion that meteoric bodies either increase in number as we approach the sun, or that meteors are so constantly losing their senses, or sense of gravity, as to be ever rushing into or against the sun? I might almost ask, do *any* meteors rush or fall into the sun? Is it probable that the *mass* of all "the countless myriads of meteors" in the solar system exceeds that of a single planet? whether that of Mercury or Jupiter does not much signify. When we take into consideration the gigantic amount of meteoric deposits required to maintain the solar heat for hundreds of millions of years, in the meteoric theory, surely the supply of meteors would long since have been exhausted, were the supply at least confined merely to the meteors under a mean distance of 0·1 belonging to our own solar system! The argument, to begin with, is in a great degree fallacious, *e.g.*, because meteors frequently strike the earth, they must, it is argued, strike the sun in vastly greater numbers, and with far greater velocities. But it is forgotten that the meteors themselves, like the earth, are revolving round the sun as a common centre, in regular orbits, and only by accident, as it were, come into mutual collision, just as the tail of a comet might pass through the system of Jupiter and his satellites; while to the end of time neither the earth nor the meteors need necessarily come into contact with the sun.

2. But it is not merely meteors belonging to the solar system which are taxed to provide fuel for our sun; *space* itself may be filled with meteors ready to impinge upon the sun. The arguments against this are: (1) judging from analogy as well as from facts, comparatively few meteors are *sporadic*, consequently the majority cannot belong to stellar space, but to our own system; (2) granting that space itself is really more or less filled with meteors, these would not necessarily rush straight into the sun, unless, as would very unlikely be the case, they had no proper motion of their own. They might be drawn into or enter our system, it is true, but, according to Schiaparelli, only to circulate like comets in definite orbits.

3. The *zodiacal light* is another victim to the emergencies of the *meteoric* theory of solar energy. Whethre composed of myriads of small meteors, or merely a nebulous appendage, or atmospheric emanation belonging to the sun, is it credible that for hundreds of millions of years there could, physically speaking, be sufficient material in the zodiacal light to maintain the sun's heat and supply all the fuel required? Has it ever yet been proved that the entire mass of matter constituting the zodiacal light, is either composed of matter in a solid state, or, if it were, that its mass would be equal to that of our own earth? If composed of separate meteors, are they not each individually revolving round the sun, rather than occupied in being gradually drawn into it as a vortex? *

Of course I do not say that meteors are *never* drawn into the sun, or that they may not occasionally and by accident enter the solar atmosphere; I have merely endeavoured to show that, from what we really do know about meteors and the laws of nature, it is highly improbable that our sun could derive, in sufficient quantity, a needful supply of fuel from meteoric sources. The comet of 1843, which approached the sun within 550,000 miles, was not sensibly deflected from its course; it is just possible that so small a thing as an aërolite might at that distance have been drawn into the sun; but is it not also possible, from what we know of comet and meteor systems, it may be wisely ordained that the smaller bodies of our solar system, such as meteors, do not as a rule approach the sun too closely; and they probably do not, if their *perihelia* distances are rarely under 10,000,000 of miles?

Aërolites are doubtless of larger size and weight than shooting stars, and, as far as is yet known, not so regular in their appearance as shooting stars; but even with that class of phenomena, we notice a certain degree of periodicity in *maxima* and *minima* for certain times of the year, tending to show that they also may be subject to regular laws, and not fall so frequently or promiscuously upon the sun's surface as has been sometimes supposed. If they do not fall in vastly greater numbers, area for area, upon the sun than they do upon our earth, certainly the dynamical effect would be very minute! I may here also observe that even these bodies generally fall to the earth without being consumed, and with a very moderate velocity; their original cosmical velocity having been lost before reaching the surface of the earth. In the case of an aërolite falling upon the sun's surface, its original velocity may similarly have been gradually checked in its passage through the solar atmosphere, and a considerable amount therefore of the calculated mechanical effect lost. Small meteors would probably be consumed thousands of miles from the real body of the sun, seeing that the sun's inflamed atmosphere is now known to extend at times some 50,000 miles. It might almost be a question whether the sun's proper heat may not even be greater than that caused by the simple friction of a meteor through the solar atmosphere!

I merely allude to these minor matters, however, in order to point out some of the numerous uncertainties and difficulties connected with this meteoric or mechanical theory of the origin and conservation of solar heat, in addition to those already alluded to, bearing more especially upon the astronomical bearings of the question. For the present it must still remain a mystery, whence or how the solar heat is maintained, or to what extent really wasted.

Prestwich, Manchester, July 11 ROBERT P. GREG

Choice of a Microscope

WITH all respect to the judgment of my friend Mr. Ray Lankester, I should like to be allowed to oppose a few of the statements made by him in his remarks on the Choice of a

* We beg to refer our readers to Jones' and Liais' observations of the Zodiacal Light. They certainly have not received the attention in this country that they deserve.—ED.

Microscope, in NATURE, No. 37. It is, I believe, quite a mistake to say that you cannot get a cheap working English instrument. The model of Crouch, of London Wall, for instance, is not very much dearer than Hartnack's small model, and yet, at the same time, is in every way better and more comfortable to work with. Crouch's rackwork is so good that for $\frac{1}{4}$ths and $\frac{1}{8}$ths there is no need to resort to the fine adjustment, except on special occasions, whereas, with the sliding tube, the fine adjustment is so continually used that it is very soon thrown wrong, to say nothing of the trouble which a beginner has in working the sliding tube successfully. I once had some of Nachet's instruments, to which Hartnack's are very like, in use in my class at University College, and the sliding movement was very successful in smashing my best specimens and injuring the front surfaces of my lenses. Then again, the English length of tube is undoubtedly an advantage for a slanting position of the microscope, and I suppose that is by far the most common position in which an instrument is used. In addition, Crouch's instrument affords an admirably effective but simple stage movement, which may be entirely removed at pleasure, and has a simple sub-stage tube, into which, if required (and in London it often becomes a necessity), a condenser might be fitted. Crouch's instrument is like Hartnack's, simple but strong, steady, and cheap; it differs in being about three times as convenient, and will, probably, last twice as long.

Nor can I agree with Mr. Lankester in recommending the general purchase of Hartnack's glasses for student's use. His No. 8, for instance, in many respects an admirable glass, is terribly close, and for this, and apparently for other reasons, very soon gets spoilt when used by students. I have been using lately for my classes at University College, a $\frac{1}{5}$th of Crouch's, which, as far as ordinary histological work is concerned, performs in the most satisfactory manner, and yet is quite a cheap glass. I suppose the question of the price of labour prevents our English manufacturers from bringing down their prices to quite the French level, but I believe we get quite an equivalent for the slight excess in the form of greater convenience and better workmanship.

M. FOSTER

Colour-Blindness

THE nature of colour-blindness has never, I think, been satisfactorily ascertained. The usual explanation appears to be that the eye of the colour-blind is insensible, or nearly insensible to light of some particular colour. This I regard as in many respects unsatisfactory, and as I am not aware that the theory which I now suggest has been advocated before, I venture to lay it before the public.

There are no doubt some cases in which the eye seems partially insensible to particular colours or to colours in general. In such cases, however, I believe there is usually defective vision, and not proper colour-blindness. Those only are to be regarded as truly colour-blind who can perceive figures distinctly, but confound colours which other persons distinguish. Such was the case, for example, with Dugald Stewart, who could not distinguish between the colour of the leaves and the fruit of a Siberian crab; but he saw both, and therefore could distinguish the colour of both from that of the sky or cloud which lay beyond them. I mention this case more especially because Stewart was a psychologist, and maintained in opposition to Reid that variety of colour is the means by which we perceive visible figure. This is at least conclusive as to the perception of variety of colours by the colour-blind, which all observations made upon them point to.

Many philosophers have attempted to explain the phenomenon by assuming an insensibility to some colour, red for example. My reasons for rejecting this explanation are: (1) that in some cases where the experiment was tried (see Prof. Wartmann's paper in the Scientific Memoirs for November 1844) the colour-blind person saw the whole of the visible spectrum; and (2) that if red (for example) were seen as black, there would be no danger of confounding it with green, which would, on this hypothesis, be the colour seen most distinctly; but, in fact, confusion in regard to one colour almost always extends to the complementary tint.

The explanation I would offer is that derived from seeing accidental or complementary colours. It is a known fact that the eye has, in general (whether natural or acquired), a peculiar aptitude for white light, and thus if I gaze on a bright surface of any other colour, and look away rapidly towards a dark ground, the complementary hue becomes immediately visible. Nor can it, I think, be doubted that the complementary hue is not produced by the act of looking away. Green, for example, is produced by the red light falling on the eye, and the effect of looking away towards the dark ground is merely to make the green separately visible by cutting off the supply of red. It previously coexisted with and modified the red, but in ordinary eyes only to such an extent as not to prevent the red from strongly predominating in the total perception. This coexistence of the complementary colour with that actually visible is, I believe, known to persons accustomed to make delicate experiments in optics. I recollect in some lectures on the subject which I attended two or three years ago (where the equality of two lights of slightly different colours had to be determined), the professor cautioned us against looking too long at the lights, as he always found in his own case that there was a change of shade and a consequent impairment of the accuracy of his determination if he did so. This I have no doubt arose from the cause I have intimated. When we bear in mind the mutual excitation of sound-vibrations, the fact will create no astonishment. Now I apprehend that in most instances true colour-blindness arises from these complementary colours being excited more rapidly and with greater intensity than in ordinary eyes. If, for example, on looking at a red object the complementary green was excited almost at once, and with such intensity as materially to modify the red; and if, on the other hand, on looking at a green object, the excitation of the complementary red took place with equal readiness and intensity, it is clear that such an eye could not distinguish red from green. Both colours would, in fact, be seen after the first instant as a white or grey. In confirmation of this view I may remark that, according to Seebeck, all the colour-blind persons whom he examined confounded the colours with grey. Another argument in its favour is, that a confusion in regard to one colour seems (according to Wartmann) always to extend to the complementary tint. Again, it is natural to suppose that the production of complementary colours will take place rapidly and with considerable intensity when the eye is unusually sensitive to the incident light. Now, I find this unusual sensitiveness noticed in several of Wartmann's examples. One young woman could read for nearly a quarter of an hour (in the evening) after any one else could. In the cases mentioned by Goethe, the sight of the young men was "very good," and they "appreciated with great delicacy the gradations of light and dark." "Many Daltonians," says Wartmann, "see better in a demi-obscurity than other persons whose sight is more piercing by day than theirs," which he goes on to say was the case with three whom he himself had examined. Lastly, from the same paper it would appear that the colour-blind are either insensible to the phenomenon of accidental (complemental) colours, or see it with great difficulty. This, of course, is just as it should be on my theory. The colour-blind man sees both colours while looking at the coloured object, and he will again see both on looking away from it at the dark ground. If, for example, the colour looked at be red, the accidental green is seen while looking at the red, and it is also vivid enough to produce a secondary accidental red on looking away. The change produced by looking away will, therefore, be very slight, and hardly, if at all, perceptible.

I do not, however, put this theory forward as a complete explanation even of true colour-blindness. In addition to accidental or complemental colours, I believe there is often another phenomenon which may be called subjective colours, which modifies the total perception. In jaundice, it is well known, that black objects will appear yellow, and Dr. Wartmann records one case in which black appeared to the eye of the patient as green or crimson. I may have something more to say on this point hereafter. In such eyes, in fact, the adaptation is not for white light, but for light of some other colour, and the whole phenomenon of accidental colours is altered accordingly.

If these views be correct, it is evident that the colour-blind man will be best able to discriminate colours when he merely takes one glance at the coloured object, and then looks away towards a dark surface. This is worth trying. The fact that form is most easily discerned by taking a pretty long look at the object, makes a man follow the same course when he wishes to discriminate colours, but the advisability of doing so may be doubted. Another consequence is, that the colour-blind man would probably discriminate colours more readily in a faint light than in a bright one. These two observations can be easily made, and if my prediction should prove correct, the result will be of practical advantage to the colour-blind as well as a confirmation of the theory.

Trinity College, Dublin, July 9 W. H. S. MONCK

THE GUATTARI ATMOSPHERIC TELEGRAPH

THIS new invention is stated to consist of certain arrangements and combinations of apparatus whereby ordinary air compressed and passed through a tube, is utilised as a means of communicating intelligence from one given point to another, effecting the same object as the electric telegraph.

The principal portion of the apparatus consists of a reservoir or air-vessel which is charged or filled with air compressed to any desired degree according to the initial velocity or force which it is requisite the movements of the air employed should possess. A double action compression pump, or any other suitable mechanism, may be employed to charge the reservoir or air-vessel, and to sustain the pressure to the required degree. The reservoir or air-vessel is connected by means of a tube or pipe with a writing apparatus of any suitable description, and such as are well known and understood, especially in connection with electro-telegraphy; the tube or pipe being provided with a cock by which more or less force may be given to the current of air whereby the writing mechanism is actuated. In order to regulate the signals, a governor or piston, actuated by hand, is employed, by which pulsations or movements of the air in the tube or pipe are transmitted through a valve which is arranged therein, the currents actuating a lever connected with the writing apparatus. For the purpose of giving or receiving signals, the before-mentioned tube or pipe is connected with a conducting tube or pipe constructed of any suitable material, and which is so arranged that communication can be established between the air reservoir, or vessel, and the writing engine which is placed at the receiving station, or *vice versa*, by means of stop-cocks which are worked by hand. An indicator is employed to show the force of the current of air passing through the transmitting tube or pipe. Similar arrangements are, of course, placed and employed at each end of communication. By means of this invention it is stated that intelligence and signals can be transmitted to any distance; any of the known receiving and recording instruments capable of being used in connection therewith being employed. It is obvious that any number of conducting tubes may be employed, the requisite currents or pulsations of air therein being produced as before mentioned. The Guattari system claims to be more simple than the electric system, both in point of construction and continuous use, for whereas in the latter case it is necessary to use the electric battery and all its accessories, by the former ordinary atmospheric air compressed will perform similar functions. It is also claimed for it that it is free from atmospheric influences, which it is well known materially disturb the electric telegraph on the occasion of storms; and that the tubes employed as the medium for conducting the air would not be subjected to accidents like the ordinary wires, and would therefore necessarily last longer, and thus prove much more economical. We understand also that it is so simple that any person may learn in a few hours how to use and work it with the greatest ease, as compared with the electric system; it is calculated that the machinery necessary to work this system could be produced at about one-half the producing and annual working cost of the electric system.

The Royal Scientific Institute of Naples has already awarded to Signor Guattari a gold medal in recognition of what they consider an important invention, adding a graceful tribute on its presentation to the effect that it was the only gold medal which the Institute had ever awarded. The following experiments were made on Monday, 11th July, 1870:—

1. Transmission by atmospheric compression by means of the large machine, obtaining answers by impulsion and repulsion, Signor Guattari having at present but one machine.

2. System of impulsion and repulsion by a naval apparatus, which may be used with five different derivations or branches.

3. Universal telegraphy, namely, despatching telegrams to one or more stations at the same time without the aid of the transmitting machine or the necessity of the sender remaining fixed to any one point.

ON DEEP-SEA CLIMATES*

RECENT investigations have certainly tended to confirm the view originally advocated by my colleague, Dr. Carpenter, and myself, that a large portion of the bottom of the present sea has been under water and continuously accumulating sediment, at all events since the commencement of the "Cretaceous period," and possibly much earlier. The marked parallelism which, setting aside all local dislocations and denudations, evidently exists between the Jurassic, the Cretaceous, the Tertiary formations, and the present sea-board, and the evident relation of that parallelism to the older rock axes, would seem indeed to indicate that the main features of the present physical geography may date from a period even anterior to the deposition of the older Mesozoic rocks. With many minor and temporary oscillations, of which we have ample geological evidence, the borders of the Oolitic, the Cretaceous, and the Tertiary seas, have apparently been successively and permanently raised, and the ocean over an area, the long axis of which may probably correspond with that of the Atlantic, proportionally contracted. The question simply is, whether, since the elevation of the Jurassic beds, any oscillation has at any time raised into dry land the whole of the trough of the Atlantic, so as to arrest the deposit of sediment abruptly over the area, and to extinguish all animal life, thus defining what seems to be popularly understood as the close of a geological period, and requiring the complete repeopling of the succeeding sea by immigration, or, according to another view, by the creation of an entirely new fauna. It seemed to us on the whole more probable that the successive elevations of the borders of the Mesozoic sea were accompanied by compensating depression and deepening of the centre of the trough, which may thus have been inhabited throughout by a continuous succession of animal forms; at all events, the onus of proof appeared to rest with those who maintained any breach of continuity.

The deep-sea dredgings on both sides of the Atlantic have brought to light a very large number of hitherto unknown animal forms, and undoubtedly the assemblage bears a decided resemblance to the fauna of the chalk—a resemblance which increases as the investigation proceeds. Probably the most striking point is the apparent identity of the material of the chalk with the chalk-mud of the Atlantic; the globigerinæ and coccoliths by whose accumulation the beds have been, and are now, being produced, seem to be the same; though, of course, it is difficult to determine with certainty the specific identity of such simple and variable forms. Sponges are abundant in both, and the recent chalk-mud has yielded a large number of the examples of the group *porifera vitrea*, which find their nearest representatives among the ventriculites of the white chalk. From Prof. Martin Duncan's report it would appear that the corals, which are chiefly confined to water of moderate depth, are most nearly allied to those of the later Tertiaries. The echinoderm fauna of the deeper parts of the Atlantic basin is very characteristic, and yields an assemblage of forms which represents in a remarkable degree the corresponding group in the white chalk. Species of the genus *Cidaris* are numerous; some remarkable flexible forms of the Diademidæ seem to approach *Echinothuria*. M.

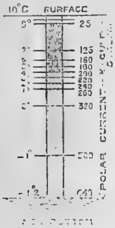
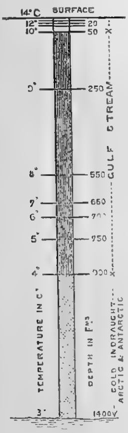
NORTH ATLANTIC OCEAN
COURSE OF THE GULFSTREAM
in July AFTER Dr A. Petermann
A. Gulfstream
B. Arctic Currents
C. Probable Course of the Antarctic Indraught

de Pourtales dredging in the Gulf Stream in the Strait of Florida has found a true *Salenia*, several representatives of the chalk forms of *Cassidulidæ*; and M. de Pourtales on the American side, and we off the west coast of Ireland and off the Shetlands, have dredged a remarkable form, appropriately named by Lyman *Pourtalesia miranda*, which is most nearly related to the Jurassic and Cretaceous genus, *Dysaster.*



Between the Faröe and Shetland Islands. 61° 21′ N. Lat., 3° 44′ W.L., Gr.

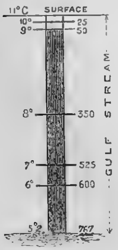
The Crustaceans of the chalk are, as yet, very imperfectly known, so that little can be founded upon them. The Mollusca have not yet been worked up, but the large number of smooth terebratulæ, and of species of the genera *Aporrhais*, *Dentalium*, *Pecten*, *Lima*, &c., from the deeper water, are highly suggestive of older times. Mollusca are, of course, most abundant in comparatively shallow water, and we were prepared to hear from Mr. Gwyn Jeffreys that out of about 120 species new to the British area, dredged in the *Porcupine* expedition, a large number date back to the newer Tertiaries.



Between Rockall & N.W. Coast of Ireland.

With these facts before us, it can scarcely be a matter of surprise that the point of view of those who are carrying on these investigations is insensibly changing, and that when the dredge comes up from a depth of one or two thousand fathoms the number of new species which it may contain is not now so much the question as the relation which these new forms may bear to their ancestors of an earlier epoch, and the light which they may be expected to throw upon types hitherto supposed to be entirely extinct.

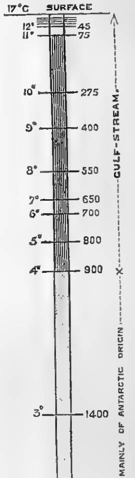
Although there is so striking a resemblance in general character between the fauna of the European chalk and that of the deeper portion of the bed of the Atlantic, especially of a band extending from a depth of 400 fathoms to 900 fathoms in the Gulf Stream area, none of the animals, with the possible exception of some of the Foraminifera, are absolutely identical. The species of *Sympagella*, *Holtenia*, and *Farrea* approach the siphonias and ventriculites very nearly, but they form a distinct subsection of the order. *Rhizocrinus* and its allies resemble *Bourgetticrinus*, and undoubtedly represent it, but there are important differences. The Saleniæ, the Cassidulidæ, and the Dysasters, &c., of the chalk mud approach their Cretaceous antetypes more closely than they do any known living forms, but they are generally dwarfed, and otherwise diverge so far as to require in most cases the establishment of new genera for their accommodation. Now, if we admit the continuous accumulation of sediment of the same character, and the persistence of the same general conditions over a large portion of the area of the present ocean from Mesozoic times, it seems at first sight more difficult to account for this great amount of modification than for the perpetual recurrence in deep dredgings of forms suggestive of close relationship to, and lineal descent from, extinct species.



South-West of the Faröe Islands. 59° 35′ N. Lat., 9° 11′ W. L., Gr.

At the bottom of the ocean, where other conditions are comparatively uniform, we may probably regard successive changes of temperature as the main cause of successive alterations in the fauna of a region, by the modification, extinction, emigration, and immigration of species. It is my object, in the present lecture, to show that in the vertical oscillations which are known to have occurred since the close of the Mesozoic period, we have a *vera causa* of alternations of temperature fully adequate to the entire result.

In order to understand this point thoroughly it will be necessary, in the first place, to pass in review the present conditions of distribution of temperature in the North Atlantic.*



Bay of Biscay. 47° 38′ N Lat., 12° 8′ W. L., Gr.

There seems to be little room for reasonable doubt that the present temperature of the basin of the North Atlantic depends, it may be said, *entirely*—for other modifying causes, such as the drift of the variable winds and the surface-heating and consequent expansion of equatorial water, are comparatively trifling—upon the Gulf Stream and the general indraught of cold water from the Arctic and Antarctic basins to supply the place of the constant warm current streaming north-eastwards from the Strait of Florida. Means of summer temperature which indicate roughly, not quite exactly, for higher temperatures, the mean amount of heat derived from the sun by direct radiation: the heat derived from all other sources, have been reduced from many thousands of isolated observations, and their results incorporated in an admirable and careful paper by Dr. A. Petermann (Geographische Mittheilungen, 1870).

The curves on the accompanying map, copied from Petermann, explain at a glance the distribution of abnormal temperature along the coasts of Western Europe, and indicate unmistakeably the source and direction of the warm current. One point only remained in doubt, namely, the depth to which the temperature of the ocean is affected by the Gulf Stream water. Now that there has been time to correlate and compare the large series of invaluable observations made with consummate skill and care by Captain Calver, R.N., during the *Porcupine* Expedition, this question may be considered solved over a considerable area, and the depth of the Gulf Stream off the west coast of Great Britain and France determined at about 800 fathoms (4,800 feet). This is so very im-

* My colleague, Dr. Carpenter, in many interesting communications on the temperature results of the *Porcupine* expedition (NATURE, Vol. i., p. 490, &c., &c.), denies that the Gulf Stream exercises any influence upon the temperature of the basin of the North Atlantic, and doubts whether it reaches the coast of Europe at all. He attributes the differences of temperature between different zones of depth to "a great general movement of equatorial water towards the polar area, of which movement the Gulf Stream contributes a peculiar case, modified by local conditions." And if I understand him aright, he supposes that this general movement is produced by some cause analogous to that which produces the general circulation in the atmosphere. I am sorry to be obliged to dissent so completely from his view on this point.

portant a matter in connection with the distribution of animal life and the other conditions of the problem at present more especially before us, and there are still so many wide differences of opinion with regard to it, even among competent authorities, that, at the risk of repeating a good deal that you know already, I will explain to you as simply as I can what appears to me to be the present state of knowledge with regard to it. This must be considered, however, merely an outline sketch, and when a phenomenon is represented as a sole cause or a sole result, I mean simply to convey that it is a cause or result so paramount as to reduce all accessories to insignificance.

The ultimate source of the Gulf Stream is undoubtedly, as has been specially insisted upon by Sir John Herschel, the equatorial current of the Atlantic, the drift of the trade winds. The path of that portion which trends north-eastwards is determined by the great initial velocity of the equatorial water which escapes from the Strait of Florida. The glory of the Gulf Stream, as it issues from the Strait, has been the theme of every physical geographer; and Mr. James Croll, in a valuable paper in the February number of the *Philosophical Magazine* on Ocean Currents, has entered into a careful examination of the actual amount of heat conveyed by the Gulf Stream from the Tropics into Temperate and Arctic regions. Mr. Croll calculates the Gulf Stream as equal to a stream of water fifty miles broad and 1,000 feet deep flowing at a rate of four miles an hour, consequently conveying 5,575,680,000,000 cubic feet of water per hour, or 133,816,320,000,000 cubic feet per day.

This mass of water has a mean temperature of 18° C. as it passes out of the Gulf, and on its northern journey it is cooled down to 4·5°, thus losing heat to the amount of 13·5° C. The total quantity of heat, therefore, transferred from the equatorial regions per day amounts to something like 154,959,300,000,000,000,000 foot-pounds.

This is nearly equal to the whole of the heat received from the sun by the Arctic regions, and reduced by a half to avoid all possibility of exaggeration, it is still equal to one-fifth of the whole amount of heat received from the sun by the entire area of the North Atlantic.

The basin of the North Atlantic forms a kind of *cul-de-sac*, and while a large portion of the Gulf Stream water, finding no free outlet towards the north-east, turns southwards at the Azores, the remainder, instead of thinning off, has rather a tendency to accumulate in the northern portions of the trough. We accordingly find that it has a depth off the west coast of Ireland of at least 4,800 feet, with an unknown lateral extension. There are no data as yet to determine the rate of the branch of the Gulf Stream which sweeps round the coast of Western Europe and into the Arctic Sea, but it must be very slow, for even so far south as at lat. 42° N. it has lost all effect upon navigation, its character as a constant current being entirely masked on the surface by the drift of the anti-trades, which has nearly the same direction.

The Gulf Stream is thus a constant "river" of hot water, forced into a particular direction by the rotation of the earth, by the constant winds, and by the configuration of the land; and accumulated and modelled by the confined basin of the North Atlantic and Arctic Sea. The cold water which replaces it is supplied under very different conditions.

Sea water increases steadily in density as the temperature falls till it reaches its freezing point, about 3° C.; the coldest water, therefore, lies at the bottom, and if over any region warm water be removed by any cause from the surface, as for instance in the case of the equatorial current and the Gulf Stream, its place will be supplied by a general indraught beneath of water from the coldest and heaviest, and consequently usually from the deepest sources from which it can be brought in by gravitation. The cold water is, however, merely drawing in to supply a vacancy, and there is no special reason why it should follow one ingress rather than another. From the low initial velocity of polar water it will tend to flow westwards in passing into lower latitudes, but that tendency will probably be entirely subordinate to specific weight in determining the course of the cold influx and the distribution of layers of water of different temperatures.

As cold water can gravitate into the deeper parts of the ocean from all directions, it is only under peculiar circumstances that any movement having the character of a current will be induced; these circumstances occur, however, in the confined and contracted communication between the North Atlantic and the Arctic Sea. Between Cape Farewell and North Cape there are only two channels of any considerable depth, one very narrow along the east coast of Iceland, and the other along the east coast of Greenland. The shallow part of the sea is entirely occupied, at all events during summer, by the warm water of the Gulf Stream, except at one point, where a rapid current of cold water, very restricted and very shallow, sweeps round the south of Spitzbergen and then dips under the Gulf Stream water at the northern entrance of the German Ocean.

This cold flow, at first a current, finally a mere indraught, affects greatly the temperature of the North Sea; but it is entirely lost, for the slight current which is again produced by the great contraction at the Straits of Dover has a summer temperature of 7·5° C. The path of this cold indraught from Spitzbergen may be readily traced on the map by the depression in the surface isothermal lines; and in dredging by the abundance of gigantic amphipodous and isopodous Crustaceans and other well-known Arctic animal forms. The other two Arctic currents along the coasts of Iceland and Greenland are likewise very apparent, taking a slightly western direction from their low initial velocity.

But while the communication between the North Atlantic and the Arctic Sea itself, a second *cul-de-sac*, is so restricted, limiting the interchange of warm and cold water in the normal direction of the flow of the Gulf Stream, and causing the diversion of a large part of the stream to the southwards, the communication with the Antarctic basin is as open as the day, a continuous and wide valley of upwards of 2,000 fathoms in depth stretching northwards along the western coast of Africa and Europe.

That the southern cold water wells up into this valley there could be little doubt from the form of the ground, but here again we have curious corroborative evidence on the map in the remarkable reversal of the curves of the surface isotherms. The temperature of the bottom water at 1,230 fathoms off Rockall is 3·22° C., exactly the same as that of water at the same depth in the serial sounding, lat. 47° 38′ N., long. 12° 08′ W., in the Bay of Biscay, which affords a strong presumption that the water in both cases is derived from the same source; and the bottom water off Rockall is warmer than the bottom water in the Bay of Biscay (2° 5′ C), while a cordon of temperature soundings drawn from the north-west of Scotland to a point on the Iceland shallow, gives no temperature lower than 6·5° C. This entirely precludes the idea that the low temperature of the bottom water of the Bay of Biscay is due to any portion of the Spitzbergen current passing down the west coast of Scotland; and as the cold current of the east of Iceland passes southwards considerably farther to the westward, as indicated on the map by the successive depressions in the surface isotherms, the balance of probability seems to be in favour of the view that the conditions of temperature and the slow movement of this vast mass of moderately cold water, nearly two statute miles in depth, are to be referred to an Antarctic rather than to an Arctic origin.

The water of the North Atlantic thus consists first of a great sheet of warm water, the general northerly reflux of the equatorial current, the most marked portion of it passing through the Strait of Florida, and the whole generally called the Gulf Stream, of varying depth, but attaining off the west coast of Ireland and Spain a depth of 800 to 900 fathoms. Secondly, of a general indraught of Antarctic water compensating at all events that part of the Gulf Stream which is deflected southwards; and thirdly, of a comparatively small quantity of Arctic water which, flowing through two or three narrow channels, replaces that portion of the Gulf Stream which makes its way into the Arctic Sea. As I have already said, the Gulf Stream loses an enormous amount of heat in its northern tour. At, say a point 200 miles west of Ushant, where the observations at the greatest depth were made on board the *Porcupine*, a section of the water of the Atlantic shows three surfaces, at which interchange of temperature is taking place. 1. The surface of the sea, that is to say, upper surface of the Gulf Stream layer, is losing heat rapidly, *a* by radiation, *b* by contact with a layer of air, which is in constant motion, and perpetually being cooled by convection; and *c* by the conversion of water into vapour. As the cooling of the Gulf Stream layer takes place principally at the surface, the temperature of the mass is kept pretty uniform by convection. 2. The band of contact of the lower surface of the Gulf Stream water with the upper surface of the water of the cold indraught. Here the interchange of temperature must be very slow, though that it does take place is shown by the slight depression of the surface isotherms over the principal paths of the indraught. The cold water being below, convection in the ordinary sense cannot occur, and interchange of temperature must depend upon conduction and diffusion, causes which in the case of masses of water of such depth must be almost secular in their action, and probably to a much greater extent upon mixture produced by local currents and by the tides. 3. The third surface is that of contact between the cold indraught and the bottom of the sea. The temperature of the surface of the earth is calculated at about 11°C., but it would be completely cooled down by anything like a movement and constant renewal of cold water; all we can say, therefore, is that contact with the bottom can never be a source of depression of temperature. As a general result, the Gulf Stream water is nearly uniform in temperature throughout the greater part of its depth; there is a marked zone of intermixture at the junction between the warm water and the cold, and the water of the cold indraught is regularly stratified by gravitation; so that in deep water the contour lines of the sea bottom are, speaking generally, lines of equal temperature. Keeping in view the enormous influence which ocean currents exercise in the distribution of climate at the present time, I think it is scarcely going too far to suppose that such currents, movement communicated to the water by constant winds, existed at all geological periods as the great means, I had almost said the sole means, of distributing heat in the ocean, and thus producing general oceanic circulation; they must have existed, in fact, wherever equatorial land interrupted the path of the drift of the trade winds. Wherever a warm current was deflected to north or south from the equatorial belt, a polar indraught crept in beneath to supply its place; and the ocean consequently consisted, as in the Atlantic and doubtless in the Pacific at the present day, of an upper warm stratum and a lower layer of cold water, becoming gradually colder with increasing depth. Wherever such conditions existed it is plain that mere vertical oscillations must have produced very decided changes of climate, through only a small number of degrees, but still very marked if the oscillation affected merely a portion of the cold underlying water, but enormous if it were sufficient to raise or depress the bottom of the sea, the principal theatre of animal life, so as to shift it from the cold layer into the warm, or from the warm layer into the cold.

One of the most striking phenomena connected with the distribution of heat in the North Atlantic is the case of the Shallow including the Hebrides, Orkney and Shetland Islands, and the Faroes, stretching westwards and northwards nearly to Iceland. The average depth is about 500 fathoms, and the Gulf Stream, which has a depth in these latitudes in summer of from 600 to 700 fathoms, occupies the whole of it, giving an abnormal temperature of something like 7° C. Owing to the peculiar conformation of the basin of the German Ocean, a tongue of cold water, with a bottom temperature of – 1° C. creeps into the valley between Scotland and Faroe, where it is overlaid by a stratum of Gulf Stream water, 150 fathoms thick. At the western mouth of the valley the cold water is banked in and retained by the water of the Gulf Stream, which is slowly passing the entrance of the gorge, giving a repetition, on a small scale, of the curious phenomenon described by Prof. Bache, off the coast of Massachusetts, as the "cold wall." My colleague, Dr. Carpenter, has conveniently called these two neighbouring districts, where the thermometer indicates 7° C. and – 1° C. respectively, the warm and cold areas. A depression, affecting that region of 250 fathoms equal to that which admitted of the accumulation of post-tertiary shells on Moel Tryfaen, would produce an extraordinary effect on its climate. In the first place, by mere subsidence, the Gulf Stream not reaching the bottom but flowing over a band of cold water, the temperature of the warm area would be reduced to, say, 3° C., and that of the cold, by an indraught of deeper water from the north, to – 2° C., but the Gulf Stream would no longer bank out the cold indraught from the north-east; which, in that case, passing down a deep open channel from the deep soundings to the west of the Loffotens, would spread along the bottom on the west coast of Scotland and Iceland, and greatly reduce its temperature, and probably entirely alter its fauna.

WYVILLE THOMSON

NOTES

WE have reason to believe that Professor Sir Wm. Thomson will be the next President of the British Association.

WE learn that the Royal Commission on Scientific Instruction and the Advancement of Science, which has met regularly two days a week, have now adjourned over the recess.

THE Royal Astronomical Society has issued a list of the members of the various learned Societies who propose to take part in the observations of the approaching total eclipse of the sun.

WE learn from the last number of the *Revue des Cours Scientifiques* which has reached us—that for the 24th inst.—that on Monday last week the Paris Academy of Sciences continued, in *comité secret*, the discussion of Mr. Darwin's nomination to fill the vacancy in the Zoological Section caused by the death of Purkinge. M. Milne-Edwards first spoke in his favour. While insisting on his own absolute opposition to evolutional doctrines, he rendered homage to the value of the special works of Mr. Darwin, especially the theory of the formation of coral islands. M. Elie de Beaumont also attested the value of this theory, and remarked that Mr. Darwin had done good work which he had spoiled by dangerous and unfounded speculations. He thought he should not be elected until he had renounced them. M. Emile Blanchard, who spoke for more than an hour, was very severe upon Mr. Darwin, styling him an "amateur intelligent," a remark capped by M. Elie de Beaumont (it is stated), who cried out, to the great indignation of M. de Quatrefages, "*C'est de la science mousseuse.*" M. de Quatrefages promised to answer M. Blanchard point by point on Monday last.

THE Archæological Congress is now in full swing at Leicester, one of the most interesting towns and localities which it is possible for such a Congress to visit. The proceedings commenced on Tuesday with an address presented by the Mayor and Corporation, followed by visits to some of the objects of interest in the town. On Wednesday the section met at the usual time, and the Abbey was subsequently visited. To-day (Thursday) there are excursions to Ashby de-la-Zouch, Tutbury, Tamworth, and Polesworth, and a *conversazione* in the evening. The future work is as follows:—Friday—Meeting of members for business; meetings of sections; excursion to Kirby Muxloe Castle; *conversazione* in the evening. Saturday—Excursion to Groby; Bradgate Park, Ulverscroft Priory, Woodhouse Chapel, Beaumanor Park, and Grace Dieu. Monday—Meetings of sections; excursion to Melton Mowbray and Oakham; *conversazione* in the evening. Tuesday—Meetings of sections; general concluding meeting.

PROFESSOR HELMHOLTZ will take up his new duties at Berlin in April, 1871.

THE Geological Survey of India, supported by the Government, have recently issued the completing part of the sixth volume of its "Memoirs." It contains a valuable paper by Mr. W. T. Blanford on the geology of the Taptee and Lower Nerbudda valleys in Western India, illustrated by maps, plates, and numerous woodcuts. Mr. Blanford describes the geology and physical geography of the country generally, giving first an account of the results obtained by previous observers, with references to their works, followed by more precise details of later observations, thereby furnishing an exceedingly valuable monograph. The view of a dyke at Koteda, near Goojree, exhibiting the trap in curved columnar masses, is a charming little picture. Mr. A. B. Wynne gives a description of some frog-beds exposed in Bombay Island in 1867. Numerous well-preserved skeletons of Oxyglossus pusillus (*Rana pusillarius*) were found associated with ribbed fragments of plants, and large, shapeless, structureless pieces of carbonised vegetable organisms. The skeletons were found in all kinds of postures: the hind legs extended, crossed, contracted, or twisted. Dr. Ferdinand Stoliczka, the palæontologist of the survey, gives a brief sketch of the osteology of the frogs discovered, with engravings of several specimens. The same gentleman, in two new parts of the "Palæontologia Indica," just issued, has given engravings and descriptions of some of the Gasteropoda of the Cretaceous rocks of southern India. This work, published at the expense of the Indian Government, is intended to comprise figures and descriptions of the organic remains found during the progress of the survey. The new parts complete the second volume of the Cretaceous fauna of India, with useful tables and an index of species. Mr. Thomas Oldham, the indefatigable superintendent of the survey, has commenced the publication of "Records" of the proceedings of the officers in various parts of India, of which the first four numbers are before us, containing much interesting geological information.

DEATH is hard on the medical profession just now. James Copland, M.D., F.R.S., died on the 17th inst., at the age of seventy-eight. From an obituary notice in the *British Medical Journal*, we learn that his principal claim to fame rests mainly on his performance of that gigantic work "The Medical Dictionary"—which he undertook, and carried to completion after a labour of thirty years. On finishing this work, he wrote in the preface that his labours, which had been incessant for many years, had been persisted in under circumstances and contingencies which few could have endured. Every line in it was written by his own hand, and all the proofs were carefully read and corrected by himself. The Dictionary is a cyclopædic *résumé* of all that has been written on the various subjects treated in it, from the earliest days of medicine down to modern times, with copious references to all the sources of information; and with all this are given the opinions which the author's observation and experience had led him to form. That one man should have undertaken and, labouring single-handed or nearly so, completed such a work, is indeed a remarkable fact. The work is a monument of calm energy and self-reliance, such as is but rarely met with.

NATURAL phenomena must be regarded by the engineer in the tropics. Here the boring worm will teach him salutary caution. In the East we have seen a railway train stopped on an incline by locusts. The locusts have a fancy for sitting on the rails, and when the engine-wheel touches them they are crushed, leaving the rails so oily that the engine slips. On one line, in the locust season, sand-boxes are used with the locomotive. Oysters are, however, a newly recorded enemy to the engineer. Some gourmand suggested the harbour of Tuticorin as a suitable place for oyster beds, and the Madras Government, doubtless appreciative of the value of oysters either for eating or for pearls, turned a deaf ear to remonstrance. Time has, however, justified the remonstrants, for, though the projectors have got an abundant supply of oysters, the harbour of Tuticorin is now said to be in danger of total destruction by the growth of the oyster beds, and the attention of the Government is seriously directed to cross the love of the oysters. The Madras coast is so ill-provided that harbours are more valuable than oysters, and a campaign will be directed against the latter, although the revenue authorities hanker after the taxes on the pearl fishery.

AN experiment, performed by M. J. M. Philipeaux, in which he transplanted one of the incisor teeth of a guinea-pig into the comb of a cock, has been referred to by M. P. Bert in his "Thesis on Animal Grafting," but M. Philipeaux thought that the examination of the specimen with an account of the experiment would be interesting to the members of the Society of Biology, and he accordingly submitted it to their inspection, with the following observations:—On January 13, 1853, M. Philipeaux, after having made an incision into the head of a young cock, introduced into it the incisor tooth of a guinea-pig that had been born a few hours previously. The tooth, very complete and furnished with its bulb, was so placed that the bulb was at the bottom of the wound and the extremity of the tooth turned outwards. On the day the experiment was made the tooth was eight millimetres long and two millimetres thick. The cock was killed ten months after the operation. The tooth, which, on the day of operation, was entirely concealed and covered in the wound, projected, when the animal was killed, five millimetres from the surface. M. Philipeaux had dissected out in the specimen the whole length of the tooth, and found that it measured no less than thirteen millimetres; it had consequently grown five millimetres. The interest of this experiment, which in other respects resembles those of Hunter and Sir A. Cooper, in which the spur of the cock was transplanted to the comb, consists in the circumstance that here a graft was accomplished in one animal of a part belonging to another, belonging to an entirely different zoological class.

WE are sorry to announce the death of Von Graefe, the most distinguished oculist in Europe. Iridectomy, the contribution to ophthalmic surgery with which his name is chiefly associated, was but one out of a multitude of operations which made his clinique at Berlin the resort of persons labouring under eye-diseases from all parts of the world.

WE have received from the Government of Victoria a most valuable collection of the Mineral Statistics of that Colony. Among the appendices is an important illustrated paper by Mr. Ulrich, F.G.S., entitled "Contributions to the Mineralogy of Victoria." We shall return, if space permits, to this interesting State paper. In the meantime, we may state that the total value of the gold raised in the Colony to the end of last year has been 152,706, 120*l*.; and that diamonds, rubies, sapphires, topaz, &c., are now being found.

WE learn from the *British Medical Journal* that M. Duruy (late Minister of Public Instruction), M. Nélaton (the great surgical celebrity of Paris), M. Husson (commonly called Sa Majesté l'Assistance Publique), and M. Milne-Edwards (the well-known semi-English Frenchman and philosopher), are at the head of a movement to found an *Ecole de Médecine* specially or women. The programme has been submitted to the Empress, accompanied by a request that she should become patron of the projected school. In France it is argued that there really is scope or something of this kind. It is alleged that the practice of medicine, from the present dull level of all being competent practitioners, is in a bad state; that it is necessary to institute a new body of practitioners, competent for drudgery and ordinary emergencies, but not competent for consulting practice. It is said that the mass of the profession are far too well educated, and that it is only by having a dash of the charlatan that even a good man can rise above the ranks. This surely is throwing a new light on the question.

THE Abbé Moigno announces in the last number of *Les Mondes* that the stone knives with which Joshua performed the rite of circumcision have been found in his tomb by the Abbé Richard. The account, which concludes as follows, we commend to the special attention of Mr. John Evans and Mr. Sorby:—"Voici donc qu'un des faits historiques les plus singuliers de la Bible a reçu la confirmation la plus éclatante, et que nous entrons en possession de silex taillés il y a 3,550 ans, plus vieux bien certainement, nous le prouverons jusqu'à l'évidence, (!) que les silex taillés de la vallée de la Somme ou des grottes d'Aurignac. Qui sait même si le spectroscope manié par des mains aussi habiles que celles de M. Sorby ne nous démontrera pas la présence, sur quelques-uns de ces silex, du sang de la circoncision." (!!)

OUR readers will recollect the important part played by the telegraph in the Seven Days' War, the introduction of this new arm, so to speak, enabling von Moltke to control all the strategical combinations with unerring accuracy, from a small room in Berlin. To the telegraph the Prussians have now added the balloon, and already we hear that the French army encamped in the environs of Metz have been surveyed with the greatest care. Surely if strategy is to play the part it did in former times in future battles, given two armies, one of which is, by means of a balloon, in electric communication with the Head-quarter Staff, in perfect knowledge of the numbers, at any one point, and the movements of the other, its success must be assured.

PERSONS wanting chemical and philosophical materials and apparatus from Germany, already experience a delay from the interrupted communications even in this beginning of hostilities.

THE heat has been so great at Dowlashéram, in the Madras Presidency, in June, that the Indian papers report many birds have died of sun-stroke.

AMONG the scientific labours of the Government in India in the departments of agriculture and horticulture, which have given such good results in tea and cinchona, may be recorded a garden at Raneekhet, the new hill station above Simla, for supplying vegetables to the troops, and an experimental cotton garden in the Boolundshur district. One chief object of the latter is to test the application of irrigation to various descriptions of cotton seed. Some appear to require water, and some to be injured, but there is no scientific record.

IN the progress of public opinion the public of Madras have come to the conclusion that the monkeys of that city, formerly held sacred, are a nuisance, and the municipality has taken measures to deport them. This requires—first, that they shall be caught. When caught they are to be tenderly treated; but for fear of their early return the aid of modern science is to be called in, and they are to be conveyed by railway trains to Tiruputty. In the distribution of animals the naturalist has thought fit to make little account of the railway, which may effect a displacement of the monkeys of India.

THE necessary operations for the construction of the sea-wall of the New Brighton Aquarium are progressing. It is expected that the aquarium will be completed and furnished by the spring of next year.

"SPONTANEOUS Generation and the Hypothesis of Physiological Units," by Herbert Spencer, is a reprint of a paper intended for the *North American Review*, in reply to an article that appeared in that journal entitled "Philosophical Biology," in which Mr. Spencer thinks that his views on the origin of life are not correctly represented.

THE *Scotsman* describes a Mirage in the Firth of Forth, the most extraordinary instance which can be remembered, which occurred on Friday afternoon. The day was very hot and sultry, and there was a peculiarity about the atmosphere which is seldom observed in this country. About midday a thin, clear, and transparent kind of vapour, through which the surrounding objects began to make their appearance in the most fantastic and grotesque shapes imaginable, settled over the sea. The phantasmagoria were principally confined to the mouth of the firth; but at one time they embraced the whole of the Fife coast as far as the eye could reach, town, village, and hamlet being depicted high up on the horizon with remarkable distinctness. Though the whole coast seemed at least half-way up the horizon, the appearances presented by the towns were very different, some of them having the houses inverted, while others appeared in the natural position. The Bass Rock, the Isle of May, and the rocks around Dunbar harbour, however, attracted most attention, both from their proximity and from the extraordinary forms which they assumed. The Bass, which at one time seemed to lie flat upon the sea, suddenly shot up into a tall spiral column, apparently ten times its usual height, surrounded by battlements rising tier on tier, and presenting a most imposing spectacle. As usual, however, the most fantastic appearances were presented by the May, which, in the course of the afternoon, underwent an almost innumerable series of phantasmagoric transformations. At one time it was apparently as round as a circle, at another seemingly draw out for miles against the horizon; now flat upon the water, then rising to ten times its usual height; occasionally portions appeared to break off and sail away, then to return and unite again—all within the space of a few minutes. Vessels in the offing appeared double—one on the water, and another inverted in the air; and in one instance three figures of one vessel were distinctly visible—one inverted, another on the sea, and a third in its natural position between the two. The fishing boats proceeding to sea in the evening underwent the same transformations when only a few yards off the shore, the double appearance being distinctly visible within a certain distance. The rocks at the harbour also seemed to play fantastic tricks, opening and shutting, rising and falling, with apparent regularity. These extraordinary illusions lasted from midday till night-fall, and excited great interest among the inhabitants of Dunbar, numbers of whom collected in the Castle Park and at the harbour for the purpose of witnessing the phenomena.

WE have received from M. J. L. Soubeiran an interesting account which he has communicated to the Société Impériale d'Acclimatation, of the progress of pisciculture in the Neilgherries, based on Mr. Day's paper in the Proceedings of the Zoological Society.

HOPKINS versus DELAUNAY

WE have received from Archdeacon Pratt a copy of a paper communicated to the *Philosophical Magazine* on Delaunay's objection to Hopkins's method of determining the thickness of the earth's crust by the precession and nutation of the earth's axis.

The archdeacon, on this most important question, states :—

"I am ready to allow, and so would Mr. Hopkins have allowed, that if the crust of the earth revolved round a steady axis, always parallel to itself in space, and if at some particular epoch a difference existed between the rate of movement of the crust and of the fluid within it, the resulting friction would gradually destroy this difference and bring about a conformity in the motion of both parts. I will even go further, and allow that the effect of the internal friction and viscidity of the fluid may be such that the resulting rotary motion may be the same as that which the whole mass would have had at the epoch if it had suddenly become one solid body and thereby suddenly retarded the rotation."

He thus illustrates his position :—

"Suppose a spherical shell or crust of mass C to have within it a solid spherical nucleus, of radius b and mass N, fitting it exactly; and the crust to receive an angular velocity of rotation around an axis fixed in the crust, the nucleus at that moment having no angular velocity; but suppose that a slight force of friction between the surfaces gradually generates a rotary motion in the nucleus; and suppose this force to vary as the difference between the angular velocities of the crust and nucleus—that is, of the surfaces in contact. Let ω and ω' be the angular velocities at the time t, k and k' the radii of gyration of the two bodies, F $(\omega - \omega')$ the force at the equator of the nucleus which represents the friction between it and the crust. Then the equations of motion are

$$\frac{d\omega}{dt} = -\frac{Fb}{Ck^2}(\omega - \omega'), \quad \frac{d\omega'}{dt} = \frac{Fb}{Nk'^2}(\omega - \omega') \quad . \quad . \quad . \quad (1)$$

Suppose also that β would have been the angular velocity, when the primitive impulse was given, on the hypothesis of the crust and nucleus being rigidly connected so as to be one mass. Then

$$\beta(Ck^2 + Nk'^2) = \alpha Ck^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Subtracting the second of equations (1) from the first, putting

$$Fb\left(\frac{1}{Ck^2} + \frac{1}{Nk'^2}\right) = c, \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and integrating, we have

$$\omega - \omega' = \text{const.} \times e^{-ct}.$$

When $t = 0$, $\omega = \alpha$ and $\omega' = 0$;

$$\therefore \omega - \omega' = \alpha e^{-ct}.$$

Hence, by the first of equations (1),

$$\frac{d\omega}{dt} = -\frac{Fb\alpha}{Ck^2}e^{-ct} = -\frac{Nk'^2 c\alpha}{Ck^2 + Nk'^2}e^{-ct}, \text{ by (3)};$$

$$\therefore \omega = \alpha - \frac{Nk'^2}{Ck^2 + Nk'^2}\alpha(1 - e^{-ct});$$

and also

$$= \beta\left(1 + \frac{Nk'^2}{Ck^2}e^{-ct}\right), \text{ by (2)}"$$

The paper then continues :—"The first of these expressions shows that the angular velocity of the crust begins with α; and when ct becomes very large indeed, it is reduced to β. Hence the effect of the constant friction of the nucleus against the inner surface of the crust is *at last* to reduce the velocity of the crust to what it would have been at first if the crust and nucleus had been one solid mass.

"We may conclude perhaps that the same effect would be produced, though in a much longer time, if the interior were not a solid sphere, but a fluid mass.

"The above reasoning shows that if the disturbing force producing precession and nutation did not exist, and the interior of the earth were fluid (whatever the thickness of the crust), it may be fairly assumed that the motion of rotation of the crust would now, the earth having existed so many ages, be exactly what it would have been had the earth been one solid mass, all difference of motion having been long ago annihilated by the internal friction and viscidity.

"But the disturbing force producing precession and nutation does exist. It consists of two parts, one constant and the other variable and periodical. The constant part is that which produces the steady precession of the axis (and which I will call for convenience the precessional force); the other produces the nutation. I will consider the precession first. Suppose now, for the sake of argument, that at the present moment, as M. Delaunay imagines, the crust and the fluid are revolving precisely as one mass, all previous differences of motion, even under the action of the disturbing force which produces precession and nutation, having been annihilated by friction and viscidity. I ask—What will be the action of the precessional force from this moment? It tends to draw the pole of the crust towards the pole of the ecliptic: and this tendency, as mathematical physicists well understand, combined with the rotary motion of the crust, produces this singular result, viz., the pole does not move towards the pole of the ecliptic, but shifts in a direction at right angles to the line joining the poles towards the west; so that the inclination of the axis to the ecliptic remains constant, but the axis shifts towards the west. The space through which it shifts in an infinitesimal portion of time varies as the length of the time and the force directly, and as the inertia of the mass to be moved inversely. The inertia of the mass depends upon the thickness of the crust only; for the friction of the fluid against the inner surface of the crust (which might, as I have shown, in the course of years, produce a sensible effect) cannot do so during the infinitesimal portion of time I am considering before the precession is actually produced. The precessional force has its full effect in producing the precession of the solid crust, the fluid not having time to diminish that effect before the axis has assumed a new position; and in this new position of the axis the precessional force is precisely the same in amount as before, to go on causing the precession as before. The precessional force is, in fact, ever alive and active, and shows this in incessantly producing the effect I have described; and the precession goes on steadily, the amount of it depending upon the mass of the crust thus moved, which the fluid has not time to retard or lessen. M. Delaunay says that 'the additional motion due to the above-mentioned causes (the disturbing forces which give rise to precession and nutation) is of such slowness, that the fluid mass which constitutes the interior of the globe must follow along with the crust which confines it, exactly as if the whole formed one solid mass throughout." In reply to this, I say that it is not the slowness of the motion, but the want of solid connection between the crust and the fluid in contact with it that affects the problem. The motion, whatever its amount, is incessantly being generated by the disturbing force, and owing to this want of solid connection, the friction of the fluid has not time during the successive moments during which the precession is generated, to stop or even sensibly to check it.

"It will thus be seen that at every instant the precessional force proceeding from the action of the sun and moon on the protuberant part of the earth's mass will, if the earth be a solid mass, have to move the whole mass; and if the earth have a solid crust only with a fluid interior, the force will have to move only the crust against the evanescent resistance of the fluid within during so short a space of time as it takes to produce precession. The resulting precessional motion will be different in the two cases; and therefore the actual amount of the precession which the earth's axis has (and which is a matter of observation) is a good test of the solidity or fluidity of the interior. This is Mr. Hopkins's method.

"The force producing nutation is much smaller, even at its maximum, than the precessional force. Its effect, however, is precisely the same in this respect—that it depends upon the mass of the solid crust, and in no respect upon the friction of the fluid within it, which has not time to influence the nutation before the nutation is actually produced.

"I do not here undertake to go into Mr. Hopkins's numerical calculations; I simply vindicate his method. I do not here consider what modification the elasticity of the solid material of the earth may have upon his numerical results. I conceive that it would have *no* effect, if the disturbing force were constant and there were no nutation. For, under the dragging influence (if I may so call it) of the constant precessional force, the solid material would be under a steady strain, and would communicate the effect of the force, continuously acting, from particle to particle of the solid part as if it were really rigid; and the resulting precessional motion would be greater or less as the mass of the solid part may be smaller or larger—that is, the solid crust thinner or thicker. But as the disturbing force is not constant, but variable, and there is constantly nutation of the axis as well as precession, the action above described will be somewhat modified;

and the elasticity of the solid material may be expected to have some influence on the result. This influence, however, will be minute, as the part of the disturbing force which is variable and produces nutation is very much smaller, even at its maximum, than the precessional force. The consideration of this matter, however, has no bearing upon the validity or not of Mr. Hopkins's method, but simply upon the numerical value of his final result, not upon the question of the fluidity or solidity of the earth's mass."

The Archdeacon is of opinion "that the strictures of M. Delaunay upon this method, which the genius of Mr. Hopkins devised, betray an oversight of the real point upon which the success of his method depends, and that this method stands unimpaired."

SCIENTIFIC SERIALS

THE *Geological Magazine* for July (No. 73) contains rather ewer original articles than usual, but what there are will be found interesting. The series of notices of eminent living geologists is continued in a notice of one of the most accomplished of the number, Professor John Phillips, of whom we have a good biography, but a very unsatisfactory portrait. Mr. Carruthers gives a notice of the so-called fossil forest near Cairo; he distinguishes a new species of *Nicolia* (*N. owenii*), and illustrates its microscopic structure as compared with that of the old species *N. ægyptiaca* Unger. — Mr. Kinahan communicates a paper containing a comparison of the geological features of Devon, Cornwall, and Galway, with a discussion of the means by which they have been produced; and Miss E. Hodgson a long disquisition on the origin and distribution of the granite-drift of the Furness district. The longest article in the journal is a report of Mr. David Forbes' lecture on Volcanoes, which will be read with much interest.

The *Journal of the Asiatic Society* for April, contains the following Natural History papers—Observations on some Indian and Malayan Amphibia and Reptilia, by Dr. F. Stoliczka. The species described in this paper have been partially collected by the author along the Burmese and Malayan coast, in Penang and Singapore, partially at the Nicobar and Andaman islands, only a few species are noticed from Java, and a few also from the N. W. Himalayas. Short notes on the geographical distribution, and on the general character of the amphibian and reptilian fauna of the Andamans and Nicobars, form a brief preface to the detailed descriptions. Complete lists of all the known species occurring on the two last-named groups of islands are appended. Dr. Stoliczka gave a short sketch of the relations existing between the Andaman and Nicobar reptilian fauna and that of Burma on the one, and that of Java, Sumatra, and the Philippine islands on the other hand. All these islands, he said, have many species in common. He also specially notices the very great number of viperine snakes (*Trimeresurus*) which are to be met with at the Nicobars, but fortunately these species appear to be less dangerous than continental forms usually are. The Nicobarese say that not a single fatal case has resulted from the bite of these *Trimeresurus*, and certainly all the specimens examined had a comparatively small poison-gland. The result of the bite is said to be only a swelling of the wounded part. Dr. Stoliczka also exhibited a specimen of the rare *Callophis intestinalis* obtained from Upper Burma. The species has the poison glands extending from the head to about one-third of the total length of the body, lying free in the cavity of the anterior part, and causing the heart to be much further removed backward than is generally the case in other species of snakes. The President thought there were one or two remarkable features in Dr. Stoliczka's interesting paper. One to which he particularly referred was the relative inefficiency of the poison in certain snakes of Penang and the Nicobars in comparison with the poison of the cognate species found in this country. He did not know whether the circumstances which rendered the possession of an invariably fatal weapon necessary to particular classes of snakes in the struggle for life, while others could maintain themselves without it, had yet received much attention. *A priori*, he thought, one would be disposed to expect that a poison which would disable without causing immediate death, would be more deterrent in its effects, and, therefore, more widely useful to its possessor, than one which killed instantly. At any rate it was curious to find some of the insular species of snakes, though provided with a perfect poison apparatus, much less fatal in the effect of their bite than other closely allied species in Bengal were. The investigation of the causes which had led to this difference ought to be attractive. A short discussion on the effects of snake poisoning ensued. Mr. Waldie desired to know what the symptoms resulted from the bite of the Nicobar vipers, and whether they are the same as are usually known to originate from the bite of other poisonous snakes. Dr. Stoliczka said that the Nicobarese only speak of a swelling of the bitten part, and that they exhibit very little fear of these snakes. Dr. Stoliczka also observed that the poison gland in the species of *Trimeresurus* which he had examined, has a simple glandular form without any appendages, but the skin forming it is very tough, and internally partitioned by numerous irregular lamellæ. The poison of the fresh snake was always present in a comparatively small quantity, and appeared less viscose than the Cobra poison. The differences between the effects of poisoning of the cobra and daboia had been pointed out by Dr. Fayrer.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, June 22.—II. "On the Physics of Arctic Ice as explanatory of the Glacial Remains in Scotland." By Dr. Robert Brown, F.R.G.S., &c. In this paper the author entered into an extended inquiry how far the formation of the boulder-clays and other glacial remains in Scotland and the North of England can be accounted for, on the theory of a great ice-covering having at one time overlain the country in much the same manner as it does now Greenland and other extreme Arctic countries. Taking the hypothesis of Agassiz as his groundwork, Dr. Brown entered into a minute description of the present glacier-system of Greenland, and the nature of Arctic ice-action; and into an inquiry how far glacial remains in Britain correspond with those at present in course of formation in Greenland and at the bottom of Baffins Bay, Davis Straits, and the fjords and bays adjoining these seas. These inquiries were commenced in the year 1861, and have been continued at intervals ever since up to the present summer in various portions of the Arctic regions, the Continent of Europe, in Great Britain, and in North America across to the Pacific. The results of these extended researches have led him to conclude—1. That the subazoic boulder-clay corresponds with the *moraine profonde* which underlies glaciers, and in all likelihood is the immediate base on which the ice-cap of Greenland rests. 2. That the fossiliferous, laminated, or brick-clays find their counterpart in the thick impalpable mud which the subglacial streams are pouring into the sea, filling up the fjords, even shoaling the sea far out, and absolutely in some cases turning the glaciers from their course into other valleys. Allowing the very moderate computation that this impalpable mud accumulates at the rate of only six inches per annum, a deposit of fifty feet in a century must form. If Scotland was at one time covered with an ice-cap, or had glaciers of any extent (as cannot be doubted), then this deposit must have been equally forming, and as a geological formation must be accounted for. No difference could be detected between this glacial mud and the present brick-clays, and every fact went to show that it was to this that we must look for the formation of these laminated fossiliferous clays. The amount of earth deposited on the bottom by icebergs was very insignificant indeed, and could in no degree account for the *boulder-clay*, though it was shown that much of the *boulder-drift* in *some places* could be so accounted for. It was, however, demonstrated that there was a great distinction between the boulders which belonged to the *moraine profonde* and those which were carried off on icebergs as part of the ordinary lateral moraines. The fjords, as already partially advocated in a paper in the Journal of the Royal Geographical Society (vol. xxxix.), he considered due to glacial action, the glaciers having taken possession of these fjords when they were mere valleys, when the coast was higher than now. He further showed that the American explorers are in error when they describe the coast of Greenland as rising to the north of 73°, and subsiding to the south of that parallel. There had been a former rise of the coast, and a fall was now in course of progress through the whole extent. Whether these had previously alternated with other rises and falls is not clearly evidenced by remains, but no doubt exists that a rise preceded the present subsidence. Numerous facts were adduced in support of this assertion. The remainder of Dr. Brown's paper was occupied in an attempt to apply the doctrines regarding the physical action of Arctic ice-action to account for the Scottish glacial remains, and to deduce therefrom evidence regarding the changes Scotland underwent during, and subsequent to, the glacial period.

Aeronautical Society, June 3.—Mr. James Glaisher, F.R.S., in the chair. The following extract from the minutes of a late meeting at Stafford House, was read by the Secretary. It was remarked how little had been done in this country either to demonstrate the possibility of navigating the air, or to prove its impracticability. Sir William Fairbairn observed that we know but little of the reaction or lifting power of various forms of screw blades in the atmosphere, relative to the force employed, though such experiments might be easily tried, and the data obtained. Mr. Brooke was of opinion that if a successful aërial machine were to be constructed, the most simple and obvious plan would be that of inclined surfaces, impelled forward horizontally. The most successful experiment that he had ever witnessed was upon this principle, the motive power being a wound-up watch spring, which, as long as the power lasted, sustained the machine; and further, that most large birds were capable, during long periods of their flight, of sustaining themselves exactly in this way. It was also remarked that we were practically ignorant of the correct laws of the sustaining power of inclined surfaces of different forms and areas, and this want of knowledge was a perpetual stumbling-block to those who were willing to spend time and money in experiments. From the fact that as the weight and size of birds increased, so did the relative wing area decrease, it would appear that the ratio of sustaining surface to weight or resistance was by no means in equal proportions. The Chairman stated that with respect to plane surfaces of various figures exposed to the direct impact of the wind, he had already been trying some experiments with such instruments as were at his disposal, and that by employing two anemometers at the same time, so as to be sure of comparative results, he found that the indication of force increased with the size of the surface; also in the two instruments, equal surfaces shaped into different contours, gave different results. These interesting experiments, so directly bearing upon the question of aërial propulsion and resistance, were still occupying his attention, but at present he could say nothing from actual experiment of the resistance of inclined surfaces of various forms. It was then proposed that an experimental fund should be raised by subscription, and that a suitable and well-finished anemometer should be constructed, having the means of instantly setting various plane surfaces at any desired angle, and capable of registering both horizontal and vertical force simultaneously for all degrees of inclination. The results to be published for the benefit of the Society. Upon this proposition being put to the meeting it was carried unanimously.

Ethnological Society, June 21.—Prof. Huxley, F.R.S., president, in the chair. Colonel Lane Fox made some remarks on the Dorchester dykes and Sinodun Hill, to which attention has recently been directed, and showed that the works are British, and not Roman. He stated that the demolition of these works had been arrested for the present.—Mr. David Forbes, F.R.S., read a paper on the Aymara Indians of Bolivia and Peru. He described them as a small, massive, thick-set race, with large heads and short limbs. The trunk is disproportionately large, and the capacity of the thorax is enormous, being adapted to meet the requirements of respiration in a rarefied atmosphere, as the Aymara lives at an elevation of from 8,000 to 16,000 feet above the sea-level. The proportions of the lower limbs are curious, the thigh being shorter than the leg; the heel is inconspicuous. In colour, the Aymara varies from copper-red to yellowish brown and blackish brown, according to the altitude at which he lives. Many of the customs of the Aymaras depend on their peculiar conditions of life. In consequence of the low boiling-point of water at such great altitudes, beans are rarely used, and the food consists chiefly of potatoes peculiarly prepared. Clay is added to the food, not for any nutritious matter in it, but apparently only to increase the bulk of the meal. In religion, the Aymaras are nominally Christians. They appear to have no system of writing. The discussion on this communication was supported by the President, Mr. E. G. Squier, Mr. Cull, Mr. Dendy, Mr. Bollaert, Mr. Harrison, and Mr. C. Markham. At the same meeting Dr. A. Campbell exhibited tracings of certain rock-inscriptions from British Guiana, and the Hon. E. G. Squier displayed a large collection of drawings, photographs, &c., from Peru.

Anthropological Society of London, June 14.—John Beddoe, M.D., president, in the chair.—Logan D. H. Russell, M.D., of Wilmington, Delaware, was elected a local secretary.—A paper, by Dr. Henry Hudson, was read "On the Irish Celt," in which the author depicted the mental and moral characteristics of that type, and drew conclusions as to the kind of government most suitable to such a people.—Mr. G. H. Kinahan contributed a paper "On the Race Elements of the Irish People." That paper entered largely into the pedigree of the chief families of Connaught and Munster, and treated of the effects of the Cromwellian and other confiscations.—The President (Dr. Beddoe) then read a paper "On the Kelts of Ireland." The principal points proved or indicated in it were the following:—That the Kelts known to the Greek and Latin authors, though they were a light-haired race as compared with the Italians, were darker than the Teutonic tribes, and that their physical type differed in other respects. That the Irish are, generally speaking, a dark-haired but light-eyed race, and that wherever there is much light hair it may be accounted for by a Danish or English cross. That the dark hair of the Irish may be, partly at least, attributed to the Gaelic Kelts. That there is less resemblance between the Irish, taken as a whole, and the Basques, who are generally considered to be the purest Iberians extant, than between the South Welsh and the Basques. That any Basque or Iberian element in Ireland is probably small, and can have only partially contributed to the prevalence of dark hair among the Western Irish. That Ugrian or Ligurian elements may also be present there. The paper was illustrated by minute details respecting the physical types in various parts of modern Ireland, including extensive observations on the colour of the eyes and hair; and the author exhibited a number of photographic and other portraits of Basques and of Bretons, Welshmen, Walloons, and other supposed descendants of the Keltic race.

Meteorological Society, June 15.—Ordinary meeting, Charles V. Walker, F.R.S., president, in the chair. Messrs. W. C. Ellis and Francis Nunes were elected Fellows, and Padre Prof. F. Denza was elected an Honorary Fellow of the society.—The following communications were made: "On the path of the large fireball of November 6th, 1869," by Prof. A. S. Herschel; "On the temperature of the air in Natal, South Africa," by R. J. Mann, M.D., F.R.A.S., &c.; "On the atmospheric pressure with relation to wind and rain," by R. Strachan, F.M.S., and "On the November meteors of 1869, as seen from the Mauritius," by Charles Meldrum, F.R.A.S.—The anniversary meeting was then held, and the report of the council on the present state of meteorological science both at home and abroad, also their report on the present state of the society, which now numbers 343 Ordinary, Life, and Honorary Fellows, and the treasurer's report were then read and adopted. The following is the result of the ballot for the officers and council for the ensuing year.—President, Charles T. Walker, F.R.S., F.R.A.S.; Vice-Presidents, Nathaniel Beardmore, C.E., F.R.S.; C. O. F. Cator; Robert J. Mann, M.D., F.R.A.S.; John W. Tripe, M.D. Treasurer, Henry Perigal, F.R.A.S. Trustees, Sir Antonio Brady, F.G.S., and S. W. Silver. Secretaries, Charles Brooke, F.R.S., F.R.C.S., and James Glaisher, F.R.S., F.R.A.S. Foreign secretaries, Lieut.-Colonel Alex. Strange, F.R.S., F.R.A.S. Council, Arthur Brewin, F.R.A.S., George Dives, F. W. Doggett, Henry S. Eaton, F. Gaster, Charles M. Gibson, Rev. Joseph B. Reade, M.A., F.R.S., W. Wilson Saunders, F.R.S., F.L.S., Thomas Sopwith, F.R.S., George J. Symons, S. C. Whitbread, F.R.S., F.R.A.S., E. O. W. Whitehouse, F.S.A., &c.

Statistical Society, June 23.—William Newmarch, F.R.S., president, in the chair. The following is the list of president, council, and officers, elected to serve for the ensuing year:—President, William Newmarch, F.R.S. Council, Major-General Balfour, C.B., Dr. Thomas Graham Balfour, F.R.S., R. Dudley Baxter, Samuel Brown, Hyde Clarke, D.C.L., L. H. Courtney, Sir C. Wentworth Dilke, Bart., M.P., Dr. W. Farr, F.R.S., W. Fowler, M.P., F. Galton, F.R.S., Right Hon. W. E. Gladstone, M.P., J. Glover, W. A. Guy, M.B., F.R.S., J. T. Hammick, F. Hendriks, J. Heywood, F.R.S., W. Barwick Hodge, F. Jourdan, Prof. Leone Levi, Sir Massey Lopes, Bart., M.P., W. G. Lumley, Q.C., LL.M., J. MacClelland, F. Purdy, Bernhard Samuelson, M.P., Col. W. H. Sykes, M.P., F.R.S., Ernest Seyd, W. Tayler, W. Pollard-Urquhart, M.P., Prof. Jacob Waley, J. Walter, M.P. Treasurer, J. T.

Hammick. Honorary Secretaries, W. Golden Lumley, Q.C., LL.M., F. Purdy, Prof. Jacob Waley.

BRISTOL

The Observing Astronomical Society.—Report of observations made by the members during the period from May 7 to July 6, 1870, inclusive. *Solar Phenomena*—Mr. John Birmingham, of Tuam, writes: "A remarkable obscuration of the sun was observed here on May 22. It lasted from sunrise to sunset, with a short interval in the afternoon of returning brightness. The sun was of a beautiful pink colour, though there was no fog whatever, and its light was so reduced as to permit a long observation of it through the telescope without the aid of a dark glass. I am informed that the same phenomenon was noticed in the South of England on the next day (the 23rd), and on that day also, but late in the afternoon, it was observed at Rohrbach (Moselle), and described by M. Hamant in a letter to the Scientific Association; so that the cause of the obscuration, whatever it was, seems to have been moving eastward and southward." Mr. T. W. Backhouse, of Sunderland, reports that in May "there was a remarkable case of a solar spot making a revolution round another. It occurred with respect to the two largest spots of a group that was half way across the northern zone on May 9. The smaller spot was south of the larger on the 7th at 3^h, but preceded it on the 12th at 21^h, the line joining the two spots having rotated through an angle of 80° or 90° in $5\frac{3}{4}$ days. This movement continued to the 15th, but this would be partly apparent owing to the group approaching the limb. By that time the larger spot was reduced to the size of the other. I cannot say whether the motion was a curve or a straight line, though it was probably the former; nor can I say which of the spots moved or whether both did. They were about 22,000 miles apart on the 9th, at 3^h; but on the 13th, at 20^h, they were 32,000 miles apart. One spot must therefore have moved, relatively to the other, about 34,000 miles in $4\frac{3}{4}$ days, or at the rate of 300 miles per hour." Mr. T. G. E. Elger, of Bedford, says: "The sun spots observed during June were, with the exception of one group, small and devoid of interest when compared with those seen in April and May. The largest spots were confined to the sun's northern hemisphere. Between the 8th and 15th the spots were all small; on the latter date there were only two groups on the disc, and these were insignificant. On the 19th a very remarkable spot was observed, it formed the preceding member of a large scattered group 2′ 52″ in length; its penumbra measured about 1′ 10″ in greatest diameter. At 10 A.M. an isolated mass of light, intensely bright, was remarked on the nucleus. This, at 2 P.M., formed a 'bridge' connecting adjacent sides of the umbra. The nucleus of this spot was very irregular in colour. At $5^h\ 15^m$ on the 19th the central portion was noted as brown and the border as black, and subsequently the variety of tint was still more marked. At 7 A.M. on the 21st, when the penumbra showed evident signs of cyclonic action, not more than half the area of the nucleus was black, the remainder was made up of patches of various shades of brown. The group disappeared at the limb on the 27th." The Rev. S. J. Johnson, of Crediton, observed numerous spots on the sun on May 13. There were then four groups with penumbræ close together. Mr. H. Michell Whitley, of Penarth, says: "June 21—I noted on the sun's disc one very large, round, and well-defined spot; on one side, however, the penumbra was invaded by two tongues of faculæ for a short distance, and in the centre of the umbra was a bright patch."

The Planet Saturn.—Mr. H. Michell Whitley repeatedly observed this object with his $6\frac{1}{4}$in. reflector. He says—"June 21. Air very unsteady, but after midnight better. The Ball—duller yellow than rings, equatorial zone yellow, north of this a pale red belt, and another farther north again, towards Pole much fainter and about midway. Pole of planet bluish grey, edges of ball slightly shaded; no other spots or markings. Ring A—Inferior in brightness to B; colour, pale yellow; no subdivisions or markings on it. Ball's division—Traced all round; widest and darkest, if at all, in Wansa; sharply defined. In colour it was not so black as the sky, but deeper than the crape ring across the ball; colour, dusky. Ring B—This ring was very bright for a short distance from its outer edge, which was verp sharply defined; colour gradually deepens and light fades towards inner edge; outer edge lemon yellow, duller and deeper inwards, strongly suspected to be streaky, but no actual subdivision seen. No line of light on inner edge of ring, which was not sharply defined. Ring C, or Crape Ring—Very delicate colour, dusky purple. I could with care, as a very fine object, trace the edge of the globe through it up to ring B, equally distinct in E and Wansa; no markings of any kind upon it.—June 28, 10^h to $11^h\ 15^m$. Power, 250; definition very fluttering. N. equatorial ruddy belt very distinct; equatorial yellow band the brightest part of the planet. Between the N. equatorial ruddy belt and N. Pole lay one or more very faint ruddy bands. Pole, pale bluish grey; no other markings. The Crape Ring very dark and distinct across the Ball.—July 2, 10^h. Definition very sharp; power 250. A glimpse observation. The two belts before mentioned very much plainer and darker than on June 21—28, and not of such a ruddy hue."

Lunar Observations.—Mr. John Birmingham, of Tuam, Ireland, reports that on June 6 he saw "A very marked central depression in the white spot of Linné though the terminator was so far away as the boundary between the Mare and the Palus Putridinus. The depression was rather east of the exact centre of the white spot, so that the western exterior slope was longer than the eastern." Mr. H. Michell Whitley has observed with great care many interesting and difficult lunar objects, and the results of his observations have been sent to Mr. W. R. Birt, F.R.A.S.

Winnecke's Comet.—Mr. George J. Walker, of Teignmouth, observed this body on June 5, 6, and 7. He says that "It looked like a tolerably bright nebula;" on the 6th, at $14^h\ 13^m$ the comet looked faint owing to the strong twilight.

Meteors.—Mr. G. J. Walker saw "a splendid meteor" on June 24. It traversed the greater part of the sky, and was much larger and brighter than Venus. It was of a blue colour. Mr. Walker adds, "I think it appeared a little to the right of Altair, and passed over Vega and on to the Pointers in Ursa Major; it had a magnificent train, and I think must have traversed an arc of about 120°. The time of its appearance, as well as I could make out from my watch, was $11^h\ 13^m$ G.M.T., and it may have been seven or eight seconds making its sweep over the heavens. I did not hear any sound with it." Mr. H. M. Whitley observed a brilliant meteor on June 29 at $11^h\ 30^m$. It was of the second magnitude. "Pale yellow; velocity very great."

A New Red Star.—Mr. John Birmingham has "frequently observed a red star in Cygnus, not, I believe, previously noticed; at least, it is not in Schjelterup's catalogue (Ast. Nach., No. 1,591), which gives a list of all the red stars known up to 1866. It is of a deep red, of about the 8th Mag., and is near a blue star of the same size. Its approximate position, compared with 32 Cygni, is about

R.A. $20^h\ 15^m\ 37^s$; Declin. + 47° 27′ 28″.

Occultation.—Mr. Walker witnessed the occultation of θ Libræ on June 11, and found that the exact time of disappearance was $9^h\ 27^m\ 55{\cdot}6^s$ G.M.T.

EDINBURGH

Botanical Society, May 12.—Sir Walter Elliot, president, in the chair.—The following communications were read:—Botanical Notes of a Journey through Spain and Portugal, by Mr. T. C. Archer; Botanical Notes on the Garden of Montserrat, Portugal, by Mr. T. C. Archer; Botanical Notes taken on the Rock of Gibraltar, by Mr. T. C. Archer; Report on the open-air Vegetation at the Royal Botanic Garden, by Mr. M'Nab.

June 9.—Sir Walter Elliot, president, in the chair. The following communications were read:—Notes on the Ipecacuanha Plant. By Dr. Gunning, Rio Janeiro. Dr. Gunning states that the Ipecacuanha plant is exceedingly scarce in the province of Rio Janeiro from having been pulled up, and no attention paid to its cultivation. It is exported from Sao Paulo, the province south of Rio, but chiefly from Matto Grosso, a thousand miles up the River Plate. At present Dr. Gunning is rearing a number of cuttings for transmission to India, where it is proposed to cultivate it extensively.—New and rare Mosses from Ben Lawers. By Dr. J. Stirton, Glasgow. In this paper the author reviewed the progress of discovery of mosses on Ben Lawers within the ten years, indicated in general terms the habitats of the rarer species, as well as their tendencies towards increased luxuriance, or gradual decay and extinction, and noticed the affinities between the Cryptogamic Flora of the mountain (Ben Lawers) and that of Scandinavia, more especially of the Dovrefield.—Notice of Grimmias, collected on Arthur Seat, near Edinburgh, by Mr. William Bell and Mr. Sadler. The authors described twelve species and several varieties of the genus Grimmia, as growing on Arthur Seat; noticed their distribution over the hill, and the kind of rocks on which they occurred.—Notes on some British Mosses. By Mr. Wm. Wilson. Mr. Wilson referred to the British species of *Andræa*, which he had revised for the second edition of his "Bryologia Britannica," and especially to *Didymodon jenneri*, a moss recently described and figured in the Society's Transactions. The latter he believed to be in no way specifically different from *Cynodontium polycarpon*.—On the Ferns found in the Valley of the Derwent. By Mr. T. W. Mawson. Mr. Mawson enumerated twenty-eight species and varieties of ferns as indigenous to the Valley of Derwentwater, including *Asplenium germanicum*, *A. septentrionale*, *Hymenophyllum wilsoni*, *Osmunda regalis*, *Ophioglossum vulgatum*, *Allosorus crispus*, &c.

PARIS

Academy of Sciences, July 18.—M. Bertrand communicated a paper by M. L. Painvin on the determination of the elements of the angle of inflexion of a developable surface defined by its tangential equations.—Several papers on physical subjects were presented, namely—an extract of a letter from M. De la Reve to M. Dumas on the magnetic rotatory powers of liquids; further researches upon electro-capillary action, and on the formation of crystallised oxychloride of copper and other analogous compounds by M. Becquerel; a memoir on the variations of temperature produced by the mixing of two liquids by M. H. Sainte-Claire Deville, in reply to the last communication by M. Jamin, and a reply by the same author to the criticisms of M. Jamin upon a memoir published in 1860; thermical researches upon the metallic character of hydrogen associated with palladium, and on a voltaic couple, in which hydrogen is the active metal by M. P. A. Favre; and a note by M. F. Lucas, communicated by M. E. Becquerel, on the possibility of obtaining fire signals visible at a great disrance, for which purpose the author proposes to employ an electric spark generated by an apparatus described by him.—M. de Saint-Venant presented a memoir on the elementary demonstration of the formula of propagation of a wave or intumescence in a prismatic canal, with remarks on the propagation of sound and light, on ressaults, and on the distinction of rivers and torrents.—A note was read by M. Sonrel on the photographic investigation of the sun at the Imperial Observatory of Paris.—MM. Becquerel and E. Becquerel presented a note on the observations of temperature made beneath the soil at the Garden of Plants from 1864-1870, by means of thermo-electric cables, with tables of results.—The following chemical papers were read:—Investigations upon the action of the chlorides of platinum, palladium, and gold upon the phosphines and arsines, by MM. A. Cahours and H. Gall; a note on the decomposition of oxalic acid by M. P. Carles, communicated by M. Bussy; and a note by M. J. Personne on the conversion of chloral into aldehyde, also presented by M. Bussy.—M. Combes presented a note by M. Flajolot on some crystallised compounds of the oxides of lead and antimony, and of oxide of lead with antimonic acid from the province of Constantine, in Algeria.—A report was read from M. Pasteur on the results of the rearing of silkworms from eggs prepared by processes of selection at Villa Vicentina.—M. C. Robin communicated a note by M. A. Sanson on the influence of the rapid development of the bones upon their density; and M. P. Balestra presented an account of his researches and experiments upon the nature and origin of marsh miasmata, from which he is inclined to believe that the miasmata of marshy places are due to the spores of algæ floating in the air.

VIENNA

Imperial Academy of Sciences, June 17.—Dr. K. Exner communicated a memoir on the sensation of light.—M. J. Schubert communicated drawings and descriptions of a lamp and of an electrical apparatus for producing sound.—M. Tschermak presented a report on the recent fall of a meteorite near Murzuk, in Fezzan.—M. K. Puschl presented a memoir on the amount of heat and the temperature of bodies.—A memoir on reflex action of the nasal mucous membrane upon respiration and the circulation of the blood, by Dr. Kratschmer, was communicated by Prof. E. Hering.—Prof. A. Winckler presented a memoir on the relations between the perfect Abelian integrals of different kinds.—M. von Littrow remarked upon the elements of Winnecke's comet, as calculated by Dr. von Oppolzer.—Prof. Hlasiwetz communicated the results of a long series of experiments made by Dr. Weselsky on the formation of the chinones; and Prof. A. Bauer noticed a compound of platinum and lead having the formula Pt + Pb.

June 23.—The following memoirs were communicated by the Secretary:—On the path of Hind's comet (1847, I.), by Dr. K. Hornstein; on similar conic sections, by M. E. Weyr; and two theories of the movement of free resting masses, by Dr. Recht.—Dr. L. J. Fitzinger communicated the third part of his critical revision of the family of the bats, including the genera *Nyctinomus*, *Thyroptera*, *Exochurus*, *Cnephaiophilus*, and *Vesperus*.—A memoir by Prof. G. Hinrichs (of Iowa), on the statistics of crystalline symmetry, was read, as also a note on the annual course of the temperature at Klagenfurt, Trieste, and Arvavaralja, by Dr. K. Jelinek.

BERLIN

Royal Prussian Academy of Sciences, May 5.—Professor Ehrenberg read a communication on the increasing knowledge of invisible life in the rock-forming *Bacillariæ* of California.

May 12.—Professor Poggendorff read a memoir upon some new and remarkable properties of the diametrical conductors of the electrical machine and on a double machine founded upon these. This paper, which is of considerable length, is illustrated with a figure of the new double machine.—Professor W. Peters read a description, illustrated with figures, of *Platemys tuberosa*, a new species of tortoise from British Guiana.

May 19.—Professor Rammelsberg read a paper on the composition of the meteorites of Shalka and Hainholz.

May 23.—Professor Ewald read a paper on some questions relating to the geology of the Andes.

GÖTTINGEN

Royal Society of Science, April 6.—A paper by M. W. Krauss on the anterior epithelium of the cornea was read.

April 27.—M. A. Clebsch communicated a paper by Prof. C. Schweigger on the size of the ophthalmoscopic picture, and M. L. Meyer read a note on the occurrence of granular cells in the nervous centres.

May 7.—Prof. Sartorius von Waltershausen read a memoir on the isomorphism of the sulphates of lead, baryta, strontian, lime, potash, soda, and ammonia.—Dr. M. A. Stern presented a simple proof of the law of quadratic reciprocity, and some propositions connected therewith.—M. A. Clebsch read a paper on certain problems of the theory of algebraic surfaces.—M. W. Klinkerfues presented a note of some investigations on the movement of the earth and sun in the æther.—Prof. Enneper read a paper on a problem of mathematical geometry, and Prof. Kohlrausch a notice of the influence of temperature on the coëfficients of elasticity of certain metals.

BOSTON

Natural History Society, *Section of Entomology*, March 23.—Mr. S. H. Scudder in the chair. "Synopsis *Pseudoscorpionidum synonymica*," by Dr. H. Hagen.—Dr. Hagen stated that Dr. A. S. Packard, jun., had recently discovered in Brunswick, Maine, and in Salem, a species of *Amphientomum*, a genus of Neuroptera, whose body is covered with scales, and heretofore known only from Ceylon.—The following paper was read:—"On the Synonymy of *Thecla Calanus*," by Samuel H. Scudder.

CONTENTS

ERRATUM.—Page 235, second column, line 24, for "Caprera" read "Capri."

THURSDAY, AUGUST 4, 1870

THE SCIENCE AND ART DEPARTMENT

THE Report of the Science and Art Department just issued is a document of such vast importance to all interested in Science or Education, that we take the first opportunity of saying something upon it. The work which has been done in Science by this Department is so little known, however, that it is necessary to preface our account of this year's report by a brief history of what has been attempted, and accomplished, in former years.

In 1853 the Board of Trade proposed to extend a system of encouragement, similar to that already commenced in the Department of Practical Art, to local institutions of Practical Science, and the Treasury at once wrote one of their classical minutes, in which they expressed the concurrence of "My Lords" generally, in the plans proposed by the President of the Board of Trade, "as the most effectual means of giving effect to the recommendation of Her Majesty at the opening of the Session, with a view to the advancement of Practical Science."

Experiments were tried in the way of Science—or Trade and Navigation—Schools at Aberdeen, Birmingham, Bristol, Leeds, Newcastle-on-Tyne, Poplar, Green's Sailor's Home, Stoke, Truro, Wigan, Wandsworth, and other places. Most of these experiments failed after a short time.

In June 1859 the minute which is the foundation of the present system of aid passed, but this minute has been greatly modified from time to time and greatly enlarged.

The plan pursued before 1859 followed, more or less, the analogy of the elementary school system. That is to say, a trained teacher was sent where a committee was formed, a certain salary guaranteed for a year or two, and so on. This kind of encouragement, however, failed. The requirement of the country was not only teachers to teach but people who wished to learn. After a short time teachers exhausted the guarantee and the schools were broken up.

The state of the country as respects science instruction for artisans at this time (eleven years ago) is well described by Dr. Hudson in a letter then written to the Education Department. In Lancashire and Cheshire, he says, there was no instruction in chemistry, except in "small classes chiefly for mutual improvement in elementary chemistry, and conducted without the aid of efficient teachers, which are in operation at Ballington, Hyde, Staleybridge, Stockport, and Burnley. In Yorkshire, the only night schools affording instruction in chemistry are at Bradford, Halifax, Huddersfield, Leeds, and Selby."

"No instruction whatever is afforded at any Mechanics' Institute in Yorkshire, Lancashire, or Cheshire; and mineralogy, as applied to mining, has only been recently added to the programme of class instruction in one single society—the Wigan Mechanics' Institution."

"In the whole district of Lancashire and Yorkshire, extending from sea to sea, there is no adult school or mechanics' institute in which theoretical mechanics is taught, ... or experimental physics." "The three Ridings of Yorkshire, with their 150 mechanics' and kindred institutions, only possess two societies, and these mere village institutes, in which instruction—Manston in Physical Science, and Shipley in Natural Philosophy—is afforded, and this to an infinitesimal amount. With two exceptions, there are no mechanics' institutions or mutual improvement societies in Lancashire in which any elementary instruction in Physics (Natural Philosophy or Mechanics) is given, and the county of Cheshire does not present one instance in which these matters receive attention in similar societies."

The essential point of the system which the department has organised to reach this terrible state of things, is that it pays simply for results with a preliminary test examination of teachers,—the Honours examination enabling teachers to show high qualifications if they possess them. And the aim has been to enlist all kinds of persons resident in different localities—sometimes the teachers of the ordinary day schools, at other times workmen who had an aptitude for teaching—to commence science instruction, and it looks very much as if this plan has met the difficulty. It has permitted small beginnings by persons conversant with a locality when outsiders could have had neither chance of doing anything, nor sufficient work to support them. It has, in fact, been a missionary effort, and as such has succeeded, and has been paid for.

So much for a general historical sketch of the *modus operandi* of the Department; let us now come to the description, and give evidence of a power at work, which, with proper encouragement, will in time do wonders. The "no schools" of 1859 were represented by 120 schools with 5,479 pupils in 1865, and by 779 schools and 34,283 pupils in the present year. Here are the general results in tabular form:—

	1868.	1869.		1870.
Number of Schools under Teachers examined	300	523		799
Number of Classes in the same	856	1,489		2,200
Number of individuals under instruction in Classes under Certificated Teachers	15,010	24,865		34,283
Number of the above who came up for examination	6,875	12,988	(about)	17,000
Number examined in addition to the above who were not in Schools under Certificated Teachers	217	246	(about)	700
Number of Papers worked in:— Subject.				
1. Practical, Plane, and Solid Geometry	1,337	2,638		3,359
2. Machine Construction and Drawing	1,671	2,987		3,656
3. Building Construction	1,185	1,998		2,631
3 (alternative). Naval Architecture	21	12		39
4. Elementary Mathematics	1,390	2,329	Stage I. II. & III.	3,837
			,, IV. & V.	108
5. Higher Mathematics	33	84	,, VI. & VII.	50
6. Theoretical Mechanics	353	629		830
7. Applied Mechanics	167	294		551
8. Acoustics, Light and Heat	769	1,352		2,021
9. Magnetism and Electricity	1,038	2,509		2,613
10. Inorganic Chemistry	964	2,173		2,694
11. Organic Chemistry	123	210		235
12. Geology	309	619		1,069
13. Mineralogy	38	67		63
14. Animal Physiology	1,182	2,227		3,705
15. Zoology	298	303		114

Total number of Papers worked	13,112	24,085		89,395

From the above table we gather that there were in May, 1869, 523 schools and 24,865 pupils; in May, 1870, 799 schools with 34,283 pupils, the number of teachers at present giving instruction in connection with the Department being nearly 1,000. Now, how is this work being done? In the first place let us say that it is going on among classes of the community which all our other educational means do not touch, and, as may be imagined, much of the work is night work; in some cases the working men taught have commenced their education by building their schoolrooms; and those who know the delights of a laboratory would think that the chemistry was acquired by apparatus and appliances which made even the simplest experiment an impossibility.

Secondly, let us say that all the year's work is brought to a focus by examinations held on the same night throughout the length and breadth of the land, the papers being sent from South Kensington to the local committees with infinite precautions, and the answers being returned sealed the same night to London. They then are handed over, with no indication as to name of candidate or place of examination, to the Government examiners, and when we state that these examiners include the names of Huxley, Frankland, Ramsay, Tyndall, and others of like calibre, we need say no more as to the rigour and fairness of the examination. Here is a table showing how this ordeal is passed :—

Year.	No. examined.	No. of Papers worked.	No. of Papers passed.
1867	4,520	8,213	6,013
1868	7,092	13,112	8,649
1869	13,234	24,085	14,550

It is impossible within the limits of an article to dwell upon the various points of inquiry and interest which lie around the working of the system: we shall be content if we have shown what it is doing, and how the teaching is being conducted. When these points are known there can be no doubt as to the importance of the work done, and, although many improvements may be required, it is clear that *in essentials* the Department is now on the right track and is doing great good. What is most required is systematising and formulating the instruction. Hitherto the teaching has been rather desultory. It is very desirable that regular systematic courses of instruction, adapted to the local requirements, should be imposed as soon as this can be done without checking the spread of instruction. Some examiners complain of "cram," but this is not limited to the South Kensington system; and the teachers complain of poor pay. This should certainly be corrected; the results they are accomplishing are too important to be ignored; and it would seem that the time had almost come for a complete inquiry into the whole system in order that this important national engine should work with the least possible friction and waste of power.

WHAT IS ENERGY?

IV.—THE DISSIPATION OF ENERGY

At this point we can imagine some champion of perpetual motion coming forward and proposing conditions of truce. "I acknowledge," he will say, "that perpetual motion, as you have defined it, is quite impossible, for no machine can *create* energy, but yet I do not see from your own stand-point that a machine might not be constructed that would produce work for ever. You tell me, and I believe you, that heat is a species of molecular motion, and hence that the walls of the room in which we now sit are full of a kind of invisible energy, all the particles being in rapid motion." Now, may we not suppose a machine to exist which converts this molecular motion into ordinary work, drawing first of all the heat from the walls, then from the adjacent air; cooling down, in fact, the surrounding universe, and transforming the energy of heat so abstracted into good substantial work? There is no doubt work can be converted into heat—as, for instance, by the blow of a hammer on an anvil—why, therefore, cannot this heat be converted back again into work?

We reply by quoting the laws discovered by Carnot, Clausius, Thomson, and Rankine, who have all from different points of view been led to the same conclusion, which, alas! is fatal to all hopes of perpetual motion. We may, they tell us, with the greatest ease convert mechanical work into heat, but we cannot by any means convert all the energy of heat back again into mechanical work. In the steam-engine we do what can be done in this way; but it is a very small proportion of the whole energy of the heat that is there converted into work, for a large portion is dissipated, and will continue to be dissipated, however perfect our engine may become. Let the greatest care be taken in the construction and working of a steam-engine, yet shall we not succeed in converting one-fourth of the whole energy of the heat of the coals into mechanical effect.

In fact, the process by which work can be converted into heat is not a completely reversible process, and Sir W. Thomson has worked out the consequences of this fact in his beautiful theory of the dissipation of energy.

As far as human convenience is concerned, the different kinds of energy do not stand on the same footing, for we can make great use of a head of water, or of the wind, or of mechanical motion of any kind, but we can make no use whatever of the energy represented by equally diffused heat. If one body is hotter than another, as the boiler of a steam-engine is hotter than its condenser, then we can make use of this difference of temperature to convert some of the heat into work, but if two substances are equally hot, even although their particles contain an enormous amount of molecular energy, they will not yield us a single foot-pound of work.

Energy is thus of different *qualities*, mechanical energy being the best, and universal heat the worst; in fact, this latter description of energy may be likened to the dreary waste heap of the universe, in which the effete forms of energy are suffered to accumulate, and, alas! this desolate waste heap is always continuing to increase. But before attempting to discuss the probable effect of this process of deterioration upon the present system of things, let us look around us and endeavour to estimate the various sources of energy that have been placed at our disposal.

To begin with our own frames, we all of us possess a certain amount of energy in our systems, a certain capacity for doing work. By an effort of his muscles the blacksmith imparts a formidable velocity to the massive hammer which he wields: now what is consumed in order to produce this? We reply, the tissues of his body are consumed. If he continues working for a long time he will wear out these tissues and nature will call for food and rest; for the former in order to procure the materials out of which new and energetic tissues may be constructed; for the latter, in order to furnish time and leisure for repairing the waste. Ultimately, therefore, the energy of the man is derived from the food which he eats, and if he works much, that is to say, spends a great deal of energy, he will require to eat more than if he hardly works at all. Hence it is well understood that the diet of a man sentenced to imprisonment with hard labour must be more generous than that of one who is merely imprisoned, and that the allowance of food to a soldier in time of war must be greater than in time of peace.

In fact, food is to the animal what fuel is to the engine, only an animal is a much more economical producer of work than an engine. Rumford justly observed that we shall get more work out of a ton of hay if we give it as food to a horse than if we burn it as fuel in an engine. It is in truth the combustion of our food that furnishes our frames with energy, and there is no food capable of nourishing our bodies which, if well dried, is not also capable of being burned in the fire. Having thus traced the energy of our frames to the food which we eat, we next ask whence does this food derive its energy. If we are vegetarians we need not trouble ourselves to go further back, but if we have eaten animal food and have transferred part of the energy of an ox or of a sheep into our own systems, we ask whence has the ox or the sheep derived its energy, and answer, undoubtedly, from the food which it consumes, this food being a vegetable. Ultimately, then, we are led to look to the vegetable kingdom as the source of that great energy which our frames possess in common with those of the inferior animals, and we have now only to go back one more step and ask whence vegetables derive the energy which they possess.

In answering this question, let us endeavour to ascertain what really takes place in the leaves of vegetables. A leaf is, in fact, a laboratory in which the active agent is the sun's rays. A certain species of the solar ray enters this laboratory, and immediately commences to decompose carbonic acid into its constituents oxygen and carbon, allowing the oxygen to escape into the air while the carbon is, in some shape, worked up and assimilated. First of all, then, in this wondrous laboratory of Nature, we have a quantity of carbonic acid drawn in from the air: this is the raw material. Next, we have the source of energy, the active agent: this is light. Thirdly, we have the useful product: that is, the assimilated carbon. Fourthly, we have the product dismissed into the air, and that is oxygen.

We thus perceive that the action which takes place in a leaf is the very reverse of that which takes place in an ordinary fire. In a fire, we burn carbon, and make it unite with oxygen in order to form carbonic acid, and in so doing we change the energy of position derived from the separation of two substances having so great an attraction for each other as oxygen and carbon, into the energy of heat. In a leaf, on the other hand, these two strongly attractive substances are forced asunder, the powerful agent which accomplishes this being the sun's rays, so that it is the energy of these rays which is transformed into the potential energy or energy of position represented by the chemical separation of this oxygen and carbon. The carbon, or rather the woody fibre into which the carbon enters, is thus a source of potential energy, and when made to combine again with oxygen, either by direct combustion or otherwise, it will in the process give out a deal of energy. When we burn wood in our fires we convert this energy into heat, and when we eat vegetables we assimilate this energy into our systems, where it ultimately produces both heat and work. We are thus enabled to trace the energy of the sun's rays through every step of this most wonderful process: first of all building up vegetable food, in the next place feeding the ox or sheep, and lastly through the shape of the very prosaic but essential joint of beef or mutton entering into and sustaining these frames of ours.

We are not, however, quite done yet with vegetable fibre, for that part of it which does not enter into our frames may, notwithstanding, serve as fuel for our engines, and by this means be converted into useful work. And has not Nature, as if anticipating the wants of our age, provided an almost limitless store of such fuel in the vast deposits of coal, by means of which so large a portion of the useful work of the world is done? In geological ages this coal was the fibre of a species of plant, and it has been stored up as if for the benefit of generations like the present.

But there are other products of the sun's rays besides food and fuel. The miller who makes use of water-power or of wind power to grind his corn, the navigator who spreads his sail to catch the breeze, are indebted to our luminary equally with the man who eats meat or who drives an engine. For it is owing to the sun's rays that water is carried up into the atmosphere to be again precipitated so as to form what is called a head of water, and it is also owing to the sun's heat that winds agitate the air. With the trivial exception of tidal energy all the work done in the world is due to the sun, so that we must look to our luminary as the great source of all our energy.

Intimately linked as we are to the sun, it is natural to ask the question, Will the sun last for ever, or will he also die out? There is no apparent reason why the sun should form an exception to the fate of all fires, the only difference being one of size and time. It is larger and hotter, and will last longer than the lamp of an hour, but it is nevertheless a lamp. The principle of degradation would appear to hold throughout, and if we regard not mere matter but useful energy, we are driven to contemplate the death of the universe. Who would live for ever even if he had the elixir of life? or who would purchase, if he might, the dreary privilege to preside at the end of all things—to be "twins in death" with the sun, and to fill up in his own experience the melancholy dream of the poet,—

> The sun's eye had a sickly glare
> The stars with age were wan,
> The skeletons of nations were
> Around that lonely man,
> Some died in war, the iron brands
> Lay rusting in their bony hands,
> In peace and famine some.
> Earth's cities had no sound nor tread,
> And ships lay drifting with their dead
> To shores where all were dumb.

B. STEWART

POPULAR PHYSIOLOGY

What shall we Teach? or, Physiology in Schools. By Edwin Lankester, M.D., F.R.S., &c., &c.

A School Manual of Health. By Edwin Lankester, M.D., F.R.S., &c., &c. (London: Groombridge and Son.)

THERE is an old saying, "that every man when he gets to be forty is his own doctor unless he happens to be a fool;" by which is meant that the pains and discomforts of ill health will, in the long run, convince most men that some knowledge of the facts of physiology and of the laws which govern the human body, is, after all, a desirable thing for the comfortable conduct of life. The main object of Dr. Lankester's pamphlet is to urge the question, "Why leave these lessons to chance and the fourth decade? Why not steal a march on bitter experience, and by making physiology a branch of general education, forewarn and forearm everyone against bodily indiscretions and against transgressions of sanitary laws?" Leaving on one side altogether the value of physiology in its scientific aspect as a means of training the mind, and taking his stand on the ground simply of the importance of it as mere information, the author works out his plea with unflagging zeal and energy. Indeed, all the pages bear tokens of almost the enthusiasm of a crusade. Into town and country, into girls' schools, boys' schools, infants' schools and universities, into corporations, vestries, and town councils, into the functions of clergymen, householders, lawyers, and domestic servants, the flag of physiology is most gallantly carried; and we can hardly imagine an impressionable general reader finishing the little work without at once rushing off to order "Huxley's Elementary Lessons" and the "School Manual of Health."

For ourselves we are free to confess, that while thoroughly sympathising with Dr. Lankester in his laments over the contemptible ignorance, and worse than ignorance, of mankind in all that relates to their bodies, we are not so sanguine as he seems to be touching the results of even general and extensive physiological teaching. We quite feel with him that it is perfectly outrageous that men and women should be so profoundly ignorant, as they are, of the nature of that prison-house from which they can never escape so long as life lasts, that our youth should, under the pretence of training, be taught things which they can never see or touch in after-life, should be made wise in phantoms and myths, and encouraged to put aside all curiosity about the things which they carry about with them always everywhere. Is it not monstrous that many a lad of eighteen should have so vivid a picture in his mind's eye, of, say, Syracuse during the Peleponnesian war, as to make people think he must have lived long years in Sicily, while the inside of his own body is to him a dim mystery, of which he can call up no clear image, but fancies it is some how or other more or less like a pig's? Some day or other men will have difficulty in believing that such a state of things could possibly have existed, and certainly the longest chapter in that great book, *De Hominum Erroribus*, will be the one which deals with the teaching of the young. At the same time, we fear that the millennium will not be very much nearer when every schoolboy knows the properties of gastric juice and even vestrymen believe in respiration. We have seen too many professors of physiology lecture on "pepsin" in the morning and rush violently into heavy dinners and indigestion in the evening, and besides, have had already too much general experience in the "*meliora probo deteriora sequor*," to feel much confidence in the reforming virtues of even the widest and most exact information, especially in everything relating to eating, drinking, and building houses. Nursemaids will continue to choke children, schoolboys to eat green gooseberries, and artizans to block up ventilators, in spite of each and all of them bearing certificates of proficiency in the knowledge of the laws of life.

Dr. Lankester's strongest point is perhaps the negative and destructive, rather than the positive and constructive, value of sound biological knowledge. Mankind suffer not so much from ignorance as from error, not so much from lack of knowledge as from the prevalence of false notions. The thing which the doctor and the sanitary reformer has to struggle against above all other things is the pertinacity with which the general public stick to false and pernicious theories, and the avidity with which they swallow everything which is absurd and ridiculous. Sometimes the attitude of the public mind towards questions of biological science is one of wholesale scepticism, sometimes of blind superstition; in all cases they appear as if they would rather be guided by any spirit than by that of patient inquiry, and of trust in conscientious and careful observation and experiment. Their minds are always readily tickled by any theory if it be extravagant enough: they run rapidly after any sign that is striking enough; but they have no taste for the sober results of sound biology. It is not enough to offer them lessons in physiology. The teacher may, perhaps, by diligence and patience at last get them to accept a part of what he teaches, but not until he uses his science as an instrument of training as well as a source of information.

And this brings us to the point in which apparently we feel obliged to break away altogether from Dr. Lankester. We quite agree with him, as we have said, in the immense value of physiology as viewed as mere information and compared with other kinds of information. But we hold very strongly to the opinion that it is training that is wanted far more than information. It is a change in the eye rather than in the picture towards which we look with hope. Beat into the general run of men some little scientific spirit, teach them how to look at the world around them in a scientific manner, how to arrive at scientific conclusions, how to approach scientific questions; put them in a proper mood, and they will then perhaps begin to become earnest physiologists and sanitary reformers. It is a right state of mind, and not a schoolboy's lesson in oxygen, that will tear down the paper pasted over the ventilator and otherwise help to lessen the labours of the coroner for Middlesex.

MÜLLER'S PHYSICS AND METEOROLOGY

Grundriss der Physik und Meteorologie. Von Dr. John Müller. Zehnte Vermehrte und Verbesserte Auflage. Mit einem Anhange, Physikalische Aufgaben enthaltend. (Erste Abtheilung. Braunschweig, 1869.)

IT is impossible to disguise or repress the feeling of covetousness with which this book of "Elements of

Physics and Meteorology" fills an English reader. In a volume which, when completed, is to contain something less than 600 pages, we have an account of the fundamental phenomena of natural philosophy, which is at once readable and scientific. It is published at 6*s*., is illustrated with 600 admirable engravings, and is to be accompanied by a collection of examples which, with the chapter on heat, will make up the remainder of the book. It is just such another treatise—as copious and accurate, and at the same time as clear and concise—that is wanted in teaching the elements of natural philosophy in England. There are a hundred schools which are compelled to put up with books twice as big as boys care to read or carry, which would introduce such a book as this at once.

The great difficulty which has to be faced and overcome in an elementary treatise of the kind is well stated by Professor Müller in the preface. "The facts of physical science ought never to be presented to the pupil in a mere dogmatic fashion, as acquired results. It is essential that he should comprehend the mode in which they have been deduced, and grasp the connection between the facts themselves and their systematic presentation in a logical system, which exhibits their mutual relations. Even in an elementary treatise like the present the reader ought to find an introduction to the processes of thinking and reasoning which are employed in physics, and should see everywhere examples and applications of the inductive method."

It is of course impossible for the author within his limits to give more than the briefest account of the main facts of the physical sciences. We turn, for instance, to the subject of thermo-electricity, the article on which, we are told in the preface, has been entirely re-written for this tenth edition. It contains just two pages. Nevertheless there is a good account of the fundamental law, and illustrations which enable the reader to comprehend in a very satisfactory way the use of the thermo-pile. There follow two pages more on animal electricity, the bulk of which is devoted to an account of the familiar electric actions exercised by certain fish, with illustrations showing the nature of the organs to which that action is due. The article closes with a few lines indicating the results obtained by Nobili and Du Bois Raymond in confirmation of the ideas of Galvani. These brief summaries of subjects could scarcely fail to be obscure were it not for the abundant diagrams which serve as texts for them.

The book before us is the condensed quintessence of Dr. Müller's well-known larger book on the same subject, which travels over the same ground, giving about four times as much space, and nearly four times as many illustrations. It is obvious, of course, what an enormous advantage it must be, in a task which is, of necessity, one of great difficulty and discretion—that of saying the very least which is requisite for clearness—to have previously arranged the subjects treated in a manner which allows a distinct perception of their relative importance. Without the larger book, this little text-book could scarcely have been what it is. We hope to see some day—the sooner the better—a comprehensive English treatise on Natural Philosophy which will take the place of Müller's large book in Germany, appealing to mathematics as little as it is possible to do without wearisome circumlocution, sufficiently simple to be accessible to any student who has a serious purpose, and at the same time scientifically accurate. From such a treatise it would be easy to condense one which should be for English schools what Prof. Müller's book is for schools in Germany. It would be extremely difficult, in any other way, to put into forty-five pages an account of the theory of sound, and its applications, so full and so simple as that which we find here. Everything is preserved in its proper proportions, and the reader rises from its perusal, not of course imagining that he knows the subject fully, but with a clear apprehension of the fundamental ideas involved, of the main questions of difficulty in the inquiry, and of the more recent discoveries which have enlarged the borders of the science. He is left, at the end of the book, with his curiosity stimulated, and not destroyed. If his after occupations give him sufficient leisure, the boy who has mastered this text-book at school will be certain to ask for more.

WILLIAM JACK

OUR BOOK SHELF

Microscopical Manipulation. By W. T. Suffolk, F.R.M.S. (Gillman, 1870.)

THIS little book is the substance of a course of instruction given by Mr. Suffolk in the spring to members of the Quekett Club. It will be useful to those persons who amuse themselves with microscopes, and do not care to purchase the scientific treatises of Dr. Carpenter or Dr. Beale. There is a chapter for the very youngest beginner on the various parts of an English compound microscope and their uses; then we have hints about the cutting of glass and the old directions as to making cells; mounting objects in balsam and in fluid is next dealt with—the old, old routine methods being detailed once again, with an allusion to Dr. Bastian's process with benzine. It is a pity that Mr. Suffolk has not made himself acquainted with some of the many methods of mounting and preparing objects in use on the Continent, which he might have picked up from Stricker's handbook, Frey's work, or other similar treatises. The best chapter in the book is that on polarised light, because it deals with a subject rather slighted in other works of this kind, in a clear and intelligent manner. We were not, however, prepared for the following in a work on microscopical manipulation:—"The undulatory motion of light would seem to be expressed with considerable clearness in the 1st chapter of Genesis, when read in the original Hebrew, which, in common with the other languages of the same family, is remarkable for the numerous inflexions of its verb, which gives it a delicacy and precision of expression unattainable in Western languages." Mr. Suffolk is quite right in considering that more attention should be paid to the use of polarised light as demonstrating structure, than has been done hitherto. A necessary step towards this is that microscopists should properly understand what are the conditions of production of colour with the polariscope, and not be content with the mere sight of a pretty display. This little book of Mr. Suffolk's will not do much, we fear, to convert what we may call microscopical play into microscopical science. Its receipts and directions are such as will be useful to the man who cares merely to make a series of pretty slides for exhibition to his friends, but do not help the student wishing to add to the storehouse of science. Nothing is said of the manner of studying living objects, living cells, living cilia, living protoplasm; nor do we find an allusion to the use of chromic acid, section instruments, methods of embedding, of gold and silver staining, or other processes important to a working microscopist. The gold and silver-staining methods might have been given if only for the benefit of those who like to make gorgeous preparations.

A small book on "Microscopical Manipulation," well up to the time, would be useful to students. We are sure Mr. Suffolk does not wish to claim this position for his digest of the older handbooks. His excuse for its publication must be that in this country there are many people who indulge in the expensive peepshows sold by our English opticians, to whom it will really be acceptable.

It must not be imagined that we for one moment object to such amusements; on the contrary, they are altogether to be commended where more serious work cannot be undertaken—and only then. E. R. L.

Notes of a Season at St. Moritz in the Upper Engadine, and of a Visit to the Baths of Tarasp. By J. Burney Yeo, M.B. (London: Longmans, 1870.)

WE commend this sensibly-written and interesting little book to the notice of our readers, many of whom, notwithstanding the outbreak of hostilities between our friends across the Channel, may yet seek health and enjoyment in these remote valleys, where it is in the highest degree improbable the tide of war will ever roll. Dr. Yeo's little brochure contains all that it is necessary the intending tourist need know, and much that the invalid ought to know before starting for the Upper Engadine. To the latter class of travellers in particular it is of no slight importance to know the nature of the lodging and food they can obtain, and the advantages to be gained from a residence in a new and untried region; and upon these points Dr. Yeo's experience enables him to speak with much confidence. St. Moritz, it must be remembered, is 6,000 or 7,000 feet above the level of the sea, and the air, though bright and clear, is by no means warm. The waters contain a small proportion of iron, and are strongly charged with carbonic acid, which may perhaps act as a stimulant both to the skin and the stomach in tolerably healthy patients; but Dr. Yeo makes some judicious remarks on their effects on those who are debilitated and exhausted, and the advantages resulting from leaving off the prescribed cold bath, and glass or glasses of cold water. The last chapter contains a capital account of the Fauna and Flora of St. Moritz and Tarasp, the latter embracing between 300 and 400 plants, arranged according to their natural orders.

Reactions-Schema für die qualitative Analyse, zum Gebrauche im chemischen Laboratorium zu Berlin. (Berlin, 1870. Verlag von August Hirschwald. London: Williams and Norgate.)

THIS is a kind of pictorial analytical table in which the characters of the precipitates obtained are indicated by coloured oblong spaces, which will, doubtless, be found very useful for impressing the appearances of the different precipitates on the mind of the student. The borax bead obtained with a compound of cobalt is represented by a blue oval, and the effect of ammonia on red litmus paper is shown by an oblong half red and half blue. The changes of colour produced by the action of sulphuretted hydrogen on a salt of mercury are indicated by an oblong of four different colours, white, yellow, orange, and black.

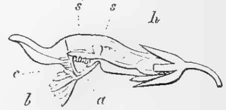
It is unfortunate that this table is not more complete; thus no means of obtaining the solution to be treated is mentioned; the destruction of organic matter before precipitation by ammonia and ammonia sulphide is omitted; the possibility of the precipitate in the third group containing phosphates, and the mode of examining it under such circumstances, is passed over entirely. The spectra of potassium, sodium, and lithium, are indicated by black lines with fine transverse white ones, representing the coloured bands, but unfortunately no means are given to show which is the more refrangible end of the spectrum. Besides these omissions there are some misprints which will no doubt be corrected in a subsequent edition.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

Fertilisation of Polygala

HAS the method of fertilisation of the milkwort, *Polygala vulgaris*, yet been described? It presents one of the most beautiful contrivances with which I have hitherto met for securing a cross through the agency of insects. The corolla consists of five petals united into one piece and folded into the form of a two-lipped tube, the upper lip of which is formed by the over-lapping edges of the corolla; while the lower lip is a somewhat cup-shaped appendage (*c*), furnished with a "beard" of gland-like bodies (*b*), and opening in front by a narrow, vertical slit. The filaments of the stamens are united throughout the greater part of their length with the corolla, but expand within the cup of the lower lip into a two-lobed membrane, crowned by the anthers (*a*). The pistil has two stigmas, one of which (*s*) is



placed at right angles to the upper side of the style and is perfect, while the other (*s*′) is transformed into a spoon-shaped, petaloid prolongation of the pistil, reaching to the opening of the lower lip of the corolla, and dividing the interior of the flower into two chambers, in the lower of which are the stamens, thus completely separated from the true stigma. The entrance to the flower, below the style and in front of the stamens, is closed by hairs pointing outwards from the flower and meeting in front, on the mouse-trap principle; but a narrow passage is left open above the petaloid stigma, and is perhaps capable of a slight distension from the flexibility of the overlapping petals. On each side of the interior of the tube of the corolla, above the style and just behind the true stigma, is a group of strong, white hairs (*h*), pointing down the tube of the corolla, and meeting above the style. If we now suppose a small insect to light upon the "beard" of the flower, it is prevented from immediate entrance by the projecting hairs, but soon finds the narrow passage leading over the stigma into the upper chamber. It is prevented by the hairs in the tube of the corolla from returning by the same path, and is obliged to crawl out through the lower chamber and over the stamens; pollen from which it will, by a repetition of the same process, convey to the stigma of the flower next visited.

In the bud the anthers are in contact with the stigma, and some caution is necessary in dissecting that they may not be crushed, giving the appearance of the pollen having been deposited *en masse* on the spoon-shaped stigma. Naturally, I believe, the pollen is never shed till after the complete expansion of the flower.

I have never actually observed any insect either in the flower or sucking nectar from it, but I have almost invariably found a few small black flies upon the bunches that I have brought in for examination.

The broad and conspicuous "wings" of the calyx having fulfilled their office of "tempting insects to their food," gradually assume the green colour of the ordinary leaves, and closing over the ripening capsule, serve probably to conceal and protect it from the attacks of some enemy.

Kilderry, Co. Donegal W. E. HART

P.S.—I have to record a similar phenomenon with respect to the holly berries of this neighbourhood to that mentioned by Mr. Henry Reeks (NATURE, June 9). I did not remark that any varieties in particular had been rejected; but few that bore fruit (of which there was a much greater quantity than usual) appeared to have lost any of it, so late as the end of May. And yet we had not fewer of the migratory thrushes than in former years, when the holly bushes were generally stripped of their berries before the end of January; and, on the other hand, we had several days of frost, extraordinarily hard for this neighbourhood. On what arguments does Mr. Reeks ground his presumption, so different from Mr. Darwin's own conclusions on the subject, that "berries obnoxious to birds will stand a better chance of propagating and increasing that variety?" If C. W. W. (NATURE, July 7) will turn to Letter 55 of White's "Selborne" he will find the following observation on the House Martin:—"The young of this species do not quit their abodes all together, but the more forward birds get abroad some days before the rest. These approaching the eaves of buildings and playing out before them make people think that several old ones attend one nest."

Our Middle-Class Schools

I WISH to bring before your readers the necessity of immediate action with regard to a branch of education at present not liable to legislative interference. Government is becoming more and more alive to the fact that Education and Science at the present are England's greatest needs; hence the steps taken to extend and enforce primary education. But whilst increased facilities are being afforded to raise the standard of primary education, secondary education is at a stand-still, and upon the whole falls far short of the point it should reach. Thousands of our middle-class schools when compared with what is required, may be placed in the same category as the old dame's school when compared with the modern national school. It requires but the slightest knowledge of the subject to know that our middle-class educational system is as a whole a mere farce, and yet so averse are we to change, that matters are allowed to go on year after year in the same old matter-of-course style without the slightest indication of reform. In order to encroach upon your space as little as possible, I will in a succinct and concise form lay before your readers a scheme which has been lately mooted, which has received the sanction of the highest authorities in these matters, and which is destined ultimately to bring about quite a new system. In speaking thus indiscriminately of our middle-class schools, I do not include many excellent institutions, in which a thorough course of training forms the routine, and which are conducted by gentlemen capable and willing to do the work required. Alas that there should be so few!

Then 1st. It is well known that individual influence is of little service. This fact supports the theory that an association must be formed, consisting of the principals and assistants of middle-class schools, and others interested in the question.

2nd. This society should have certain objects, and its members combined should use their utmost endeavours to assist in carrying out these objects. A few of the aims would be as follows:—

α. The institution of normal colleges for the training of gentlemen who wish to enter the scholastic profession.

β. To recognise some examination, diploma, &c., as sufficient guarantee of the capabilities of gentlemen entering the profession, and insist that such gentlemen shall have this diploma. The evils arising from the incapability of so many of our masters cannot be over-estimated.

γ. The necessity of Government or other central supervision and examination of *every* school. At the present moment the standard of a school is calculated by *nothing*. An advertisement perhaps appears, stating that *all* boys sent to special examinations have passed; and instances are known where *one* boy has been sent up to such examination. It is impossible to decide upon the general tone of a school by the examination of a *few* of the best boys.

δ. The institution of a club-house in London where appointments could be made, business transacted, &c., and attached to it some means by which the incubus of agents could be avoided.

ε. Periodical meetings, &c., &c.

I am afraid this letter is running to an inordinate length, but I just wish to add that invitations have been issued by the editor of the *Quarterly Journal of Education* to a few representative gentlemen for a private preliminary meeting to be held in September next, when the above scheme is to be discussed. Any gentleman wishing to take part in that meeting should address the editor upon the subject. I might have referred to the failure of the College of Preceptors to do the least good. What we must have is an obligatory examination of the whole school, and every school; not leaving it to the whim of the principals. Neither are assistant masters treated as they should be by the College of Preceptors.

X

The Source of Solar Energy

MR. GREG ascribes to me views I do not hold, and then employs my own reasoning to overthrow them. He must have formed his conceptions of my theories from Prof. Pritchard's critique of my "Other Worlds"—a most unreliable source.

To begin with,—I do *not* believe that the solar heat supply is solely derived from the downfall of meteors. I have impressed this very clearly at p. 54 of my "Other Worlds."

I do not believe that *any part whatever* of the solar heat supply is derived from meteoric *percussion*, nor that any meteor ever comes within tens of thousands of miles of the sun's surface in the solid state.

Mr. Greg is very careful to show me that the meteor-systems encountered by the earth cannot fall into the sun. I dwell on this very fact at p. 203 of "Other Worlds"—I say, *totidem verbis*, that no known meteoric system can form a hail of meteors upon the sun. "It is forgotten," says Mr. Greg, "that the meteors themselves revolve round the sun," &c. If *he* has at any time forgotten this, I certainly have not.

"Has it ever been proved," he asks me, "that the entire mass of meteors constituting the zodiacal light, is either composed of matter in a solid state, or, if it were, that its mass would be equal to that of our own earth?" I answer, as Mr. Greg would—"No, it has not been proved, nor is it by any means probable."

There is nothing new to me in Mr. Greg's letter, and little which I have not described myself long ago in the *Intellectual Observer and Student* of 1867, 1868, and 1869. To suppose that I should venture to treat at all of meteoric astronomy, in ignorance of such elementary facts—the very A B C of the science—is not complimentary. Mr. Greg might, at least, have examined what I have written before assigning to me the absurdities he attacks so successfully.

The fact is, this matter of the solar energy only comes in *par parenthèse* in my "Other Worlds." I express no confident opinion whatever about it. I point to some deductions from known facts, and respecting *them* express a certain feeling of confidence. It is not my fault (nor, indeed, can I blame Mr. Greg) if Prof. Pritchard has tacked my words "I am certain" (used with reference to reliable inferences) to a theory respecting which I have distinctly written, that "I should not care positively to assert" its truth. Even that theory is not the absurd one attacked (very properly) by Mr. Greg.

For the rest, most of Mr. Greg's letter is sufficiently accurate, but there are two mistakes in it.

1. We have abundant evidence that the density of the aggregation of cometic perihelia increases rapidly near the sun. For example, whereas between limits of distance 40,000,000 and 60,000,000 miles from the sun this density is represented by the number 1·06, it is represented by the number 1·67 for limits 20,000,000 and 40,000,000 miles, and by the number 8·65 within the distance 20,000,000 miles. The evidence derived from this observed increase of aggregation is not affected by what we know of those cometic or meteoric systems whose orbits nearly intersect the earth's (for they must form but the minutest fraction of the total number) nor by the observed minimum perihelion distance of cometic orbits (for observed comets are but the minutest fraction of the total number).

2. It makes no difference whatever as regards the force-supply of the solar system, whether the substance of a meteor reaches the sun in the solid, fluid, or vaporous state. Given that the substance of a meteor, moving at one time with a certain velocity at a certain distance from the sun, is at another time (after whatever processes) brought to rest upon or within the sun's substance, then either the "force-equivalent" of its motion has been already distributed or the substance of the meteor is in a condition to distribute that "force-equivalent" mediately or directly. In other words, either heat and light have been already distributed, or the central energy has been recruited to the full extent corresponding to the mass, motion, and original distance of the meteor.

I may express here my agreement with the opinion of the Editor of NATURE that the observations made on the zodiacal light by Lieut. Jones and M. Liais ought to be taken into account in any theory of that mysterious object. Taken in conjunction with the other known phenomena of the zodiacal light, they admit of but one interpretation as to the position, dimensions, and general characteristics of the object. Taken alone, we might infer from them that the zodiacal light is a ring of bodies or vapours travelling around the earth (at a considerable distance);

other phenomena suggest that the zodiacal light is a disc of bodies or vapours travelling around the sun; yet others suggest that the zodiacal light is a phenomenon of our own atmosphere. But the only theory which accounts at once for *all* observed phenomena, is that which regards the zodiacal light as simply due to the continual presence in the sun's neighbourhood of bodies or vapours (meteoric or cometic, or both) which come there from very far beyond the earth's orbit, and pass away again on their eccentric orbits. A disc thus formed of continually varying constituents would shift in position, and would wax and wane in extent as well as splendour, precisely as the zodiacal light is observed to do.

RICHARD A. PROCTOR

Spontaneous Generation

THE physical capacity of fungus-spores to throw out mycelium, and from that to be able to reproduce a parent (or, according to Dr. Bastian, to produce a fungus *de novo*), shows a complicated organisation greatly above that of the monad. From a careful examination of Dr. Bastian's experiments and figures, I am led to believe that the majority of the ovoid bodies referred by him to fungus-spores are nothing of the kind, and that if they really belong to the vegetable kingdom at all, they are perfect unicellular plants in themselves reproducing their kind by subdivision; the presumed *mycelium* I should refer to the bursting of the cell-walls, and consequent discharge of the contents, a by no means uncommon occurrence with unicellular organisms. It is, however, impossible to follow the author in his speculations regarding these bodies, as his measurements are so imperfect, and in several instances, where most wanted, omitted altogether. A few of the bodies certainly bear an external appearance to fungus-spores (for instance C, Fig. 11, which might be referred to *Russula* or *Scleroderma*), but as no size is given it is impossible to form an opinion. Perhaps Dr. Bastian will say on what data he refers such objects as are shown on Fig. 3, to fungus-spores, and by what characters he knows the mycelial filaments to be such: the "half-grown" spore (?) described on page 197 has most extraordinary characters for such an object; for, says the author, "the nuclear particle within was seen moving from end to end of the cell."

Had not Dr. Bastian distinctly affirmed that the spores were generated at once from heterogenous materials, I should have assumed his belief in the presence of the perfect plants in the infusions, though the detached spores were all he met with in his experiments; for if any organism originates independently of a parent similar to itself, surely it is reasonable to expect the production to be at once perfect, and not in the egg state. Could an oviparous animal be produced from heterogenous materials, surely one would not expect eggs first to appear. In referring these unicellular bodies to spores, Dr. Bastian appears to me to have defeated the very object he had in view.

That some of the bodies figured are *bona fide* spores of fungi seems very probable, and that they were produced by ordinary parents, seems equally so, for the slight neck-like elongation or spot, which is analogous with the placental scar in animals and flowering plants, is clearly present in the lower right-hand object (Fig. 11) and the lower left-hand object (Fig. 13). If these things were evolved without parents, surely nature would not have given them an umbilicus; it is far more reasonable to suppose that true spores got into the infusions (and perhaps germinated) by some accident similar to the three recorded instances where foreign bodies were undoubtedly found. (Note, p. 197.)

It seems to me rational enough to suppose that unicellular bodies and objects of the lowest possible organisation may be heterogenously produced from the inorganic world, for here the line between one and the other is so fine as scarcely, if at all, to be perceived; indeed, the Brownian motion of monads, some spermatozoids, and the particles forming many inorganic infusions, are scarcely, if at all, to be distinguished from each other. From monads and unicellular organisms, however, spore-producing fungi are greatly removed, and the economy, functions, and structure of most of the latter are now so well known, that it would be simply impossible to convince any botanist that a spore like C (Fig. 11) could be produced from any other quarter than the hymenium of a well-defined parent.

I cannot see that the production of motile zoospores in Achlya (p. 174) has any bearing on the subject, as here we have an already *living* parent; and motile zoospores are by no means uncommon in the vegetable kingdom; their movements, however, so far as I have been able to observe them, do not differ from the Brownian movements seen in the inorganic world.

It is clear that no definite conclusions can be arrived at regarding these bodies and their production till a series of accurate figures is published to an *uniform scale* (with an indication of the colour of the cells, &c.), enlarged at least 2,000 diameters, for even then a monad would be no larger than a pin's-head. It will then be possible to compare the bodies with actual fungus-spores and other bodies well known to botanists and zoologists.

Prof. Wanklyn appears to be unable to estimate the number of germs of fungi known to exist in the atmosphere. That "there must be very many of them" is apparent from the calculation that, if each spore of one species only of one of the higher fungi germinated and reproduced its parent, the children would, in the first generation and in the course of a very few days, form a carpet all over the earth. Now, as fungi abound everywhere in myriads, and the family is almost illimitable, the number of diffused germs is evidently beyond all calculation; their size, too, is often so small that twenty could be conveniently accommodated on the diameter of a single human blood corpuscle. That they are alive is proved by the readiness with which, under favourable conditions, they may be made to germinate. It must also be admitted, in Prof. Wanklyn's favour, that "they must weigh something," though I am not aware of any attempt in that direction at present. Some of their "remarkably small" component parts are, however, made manifest by chemical reaction.

WORTHINGTON G. SMITH

Mildmay Park, London

Super-Saturation

THE following experiments may be found interesting from their bearing on the latest theories advanced on the subjects of super-saturation and the so-called inactive state of bodies. Professor Tomlinson's theory is that a super-saturated solution adheres as a whole to a chemically clean surface, but that a differential adhesion takes place in presence of a chemically unclean surface, because the salt or gas adheres to such a surface while the liquid does not; the former is consequently liberated. The presence or absence of grease is then stated to constitute chemical uncleanness or cleanness. If a greasy surface can be rendered inactive, it is clear that both these propositions cannot be true; either grease is not of itself a cause of uncleanness, or unclean surfaces are not necessarily active ones. The following experiments prove that the fats may be rendered inactive by the same processes which are applied to rods of glass or metal.

1. A bit of composite candle was melted with a very little alcohol; a glass rod was dipped in, allowed to cool, passed through flame of a Bunsen's burner, and a drop of melted fat deposited on surface of supersaturated solution of zincic sulphate. The fat solidified without affecting the solution even on prolonged agitation. A crystal of the salt caused instant solidification.

2. Some solution boiled remained supersaturated for a fortnight with a crust of fat on the top.

3. Ordinary tallow treated as No. 1. Inactive in solution of sodic sulphate solution; touched with finger, crystallised at once.

4. Lard cleaned simply by melting on rod passed through flame, allowed to cool, stirred in solution of sodic sulphate. Inactive. Other end of rod active at once.

5. Same solution boiled; cooled, stirred with rod, treated as the last, and left exposed to the air for 15 minutes. Did not crystallise. This experiment is interesting, as showing that greasy substances are not specially liable to be made active by exposure to ordinary air.

6. Some tallow was melted in a test-tube without precautions of any kind, and while melted was poured to the depth of half an inch on to solutions of ferrous, cupric, and sodic sulphates. In each case it was inactive. This is conclusive on the point in question.

Theoretical objections have been urged against the definition of chemical uncleanness, and I think this might now be surrendered.

Professor Tomlinson may very likely be right in looking to adhesion for an explanation of these phenomena; at all events, far greater probability seems to attach to this view than to that put forth by M. Gernez, adopted by Jamin, and even, I believe, favourably noticed by the Academy itself; which is that only a crystal of the same salt can induce crystallisation. This latter view is open to the theoretical objection that it necessitates our believing that all salts capable of supersaturation are everywhere and at all times present in the atmosphere. Mr. Tomlinson has shown experimentally that a crystal of the salt properly treated can be inactive in a solution of sodic sulphate.*

The following experiments show that an atmosphere presumably saturated with the salt may be inactive without any precautions whatever:—

7. Three solutions of sodic sulphate were prepared; a glass rod was dipped in melted tallow and left to cool for five minutes in a bottle of the salt, without touching the salt or the sides of the bottle. Then the three solutions were successively touched with the rod; inactive in all. Rod replaced in the bottle for ten more minutes; then all three again touched. The third crystallised after a minute or two. Rod replaced for fifteen minutes; active only in the second; replaced for fifteen minutes, active in the last. Thus this greasy rod was inactive in one of the solutions after an exposure of thirty minutes, and after being six times dipped in solutions of the salt.

8. An open test tube, containing a strong solution of sodic sulphate, remained supersaturated for a week suspended in the same large bottle of the salt. The bottle was frequently moved without producing any effect. On removing the cork, the solution crystallised instantly.

On the whole I am afraid we must for the present fall back upon that refuge for the destitute, "Catalytic action."

Birmingham — J. G. Grenfell

Derivation of the Term "Horse-Chestnut"

The explanation of the above name by Mr. E. A. Connell in your last issue, though ingenious, is not, I think, the true one. In a work entitled "Etymons of English Words," by John Thomson, Edinburgh, 1826, the term is explained thus:—"Horse-Chestnut. The *harsh*-chestnut; but the F. and the Swedes have translated it as *horse*." Following this he gives in support of *horse*, being the corruption of harsh, horse-faced, *harsh*-faced, *hard*-featured, horse-radish, *harsh*-radish;" and *harsh, rough, sour*, austere, grating, S. *hærsk*, T. *harsch*, D. *harsk*. So that, accepting this explanation, harsh-chestnut is the more scientific term. — J. Jeremiah

Trehelig, Llangadock, Carmarthenshire, July 16

Ozone and Thunderstorms

In reference to the production of ozone it may interest your readers to know that the quantity developed here has been unusually great during the last few days. On Sunday evening, during the electrical agitation that occurred and ended in a slight discharge, accompanied by heavy rain, we had the highest reading. Mr. Burrows' test paper registered 9, and was almost black. This observation was taken at 10 A.M. During the period of this development the air was very moist. Last evening and this morning have caused the ozonometer to register 7, and this is above the average. To-day, Tuesday, the hygrometer indicated the point of saturation. I may add that old Gilbert White's remark as to activity of swifts during thundery weather has been greatly confirmed. They have kept up an almost incessant screaming during the last few days.

Great Malvern, August 2 — Samuel Barber

The Sun's Corona

A letter of mine, addressed to you a fortnight since, has, I fear, miscarried. It had special claim to admission as complaining of an editorial remark.

I now renew my objection to the editorial note upon my letter referring to Professor Pritchard's critique on my "Other Worlds." As an uncourteous comment upon a passage in which I had paid a high but not undeserved compliment to Mr. Lockyer, I had just reason to be surprised at its appearance.

First, because my account of Mr. Lockyer's views respecting the corona agrees in all essential points with that given in the note, whereas the contrary is implied.

Secondly, because I have not mis-stated Dr. Gould's evidence, though forced to interpret it otherwise than he does.

Thirdly, because my whole reasoning on the corona has been founded on evidence, and is therefore unjustly described in the note as "evolved from the depths of my moral consciousness" (an old witticism, which, however, would have borne repeating had it been to the point.) *

To the personalities in the note, as to the reference to my age, and so on, I make no objection whatever, caring only to notice what seems worthy of notice.

Let me add, however, my protest against a mode of speaking which implies that observers only are to be considered as astronomical *workers*. Not on my own account, but on behalf of a long list of honoured names, I oppose the assumption that the careful study of observations (whether those observations have been made by others or not) is not to be regarded as work. If observers claim with pride such names as Herelius, Galileo, Tycho Brahe, Bradley, and many more, the advocates of thoughtful theorising may point no less confidently to Copernicus, to Kepler, and to Newton, and in our own times to Adams and Leverrier. Those who, like the Herschels, have been able to work successfully in both ways, are few indeed in number.

Observations will never be so little useful as when the attempt to utilise them is discouraged.

Richard A. Proctor

P.S.—Mr. Lockyer seems not to be aware that what he claims to have proved respecting the corona is accepted by me as proved, and forms an essential part of my theory. I am as well satisfied as he can be (and on the same grounds) that the corona is not a solar atmosphere.

* It would seem from the experiments of Dr. L. C. de Coppet (which do not appear to be as well known as they deserve) that the treatment adopted by Mr. Tomlinson for rendering the sodic sulphate inactive really changes the salt. Dr. de Coppet finds that a supersaturated solution of sodic sulphate may be prepared by dissolving the anhydrous salt in cold water; and he writes—"I have arrived at the conclusion that the anhydrous sodic sulphate obtained by the efflorescence of the crystals with ten molecules of water, undergo a change of constitution when heated to temperatures superior to 33° or 34°; for the contact of a particle of the effloresced sulphate always causes the crystallisation of a supersaturated solution of this salt, whereas anhydrous sodic sulphate heated above 33° does not necessarily determine the crystallisation."—Bull. Soc. Vaud. Sc. Nat. X., p. 151.

[These experiments render it probable that the so-called supersaturated solutions really contain the anhydrous salt in a state of unstable equilibrium, only requiring a disturbance to cause it to assimilate water, and thus produce a less soluble compound.—Ed.]

* Still holding to our comments we gladly state that they were not written in the spirit in which Mr. Proctor has read them. He is known to all as an astronomical worker, and our objection to his mathematical result was that it was based upon data among which the principal point at issue was accepted as proved.—Ed.

VON GRAEFE

Speaking of the loss of Von Graefe, whose death, at the age of forty-one, we reported last week, the *Revue des Cours Scientifiques* remarks that Germany has sustained a loss equal at least to the loss of a battle. Von Graefe's death was the sequel of a long consumption, during which he neither diminished his work nor took ordinary precautions. His grand discovery of the cure for Glaucoma was made when he was only twenty-six years old. The *British Medical Journal* thus sums up his professional worth:—

In him the world loses its foremost opthalmologist, one whose brilliant originality was equalled only by his steady industry. Not only was Graefe great in the practice of his profession, but as a teacher his influence was almost unbounded. Although comparatively young himself, he had taught almost all the present school of ophthalmic surgeons. His introduction of iridectomy was, without doubt, the greatest step in the operative surgery of the eye since the introduction of operations for the cure of cataract. Probably, there are now living some thousands in the possession of sight, who but for him would have been in darkness. It is one of those gains which is complete in itself, permanent, and beyond the reach of scepticism. It is priceless. Graefe was an untiring observer, and never allowed his pressing engagements to interfere with the record of his vast experience for the good of others. Although he had done a vast amount of other work, still, however, his discovery of iridectomy shines with such pre-eminent lustre that the inscription,

"He cured Glaucoma,"

would be by no means inappropriate. As a man, Graefe was everything that is admirable, and secured the love of all who knew him. He was open, generous, unostentatious, eager both to give and receive knowledge. His personal appearance was as remarkable as the qualities of his mind. The *Wiener Medizen Wochenschrift*, in announcing Graefe's death, says: "German science loses in him one of her greatest celebrities, and suffering humanity one of its greatest benefactors. With Graefe, a combination of geniality, erudition, self-devotion, energy, and amiability, such as is rarely found in one man, has descended into the grave. His name will ever remain most prominently connected with the history of ophthalmic surgery."

*THE CONTINUITY OF THE GASEOUS AND LIQUID STATES OF MATTER**

IT may be truly affirmed of Physical Science, that its history, for some generations at least, has been one of rapid progress and unceasing change, and that its most earnest promoters have not claimed infallibility for their opinions, nor finality for their results. Its advancing progress has been marked by eras when some long-accepted theory or hypothesis, which had appeared so closely in accordance with all known experiments and observations as to have been received as an obvious truth, has, by further experiments extending into regions previously unexplored, been found to be a faulty or incomplete representation of the phenomena.

Such an era has occurred in the discovery recently announced by Dr. Andrews of the Continuity of the Gaseous and Liquid States of Matter.

We have all been accustomed to consider matter as existing in one or other of three states,—the solid, liquid, and gaseous.

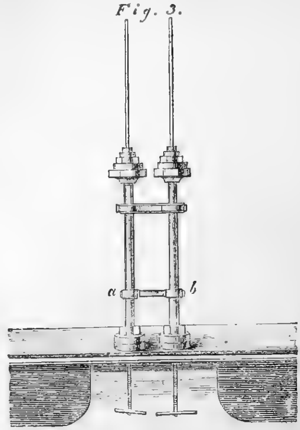
Fig 1.

Fig. 2.

The transition, from any one of these states to another, has hitherto been regarded as necessarily abrupt; at least, if we except the imperfectly understood conditions of softening or plasticity, assumed by such bodies as glass or iron, when gradually passing from the solid to the molten condition. The true state of the case is now found to be very different.

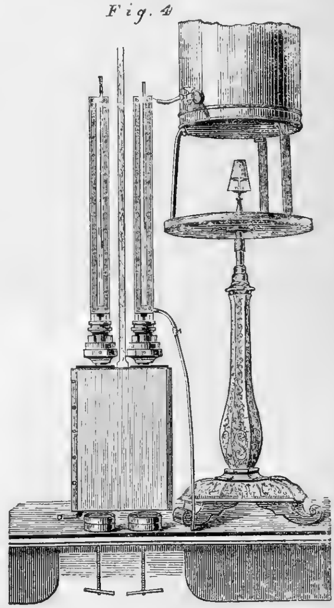
The memoir of Dr. Andrews, of which we propose to give an account in this article, opens with the following historical *résumé* of previous researches bearing more or less in the direction of his investigations:—"In 1822 M. Cagniard de la Tour observed that certain liquids, such as ether, alcohol, and water, when heated in hermetically sealed glass tubes, became apparently reduced to vapour in a space from twice to four times the original volume of the liquid. He also made a few numerical determinations of the pressures exerted in these experiments. In the following year Faraday succeeded in liquefying, by the aid of pressure alone, chlorine and several other bodies known before only in the gaseous form. A few years later Thilorier obtained solid carbonic acid, and observed that the coefficient of expansion of the liquid for heat is greater than that of any aëriform body. A second memoir by Faraday, published in 1845, greatly extended our knowledge of the effects of cold and pressure on gases. Regnault has examined with care the absolute change of volume in a few gases when exposed to a pressure of twenty atmospheres,

Fig. 3.



and Pouillet has made some observations on the same subject. The experiments of Natterer have carried this inquiry to the enormous pressure of 2,790 atmospheres; and although his method is not altogether free from objection, the results he

Fig. 4



obtained are valuable, and deserve more attention than they have hitherto received."

In 1861 a brief notice appeared of some early experiments by Dr. Andrews in this direction. Oxygen, hydrogen, nitrogen,

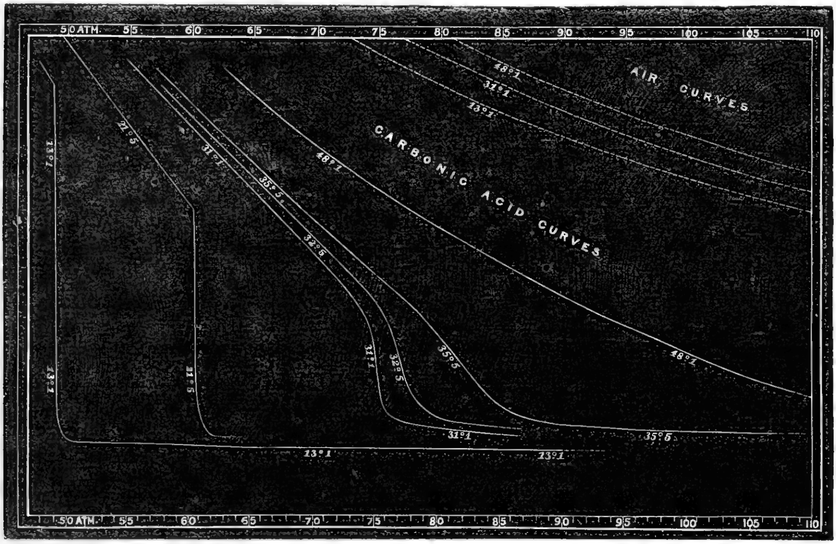
*"The Bakerian Lecture for 1869." By Thomas Andrews, M.D., F.R.S. (Abridged from an Original Essay of Professor James Thomson, LL.D.)

carbonic oxide, and nitric oxide were submitted to greater pressures than had previously been attained in glass tubes, and while under these pressures they were exposed to the cold of the carbonic acid and ether bath. None of these gases exhibited any appearance of liquefaction, although reduced to less than $\frac{1}{500}$ of their ordinary volume by the combined action of cold and pressure. Subsequently, in the third edition of Miller's "Chemical Physics," published in 1863, a short account, communicated by Dr. Andrews, appeared of some further results he had obtained, under certain fixed conditions of pressure and temperature, with carbonic acid. These results constitute the foundation of the researches which form the general subject of the present article, and the following extract from the original communication of Dr. Andrews to Dr. Miller may here be quoted:—"On partially liquefying carbonic acid by pressure alone, and gradually raising at the same time the temperature to 88° Fahr., the surface of demarcation between the liquid and the gas became fainter, lost its curvature, and at last disappeared. The space was then occupied by a homogeneous fluid, which exhibited, when the pressure was suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout its entire mass. At temperatures above 88°, no apparent liquefaction of carbonic acid or separation into two distinct forms of matter could be effected, even when a pressure of 300 or 400 atmospheres was applied. Nitrous oxide gave analogous results."

For his recent researches Dr. Andrews again selected carbonic acid as the substance for investigation. He devised for his experiments an apparatus, novel in construction, and well suited to exhibit the properties acquired by fluids under very varied conditions of pressure and temperature. The carbonic acid was contained in a glass tube, capillary in the upper and larger part of its length, and for the remainder, of the widest bore in which a column of mercury would remain without displacement when the tube was placed in a vertical position. A movable column or bar of mercury confined the gas to be operated on. This glass tube was secured by careful packing in a massive end-piece of brass, which carried a flange, by means of which a water-tight junction could be made with a corresponding flange, attached to a cold-drawn copper tube of great strength. To the other end of the copper tube a similar end-piece was firmly bolted. The latter carried a fine steel screw, 7 inches long, which was packed with such care that the packing was capable of resisting a pressure of 400 atmospheres or more. A section, exhibiting all the details, is given in Fig. 1. Before commencing an experiment the body of the apparatus was filled with water; the upper end-piece, carrying the glass tube, in which was the gas to be operated on, was firmly secured in its place, and the pressure was obtained by screwing the steel screw into the water chamber. In Fig. 2 the same apparatus is shown with the modifications required when the gas or liquid is exposed to very low temperatures under high pressure. The end of the capillary tube dips into a bath of ether and solid carbonic acid, under a bell jar, from which the air may be exhausted.

In order to estimate the pressure exerted in these experiments, a duplex or compound form of the apparatus was employed, as shown in Fig. 3. The two sides of the apparatus freely communicate through *a b*, so that on turning either of the steel screws the pressure is immediately transmitted through the entire apparatus. In the second tube a known volume of air is confined, and the pressure is approximately estimated by its contraction.

Figure 4 exhibits the complete apparatus with the arrangements for maintaining the capillary tubes and the body of the apparatus itself at fixed temperatures. A rectangular brass case, closed before and behind with plate glass, surrounds each capillary tube, and allows it to be maintained at any required temperature by the flow of a stream of water. In the figure, the arrangement for obtaining a current of heated water in the case of the carbonic-acid tube is shown. The body of the apparatus itself, as is shown in the figure, is enclosed in an external vessel of copper, which is filled with water at the temperature of the apartment. This latter arrangement is essential when accurate observations are made.



The temperature of the water surrounding the air-tube was made to coincide, as closely as possible, with that of the apartment, while the temperature of the water surrounding the carbonic-acid tube varied in different experiments from 13° C. to 48° C. In the experiments as they were performed, the mercury did not come into view in the capillary part of the air-tube till the pressure amounted to about forty atmospheres. The volumes of the air and of the carbonic acid were carefully read by a cathetometer, and the results could be relied on with certainty to less than 1-20 of a millimetre or 1-500 of an inch. We must refer the reader to the original memoir for an account of the details of the experiments, and of the numerous precautions adopted to secure accuracy. The object of the present article is to place as clearly as possible before his mind the main results arrived at, and the general features of the apparatus employed.

In the above diagram, we have a graphical representation of the results of a large number of comparative experiments on air and carbonic acid, under pressures ranging from 48 to 107 atmospheres, and at temperatures for the carbonic acid varying from 13°·1 C. to 48°·1 C. The dotted lines (*Air Curves*) represent a portion of the curves of a perfect gas (assumed to have the same volume originally at 0° C., and under one atmosphere as the carbonic acid), for the temperatures of 13°·1 C., 31°·1 C., and 48°·1 C. The lines designated *Carbonic Acid Curves* show the volumes to which the carbonic acid is reduced at the temperatures marked on each curve, and under the approximate pressures indicated by the numbers at the top and bottom of the figure. Ordinates drawn from the inner horizontal line at the lower part of the figure to meet the curves, will represent the volume of the carbonic acid. These ordinates do not always refer to homogeneous matter, but sometimes to a mixture of gas and liquid.

It will be observed that in the curves for 13°·1 C. there occurs an abrupt, or almost quite abrupt, fall, when a pressure of about 49 atmospheres has been attained. The curve for 21°·5 C. exhibits a corresponding fall, but not till a higher pressure (about 60 atmospheres) has been reached. On close inspection of the figure, a slight deviation from perfect abruptness will be observed in the portion of the curves representing these falls, which Dr. Andrews showed to be due to a trace of air (about $\frac{1}{500}$ part) in the carbonic acid with which the experiments were made. Had the carbonic acid been absolutely pure, there can be no doubt that the fall would have been quite abrupt.

In the curve for 31°·1 C. there is no abrupt fall; but a rapid descent, indicating a corresponding diminution of volume, occurs between the pressures of 73 and 75 atmospheres. As the temperature rises this descent becomes gradually less marked, and when a temperature of 48°·1 C. has been attained, it has almost, if not altogether, disappeared.

At any temperature between −57°C., and 30°·92 C., carbonic acid, under the ordinary pressure of the atmosphere, is unquestionably in the state of a gas or vapour. If within these limits we take a given volume of carbonic acid, and gradually augment the pressure, the volume will steadily diminish, not however uniformly, but according to a more rapid rate than the law for a perfect gas, till we reach the point at which liquefaction begins. A sudden fall or diminution of volume will now take place, and with a little care it will be found easy so to arrange the experiment that part of the carbonic acid shall be in the liquid, and part of it in the gaseous state; the carbonic acid thus coexisting in two distinct physical conditions in the same tube, and under the same external pressure. But if the experiment be made at 30°·92 C., or any higher temperature, the result will be very different. At 30°·92 C., and under a pressure of about 74 atmospheres, the densities of liquid and gaseous carbonic acid, as well as all their other physical properties, become absolutely identical, and the most careful observation fails to discover any heterogeneity at this or higher temperatures in carbonic acid, when its volume is so reduced as to occupy a space in which, at lower temperatures, a mixture of gas and liquid would have been formed. In other words, all distinctions of state have disappeared, and the carbonic acid has become one homogeneous fluid, which cannot by change of pressure be separated into two distinct physical conditions. This temperature of 30°·92 is called by Dr. Andrews the *critical point* of carbonic acid. Other fluids which can be obtained in both the liquid and gaseous states have shown similar phenomena, and have each presented a critical point of temperature. The rapid changes of density which slight changes of temperature or pressure produce, when the gas is reduced at temperatures a little above the critical point, to the volume at which it might be expected to liquefy, account for the flickering movements referred to in the beginning of this article.

The general conclusions arrived at we give in the words of the original memoir. "I have frequently exposed carbonic acid," observes Dr. Andrews, "without making precise measurements, to much higher pressures than any marked in the tables, and have made it pass, without break or interruption, from what is regarded by every one as the gaseous state, to what is, in like manner, universally regarded as the liquid state. Take, for example, a given volume of carbonic acid gas at 50° C., or at a higher temperature, and expose it to increasing pressure till 150 atmospheres have been reached. In this process its volume will steadily diminish as the pressure augments, and no sudden diminution of volume, without the application of external pressure, will occur at any stage of it. When the full pressure has been applied, let the temperature be allowed to fall, till the carbonic acid has reached the ordinary temperature of the atmosphere. During the whole of this operation, no breach of continuity has occurred. It begins with a gas, and by series of gradual changes, presenting nowhere any abrupt alteration of volume or sudden evolution of heat, it ends with a liquid. The closest observation fails to discover anywhere indications of a change of condition in the carbonic acid, or evidence, at any period of the process, of part of it being in one physical state and part in another. That the gas has actually changed into a liquid would, indeed, never have been suspected, had it not shown itself to be so changed by entering into ebullition on the removal of the pressure. For convenience this process has been divided into two stages, the compression of the carbonic acid, and its subsequent cooling; but these operations might have been performed simultaneously, if care were taken so to arrange the application of the pressure and the rate of cooling that the pressure should not be less than 76 atmospheres when the carbonic acid had cooled to 31°.

"We are now prepared for the consideration of the following important question. What is the condition of carbonic acid when it passes, at temperatures above 31°, from the gaseous state down to the volume of the liquid, without giving evidence at any part of the process of liquefaction having occurred? Does it continue in the gaseous state, or does it liquefy, or have we to deal with a new condition of matter? If the experiment were made at 100°, or at a higher temperature, when all indications of a fall had disappeared, the probable answer which would be given to this question is that the gas preserves its gaseous condition during the compression; and few would hesitate to declare this statement to be true, if the pressure, as in Natterer's experiments, were applied to such gases as hydrogen or nitrogen. On the other hand, when the experiment is made with carbonic acid at temperatures a little above 31°, the great fall which occurs at one period of the process would lead to the conjecture that liquefaction had actually taken place, although optical tests carefully applied failed at any time to discover the presence of a liquid in contact with a gas. But against this view it may be urged, with great force, that the fact of additional pressure being always required for a further diminution of volume, is opposed to the known laws which hold in the change of bodies from the gaseous to the liquid state. Besides, the higher the temperature at which the gas is compressed, the less the fall becomes, and at last it disappears.

"The answer to the foregoing question, according to what appears to me to be the true interpretation of the experiments already described, is to be found in the close and intimate relations which subsist between the gaseous and liquid states of matter. The ordinary gaseous and ordinary liquid states are, in short, only widely separated forms of the same condition of matter, and may be made to pass into one another by a series of gradations so gentle that the passage shall nowhere present any interruption or breach of continuity. From carbonic acid as a perfect gas to carbonic acid as a perfect liquid, the transition we have seen, may be accomplished by a continuous process, and the gas and liquid are only distant stages of a long series of continuous physical changes. Under certain conditions of temperature and pressure, carbonic acid finds itself, it is true, in what may be described as a state of instability, and suddenly passes, with the evolution of heat, and without the application of additional pressure or change of temperature, to the volume which by the continuous process can only be reached through a long and circuitous route. In the abrupt change which here occurs, a marked difference is exhibited, while the process is going on, in the optical and other physical properties of the carbonic acid which has collapsed into the smaller volume, and of the carbonic acid not yet altered. There is no difficulty here, therefore, in distinguishing between the liquid and the gas. But in other cases the distinction cannot be made; and under many of the conditions I have described it would be vain to attempt to assign carbonic acid to the liquid rather than the gaseous state. Carbonic acid, at the temperature of 35°·5, and under a pressure of 108 atmospheres, is reduced to $\frac{1}{430}$ of the volume it occupied under a pressure of one atmosphere; but if any one ask whether it is now in the gaseous or liquid state, the question does not, I believe, admit of a positive reply. Carbonic acid at 35°·5, and under 108 atmospheres of pressure, stands nearly midway between the gas and the liquid; and we have no valid grounds for assigning it to the one form of matter any more than to the other. The same observation would apply with even greater force to the state in which carbonic acid exists at higher temperatures and under greater pressures than those just mentioned. In the original experiment of Cagniard de la Tour, that distinguished physicist inferred that the liquid had disappeared, and had changed into a gas. A slight modification of the conditions of his experiment would have led him to the opposite conclusion, that what had been before a gas was changed into a liquid. These conditions are, in short, the intermediate states which matter assumes in passing, without sudden change of volume, or abrupt evolution of heat, from the ordinary liquid to the ordinary gaseous state.

"In the foregoing observations I have avoided all reference to the molecular forces brought into play in these experiments. The resistance of liquids and gases to external pressure tending to produce a diminution of volume proves the existence of an internal force of an expansive or resisting character. On the other hand, the sudden diminution of volume, without the application of additional pressure externally, which occurs when a gas is compressed, at any temperature below the critical point, to the volume at which liquefaction begins, can scarcely be explained without assuming that a molecular force of great attractive power comes here into operation, and overcomes the resistance to diminution of volume, which commonly requires the application of external force. When the passage from the gaseous to the liquid state is effected by the continuous process described in the foregoing pages, these molecular forces are so modified as to be unable at any stage of the process to overcome alone the resistance of the fluid to change of volume.

"The properties described in this communication, as exhibited by carbonic acid, are not peculiar to it, but are generally true of all bodies which can be obtained as gases and liquids. Nitrous oxide, hydrochloric acid, ammonia, sulphuric ether, and sulphuret of carbon, all exhibited, at fixed pressures and temperatures, critical points, and rapid changes of volume with flickering movements, when the temperature or pressure was changed in the neighbourhood of those points. The critical points of some of these bodies were above 100°; and in order to make the observations, it was necessary to bend the capillary tube before the commencement of the experiment, and to heat it in a bath of paraffin or oil of vitriol.

"The distinction between a gas and vapour has hitherto been founded on principles which are altogether arbitrary. Ether in the state of gas is called a vapour, while sulphurous acid in the same state is called a gas, yet they are both vapours, the one derived from a liquid boiling at 35°, the other from a liquid boiling at −10°. The distinction is thus determined by the trivial condition of the boiling-point of the liquid, under the ordinary pressure of the atmosphere, being higher or lower than the ordinary temperature of the atmosphere. Such a distinction may have some advantages for practical reference, but it has no scientific value. The critical point of temperature affords a criterion for distinguishing a vapour from a gas, if it be considered important to maintain the distinction at all. Many of the properties of vapours depend on the gas and liquid being present in contact with one another; and this, we have seen, can only occur at temperatures below the critical point. We may accordingly define a vapour to be a gas at any temperature under its critical point. According to this definition, a vapour may, by pressure alone, be changed into a liquid, and may therefore exist in presence of its own liquid; while a gas cannot be liquefied by pressure, that is, so changed by pressure as to become a visible liquid distinguished by a surface of demarcation from the gas. If this definition be accepted, carbonic acid will be a vapour below 31°, a gas above that temperature; ether, a vapour below 200°, a gas above that temperature.

"We have seen that the gaseous and liquid states are only distant stages of the same condition of matter, and are capable of passing into one another by a process of continuous change. A problem of far greater difficulty yet remains to be solved, the possible continuity of the liquid and solid states of matter. But this must be a subject for future investigation; and for the present I will not venture to go beyond the conclusion I have already drawn from direct experiment, that the gaseous and liquid forms of matter may be transformed into one another by a series of continuous and unbroken changes."

JAMES THOMSON

NOTES

AT last a sum of money has been voted for a new Natural History Museum. In introducing the vote the Chancellor of the Exchequer said the British Museum had long been suffering from repletion, and there were no means of exhibiting the valuable articles which, from time to time, were bought for the national collection. Five years ago the trustees resolved in favour of separating the collections, and it had been determined to separate the natural history department from the books and antiquities. For the natural history collection the typical mode of exhibition had been decided on, and the building required must cover at least four acres. Even the present collection would pretty well fill a building of these dimensions, and provision must be made for further extension. The question was, where should this building be situated? and after referring to possible sites he referred to the locality which we were enabled to state some time ago had been chosen—a plot of ground 16½ acres in extent, which the trustees of the Exhibition of 1851 sold to the Government at 7,000*l.* an acre. It therefore cost 120,000*l.*, but is now worth 100,000*l.* more. The sale was coupled with the condition that any building erected upon the land must be for purposes of science and art. For seven years the land had remained waste, a sort of Potter's field, and a scandal to that part of the metropolis. The Government now proposed to place on that piece of land the museum required for the natural history collection. It would occupy four acres; there would be room for wings, and the outside estimate for the building was 350,000*l.*, not an unreasonable price, considering its extent. For the present, however, the Government merely asked for a small vote to enable them to clear the ground, and in order to take the opinion of the House. Railway communication had now made South Kensington easily accessible, and unless a more eligible, a more accessible, and a cheaper site could be suggested, he hoped the Committee would agree to the proposal. He might add that, if it were hereafter thought desirable to do so, there would be room enough on the same site for the Patent Museum, the necessity of which had been much insisted on. We trust that after the discussion which followed the introduction of the vote the scientific men will speak for themselves, and again let their wishes and opinions be heard.

THE American Association for the Advancement of Science met yesterday (Wednesday) at Troy. Professor W. Chauvenet is president for the year.

IT is gratifying to learn that some of the recommendations of the Royal Commission on Military Education, which were most inimical to the scientific instruction of the army, will not be carried out.

BY Imperial decree the *Association Scientifique de France* has been acknowledged to be an *établissement d'utilité publique.*

THE French observers are making preparations for a combined attack on the 10th of August meteors.

THE list of pensions granted during the year ended the 20th of June, 1870, and charged upon the civil list (presented pursuant to Act 1 Victoria, cap. 2, sec. 6) has been published this week. Among them we note the following:—Mr. Augustus De Morgan, 100*l.*, in consideration of his distinguished merits as a mathematician; Mrs. Charlotte J. Thompson, 40*l.*, in consideration of the labours of her late husband, Mr. Thurston Thompson, as Official Photographer to the Science and Art Department, and of his personal services to the late Princ Consort; Dame Henrietta Grace Baden Powell, 150*l.*, in consideration of the valuable services to science rendered by her husband during the 33 years he held the Savilian Professorship of Geometry and Astronomy at Oxford; Miss Margaret Catherine Ffennell, Miss Elizabeth Mark Ffennell, and Mrs.

Charlotte Carlisle, formerly Ffennell, wife of Captain Thomas Carlisle, jointly, and to the survivors or survivor of them, 30*l.*; Miss Margaret Catherine Ffennell, 10*l.*; Miss Elizabeth Mark Ffennell, 10*l.*; Mrs. Charlotte Carlisle, 10*l.*, in recognition of the labours of their father in connection with the salmon fisheries of the United Kingdom; Mrs. Jane Dargan, 100*l.*, in recognition of the services of her late husband, Mr. William Dargan, in connection with the Dublin Exhibition of 1853, and other works of public importance in Ireland; Mrs. Charlotte Christiana Sturt, 80*l.*, in consideration of the services rendered by her late husband, Captain Charles Sturt, by his geographical researches in Australia; William Henry Emmanuel Bleek, Doctor of Philosophy, 150*l.*, in recognition of his literary services, and in aid of his labours in the department of philology, especially in the study of the South African languages.

THE Radcliffe Observer, the Rev. R. Main, has recently presented his annual report to the Board of Trustees. It concludes as follows:—"An unusually large number of meridional observations have been made, and their reductions kept up to their usual stage; a Second Radcliffe Catalogue of Stars (a work of very considerable labour in its compilation) has been printed and published, in addition to a new ordinary annual volume of the Radcliffe Observations; and, notwithstanding the amount of work of an unusual character which has been performed, none of the ordinary details, either of scientific or of clerk-like work, have in any sensible degree fallen behind or been neglected. I confess that I am well satisfied with what has been accomplished (all of it, in my judgment, being of great utility), and altogether it affords a good specimen of what can be accomplished by a small staff of astronomers well skilled in the making and reducing of observations, and devoting themselves steadily and without intermission to the carrying out of a certain number of definite aims on a plan well prepared and studied beforehand."

MR. JOHN HILTON, F.R.S., late President of the Royal College of Surgeons, who for twenty years has filled the office of surgeon to the above institution, has just been unanimously elected by the governors Consulting Surgeon—an honour which, adds the *Medical Times*, has not been bestowed on any member of the surgical staff since Sir Astley Cooper.

A COMMITTEE has begun operations at the Society of Arts for inquiring into the relations of inventors with the Government departments, and the treatment by these latter of scientific inventions. Considerable zeal is shown on the subject, and the whole question of scientific tribunals will be made matter of discussion. Printed forms for collecting the opinions of those interested will be extensively circulated.

THE Statistical Society has entered on a new epoch of activity. Formerly its presidents were statesmen, but it determined lately, like other learned Societies, to select its president from among its own working members, by choosing Mr. Newmarch, F.R.S. This has been attended with more vigorous action of the Council, and corresponding interest among the Fellows. For the first time the Society, the resources of which have always been limited, gives a premium, having received a donation of fifty guineas from Mr. Wm. Taylor, a Fellow. The Taylor premium is to be devoted to an essay on the subject of Taxation in England, and it appears likely that it will be the means of bringing out many new points on an old and trite subject.

IN order to encourage science our authorities have accorded to graduates of the Lahore University the envied privilege of being seated in Durbar and on other state occasions.

THE first of the Quarterly Weather Reports of the Meteorological Office, with pressure and temperature tables for the year 1869, and notes on Easterly Storms, issued by the Meteorological Committee, embodies the results of observations made at the observatories of Kew, Stonyhurst, Glasgow, Aberdeen, Armagh, Falmouth, and Valencia, during the first three months of last year. The succeeding quarterly numbers for the year will follow as quickly as possible, and the journal will in future appear regularly at intervals of three months. The first number contains complete tables for pressure and temperature, &c., for the year 1869, and the plates exhibiting the continuous registration of these observations for the quarter are arranged to show at one view the instrumental curves at each of the stations for five days, one plate comprising pressure and temperature, while another shows the direction and velocity of the wind, scales of measurement being given at the sides both on the British and French systems. We shall return to this report.

THE *Engineer* states that the new dye known as soluble garnet seems to be coming more largely into use on the Continent, and as the colours produced with it are exceedingly brilliant, similar to those obtained with archil, but much more stable when exposed to light and air, the garnet dye is likely to become a great favourite. The dye was first prepared by Casthelaz of Paris, and is the ammonia salt of isopurpuric acid, which is formed by the action of a metallic cyanide upon picric acid. It is not prepared from the pure crystallised, but from an inferior kind of picric acid, and is probably destined to replace the archil in many cases, in imparting to wool all shades from garnet to chestnut brown. It may be readily combined with other pigments, so that a number of different colours may be obtained. According to Casthelaz, the dyeing of wool and of silk is effected by the addition of an organic acid to the bath, for instance, acetic or tartaric acid, mineral acids being excluded. The dye bath for silk should be cold or tepid in the beginning. Different shades in red and brown are thus obtained that are dependent upon the concentration of the bath, the nature of the mordant, and the time of the operation.

IN the attempts now being made further to utilise the hill regions of India for English residence, the Observatory at Nynee Tal, itself a hill town, is to be removed to Raneekhet, which is said to be chosen by some of its patrons as the future hill capital of India.

A HORTICULTURAL establishment has been opened at Guatemala for the export of the seeds, flowers, and young plants of the country.

THE Peruvian Government is endeavouring to develop the saltpetre district of Tarapaca.

A RICH silver mine has been discovered by Messrs. Lepiani and Steffani near Huamantanga, in Peru, and measures are taken for working it.

THE field of the new silver mines near Cobija, in Bolivia, the discovery of which was reported by us, is stated to be 3,000 to 5,000 marcs per cajou, or from 700*l.* to 1,200*l.* of silver per ton of ore.

ON the 16th June an earthquake was felt all over the state of Nicaragua. At Granada, alarming noises were heard from Momotombo, an extinct volcano in the neighbourhood.

ON the 26th May there was a tremendous earthquake at Lima, the first for a long time. It was also felt at Callao.

AMONG the sums voted last week by the House of Commons in Committee of Supply were the following:—64,721*l.* for Public Education in Great Britain; 164,836*l.* to complete the vote for the Department of Science and Art (being an increase of 11,883*l.* on the vote of last year); 51,255*l.* to complete the vote for the Museum; 6,827*l.* for the University of London; 8,220*l.* for the salaries and expenses of the Endowed Schools Commission; 12,894*l.* for the Scottish Universities; 2,140*l.* for the Queen's University, Ireland; and 2,915*l.* for the Queen's Colleges, Ireland. The total educational estimate for the year was stated by Mr. Forster to be 914,721*l.*, being a net increase of 74,010*l.* over that of last year. The day scholars in average attendance have increased from 1,082,000 to 1,200,000. There are 223 more male and 104 more female teachers than last year. Since 1868 the number of Science schools has increased from 300 to 810, and the number of scholars is now nearly 30,000; the number of scholars in Art has increased since last year from 123,562 to 157,198. The increase in the number of scholars in the regular schools is stated to be in excess of the increase of population. These statistics are interesting, as showing that the increased desire for education in the country at least keeps pace with the advance of opinion among the governing classes in favour of a truly national system of education. The query whether prevention is better than cure is forcibly suggested by three other votes which were passed on the same night:—315,627*l.* for convict establishments in England and the colonies, 203,880*l.* for the maintenance of juvenile prisoners in reformatories, and 643,070*l.* for the constabulary force in Ireland. When shall we arrive at the pitch of civilisation of one of the Swiss Cantons, where the expenditure for educational purposes exceeds that for all other purposes put together?

WE learn from the last report of the Geological Survey of Italy (R. Comitato Geologico) that that body will publish a geological map of Italy on the scale of 1 to 600,000 during the course of next year. The map is that which was compiled by Professor I. Cocchi in 1867 and sent to the Universal Exhibition in Paris. It was a hand-coloured map, the Ordnance map of Upper and Central Italy in six sheets being used as a basis. In compiling this map Professor Cocchi made use of all the published and unpublished materials that he could find. The most southern provinces of the Peninsula and Sicily were not however represented, for although notes and papers on their geology were not wanting, that part of the kingdom had not been mapped geologically. The new map will be divided into four sheets, and new plates will be engraved copying the topography of the Ordnance map, and introducing such modifications and improvements as may be deemed necessary for the new object to which the map is to be applied. The colouring will be done by chromolithography. Accompanying the map there will be a short descriptive memoir and two geological sections, one along the length and the other across the breadth of the country.

M. DIAMILLA-MULLER calls upon all directors of magnetical observatories to observe the declination and inclination every ten minutes from midnight 29th of August (Paris time), to the next midnight, and send the results to him at the bureaux of the Association Scientifique de France. He adds, "On croyait généralement que le soleil agissait indirectement par suite des changements de température qu'il produit à la surface de la terre. J'avais déjà présenté l'hypothèse, basée sur les observations d'Arago, tendant à établir que l'action directe du soleil sur le magnétisme est absolument semblable à l'action d'un aimant sur le fer. Cette théorie est confirmée par les observations faites dans les Colonies anglaises, où l'on remarque l'opposition de signe que le changement de déclinaison du soleil imprime aux courbes qui représentent la variation magnétique dans les pays tropicaux. Il est nécessaire de constater, par une observation directe, que cette loi d'opposition, en rapport avec la déclinaison solaire, s'exerce dans toutes les régions du globe."

PROF. LIONEL BEALE's inaugural lecture to the course of Pathological Anatomy, delivered at King's College, May 5th, 1870, is issued as a separate publication, with the title "On Medical Progress; in memoriam R. B. Todd."

THE third part is published of Dr. Manzoni's "Bryozoi fossili Italiani," accompanied by four plates.

ANOTHER contribution to astronomical literature lies on our table, in the shape of the second volume of "Astronomical Observations taken during the years 1865-69, at the private Observatory of Mr. J. G. Barclay, of Leyton."

MR. KEITH JOHNSTON, jun., publishes, in his usual admirably clear style, a map of the Lake Region of Eastern Africa, showing the sources of the Nile, recently discovered by Dr. Livingstone; with notes on the exploration of this region, its physical features, climate, and population.

*ON VOLCANOES**

VOLCANOES are but so many existing proofs of the activity of internal forces at the present moment, and, as a geologist, I may be almost pardoned if I regret that we do not in our happy isles possess even a single example of an active volcano.

As regards the geographical distribution of recent volcanoes, a glance at the geological map of the world will suffice to show that they are in reality scattered all over its surface, yet, it may be added, more rarely occurring at any great distance from the sea, although exceptional instances are met with inland, in all the four quarters of the globe.

In the North we find the volcanoes of Iceland, Jan Meyen, Kamskatca, Alaska, and others; whilst the Antarctic voyages of Ross proved that the mountains of the land nearest accessible to the South Pole were also active volcanoes.

At the equator, all but innumerable volcanoes are seen in the islands of the Indian and Polynesian Archipelagos, as well as in the Pacific and Atlantic Oceans, and on the main land of South America. Midway between the Equator and the Poles are situated the volcanoes of New Zealand, the Canaries, Cape Verde, Azores, and Sandwich Islands, as also those of Arabia, Eastern Africa, Mexico, Central America, and the volcanoes of the whole range of the Andes down to Terra del Fuego. Nearer home, Vesuvius, Etna, Stromboli, Santorin, and numerous others in the Mediterranean, if not so grand in their dimensions as some of those previously referred to, still present on the large scale all the various aspects of volcanic phenomena, both submarine as well as terrestrial.

If now, however, we take a broader view of volcanic phenomena, and, in addition to the before-mentioned still existing proofs of the general distribution of volcanic centres, as they have been termed, we also take into consideration the occurrence of eruptive rocks of similar origin which are everywhere found disturbing and breaking through the strata of even the oldest rock formations, it will be seen, as least as far as the geology of the earth's surface is at present known to us, that there is scarcely a single area of any magnitude, of either the land or sea, which, at some period or other, has not been broken through or disturbed by what may be termed volcanic forces acting from within the mass of the earth itself; and it is impossible to come to other than the conclusion that these agencies must have played a most important part in determining the main features of the earth's external configuration as well in our times as throughout all periods of its history.

If now the question be asked, what is a volcano? the simplest reply would be "a hole in the ground deep enough to reach such portions of the interior of the earth as are in a molten condition."

In ordinary language, however, the appellation of volcano is usually restricted to those cone-shaped mountains, from the hollow summit of which flames, smoke, and vapours are at times seen to ascend, and which occasionally break out into more imposing activity by vomiting forth showers of ashes and fragments of incandescent rock, or by pouring out torrents of molten stone, to deluge and devastate the unfortunate country in the vicinity.

It having always been admitted that volcanoes owed their origin to forces operating from below, it was suggested by Von Buch, and supported by Humboldt and others, that volcanic cones must be formed by some portion of the surface of the earth, weaker than the rest, being forced out, or, as it were, thrown up like a soap-bubble by the pressure of the vapour and gases confined below, the strata being thereby elevated, fractured, and tilted up on all sides, so as to produce a conical elevation, the central fissure in which became a crater or vent for the escape and passage of the gaseous and liquid emanations from below.

* Outline of a Lecture delivered at St. George's Hall, Langham Place, 9th June, 1870, by David Forbes, F.R.S.

This hypothesis, which accounted for the formation of volcanic cones and craters by a process of upheaval, or, as it was termed, the "crater of elevation," is here alluded to, only because it for a long time was accepted by many eminent men of science, until the subsequent researches, especially of Mr. Scrope and Sir Charles Lyell, demonstrated conclusively that it is not confirmed when their actual structure is studied in the field, and explained their true formation, by what is now termed the "crater of eruption" theory.

If we imagine a volcanic cone cut through its centre, so as to present us with a section of its entire mass, it will be seen that the mineral matter of which it is composed possesses in itself a sort of arrangement in layers, which at first sight somewhat resembles beds of ordinary sedimentary origin broken through and tilted up towards the centre; a closer examination, however, shows that these layers were never at any time horizontal, but that, on the contrary, they had from the very first been deposited in the same inclined position in which they are now seen, and that they must have been formed subsequently, not previous to the opening of the crater itself, since they are entirely composed of matter thrown up from its orifice.

The commencement of an eruption is known in most cases by certain preliminary symptoms indicative of great internal disturbance, such as rumbling noises, and sounds as if of explosions below, which have been likened to subterranean thunder. The surface waters, springs and wells in the vicinity generally acquire an unusually high temperature, diminish in volume or disappear altogether, and repeated earthquake shocks more or less severe are felt, which eventually culminate in a grand convulsion, by which the surface is rent asunder with fearful violence, allowing immense volumes of previously pent up vapour and gases to rush forth from the fissure with such impetuosity as to hurl high into the air huge fragments of the shattered rocks, along with vast quantities of molten lava, in so liquid a condition that during its ascent it is seen to be splashed about in the air like water, and to become separated into particles of all sizes. Vast quantities of these particles, to which the name of volcanic ash or dust has been applied, are instantaneously reduced to so fine a state of division, literally "blown to atoms," as to become converted into an almost impalpable powder, capable of being carried away by the winds prevailing during an eruption to distances of even hundreds of miles from the orifice from which they had been ejected, and ultimately settle down on the land or in the sea to form deposits, whose nature would often be a puzzle to geologists, did not the microscope at once reveal their true mineral character and volcanic origin. Other particles less finely divided become granulated and fall down from the air in the shape of small black grains, known as volcanic sand; whilst still larger portions, owing to the bubbles of vapour or gas entangled in their substance, descend as black porous or spongy stones, from the size of a pea to that of one's head, or larger; and have received the names of Lapilli, scoriæ, or volcanic cinders, from their presenting much the appearance of an ordinary cinder from a coal fire. Although the scoriæ thrown up by volcanoes are in major part of a dark colour, there are also others (called trachytic) much lighter both in colour and weight, which are usually more common at the commencement of an eruption, the ordinary pumice stone which is imported in large quantities from the volcanoes in the Lipari Islands, for the use of the painters, &c., is an example of this variety familiar to you all. A peculiar form of lava is produced by the currents of wind blowing over the surface of the molten matter in the crater, catching up portions of it and drawing them out into long slender filaments like hair or spun glass of all shades of black, brown, or yellow. In the Sandwich Islands, where this variety is very abundant, it is called Pele's hair, from the name of one of their ancient goddesses. In the intervals of an eruption, or after the greatest force of the rush has spent itself, the vapours often rise through the molten lava in the crater, in smart puffs which carry up with them portions of the fluid lava high into the air, whence they descend consolidated as spheres or somewhat elongated bodies consisting of an external shell of solid lava, hollow or only filled with vapour or gas in the centre. From their resemblance to military projectiles, these bodies, which vary from the size of an orange to that of a pumpkin, have received the name of volcanic bombs.

The mineral matter thrown up into the air from a volcanic vent necessarily descends again by virtue of its own weight, a portion drops back into the crater, but the major part falling beyond it, accumulates around its brink to form a mound, which, since the larger and heavier pieces are not projected to so great a distance as the others, keeps, as it increases in size, raising itself more rapidly in height nearest around the vent, then farther off, and thus builds up a hollow cone, the throat or chimney of which is kept open, at least during the continuance of an eruption, by the upward rush of the gases and vapours forced through it by the pressure below. The action of the heat being of course much more intense in the chimney or throat of the crater, now causes, the at first comparatively loose materials which formed its walls, to soften and cement themselves together on the inside into a sort of compact stony tube of communication with the lower regions, much more solid and resistant than the rest of the mass of which as before described the entire cone had been built up. Once this is the case, the molten lava, forced up by the gaseous pressure below, frequently ascends into the crater itself, and overflowing its brim, pours down the outside of the cone, just like water when placed over too rapid a fire is seen to boil over the edge of the pot in which it is heated. These occasional overflows of lava explain how in the section of a volcanic cone layers of more compact lava are so frequently seen alternating with those of the porous scoria and volcanic sand before described. In more rare instances, as for example in the eruption of Mauna Loa, in the Sandwich Islands, in February 1859, the lava is ejected in so wonderfully liquid a condition, and in such enormous volumes, as to present the appearance of a red-hot fountain; the jet of molten lava thrown up from the crater on that occasion is described as about 250 feet in diameter, and as rising some 500 feet above the level of the brim of the crater itself. Occasionally, during an eruption, the rim of the crater, unable to support the weight of the molten lava which fills it, gives way at its weakest point, the lava bursting out and carrying away one side of the cone itself; at other times the lava, after having risen some height up the crater, finds out a point of weakness and breaks through, discharging itself by a fissure some way up the side of the cone, as was the case with the volcano of Sajama, in Bolivia, in 1859, and with Etna in 1865. In many eruptions the lava does not ascend at all into the crater, but breaks out at the very base of the cone, or even at some considerable distance from it, through a subterranean passage. This took place in the eruption of Kilauea, in the Sandwich Islands, in June 1840, when the lava first showed itself at the surface at Arare, some six miles eastward of the crater which supplied it. In fact, most volcanoes will, upon examination, be found at one or other period in their history to have presented examples of more than one, if not of all, these different modes of discharging their molten products.

The eruption of Etna in 1865, which I witnessed, did not proceed from the summit or main crater, but broke out on the side of the mountain, about 5,000 feet above the level of the sea. Along the fissure or rent formed by this convulsion, no less than seven distinct cones rose up at intervals, building themselves up very rapidly from the enormous quantities of scoriæ which were thrown up from their rents; as they became larger the bases of several of these cones extended until they united, and so formed a range of hills, the summits of which in but a few weeks reached the height of several hundred feet, and entirely changed the character of the scenery of this part of the island. The four lowest cones were the most active, but from none of their craters was there any overflow of lava, which, however, poured out from the very base of the cones, forming a fiery river apparently about three miles across, which destroyed all before it, cutting through a large pine forest, and at one place leaping like a cascade of liquid fire over a precipice some 150 feet in height.

The formation of a new or re-opening of an old volcanic vent is usually accompanied by a terrific explosion, often to be heard at immense distances; thus, in 1812, the outburst of the volcano of San Vincent was heard in the north of South America some 700 miles distant. The enormous force developed by the rush of gases and vapours from the fissure may be imagined when it is known that in the eruption of Mount Ararat, in 1840, huge masses of rock weighing as much as 25 tons were thrown out of the crater; Cotopaxi is said to have even hurled a 200-ton rock to a distance of nine miles; whilst the volcano of Antuco, in Chili, in 1828, sent stones flying to a distance of 36 miles.

The issue of gaseous matter from the crater of a volcano is often described as a column of flame; this is incorrect, for although possibly a little burning hydrogen or sulphuretted hydrogen might be present, especially on the outer edge of the column, the appearance of a column or fountain of flame is in reality due to the gaseous matter of which it consists being illuminated by the fragments of red-hot rock and molten lava thrown up along with it (like sparks in fireworks), assisted by the reflection from the red-hot sides of the crater itself, and from the surface of the molten lava below.

The chemical composition of the gasiform emanations from volcanoes proves that they are in greater part incombustible, and therefore does not support the idea that the body of such a column of vapour and gases could be in flames, *i.e.*, actually burning. On the outside of the column, however, innumerable brilliant scintillations of a bluish colour are frequently seen, due to particles of sulphur taking fire as they come in contact with the outer air, and patches of melted sulphur are splashed about, burning brightly as they fall through the air on to the slopes of the cone. The emission or belching forth, as it has been called, of the gaseous matter with its accompanying red-hot ashes and scoriæ, is more an intermittent than a continuous operation. When an eruption is at its height the spasmodic puffs or blasts are jerked out at intervals of but a few seconds, attended by a terrific roaring or bellowing noise difficult to describe in words.

The buried cities of Stabia, Herculaneum, and Pompeii, covered up in parts to the depth of 100 feet by the ashes of Vesuvius, are ocular proofs of the vast quantity which can be sent out of a volcanic vent during an eruption. The volcano of Sangay, in Ecuador, in constant activity since 1728, has buried the country around it to a depth of 400 feet under its ashes, and a French geologist has estimated that in the course of only two days the volcano of Bourbon has thrown out no less than 300,000 tons of volcanic ashes. The immense distances to which these may be transported by the winds is no less surprising; the ashes of Vesuvius, in the eruption which buried Pompeii, darkened the sun at Rome, and were carried as far as Syria and Egypt; those from San Vincent, in 1812, are reported to have made the sky as dark as night in the Barbadoes; and in Iceland, in 1766, the air became so charged with ashes for a distance of 150 miles around Hecla, that even the brightest light could not be distinguished at a few yards.

Amongst the still active volcanoes we meet with some whose craters are several miles in diameter, encircled by precipitous sides rising to even a thousand feet above the bottom of the crater when at rest, which, as in the Sandwich Islands, may contain reservoirs, or rather lakes of liquid lava, two to four miles across, and at times send forth rivers of molten stone several miles in breadth, extending their fiery inundation to a distance of even forty miles from the crater whence they issued. In the eruption of Hualalai, in 1801, a lava current, after reaching the coast, poured out such volumes of melted matter as to fill up a bay some twenty miles deep, and in its place extend a headland some three or four miles farther into the sea. The rate at which these rivers of molten stone flow is a very varying one; in 1805 the lava current from Vesuvius is said to have run down the first three miles in four minutes, yet only completed its total distance of six miles in three hours; and in 1840 that from Mauna-Loa advanced no less than eighteen miles in two hours; whilst on the other hand it is recorded that during the eruption of Etna, which commenced in 1614, and continued many years, the lava stream only completed a distance of six miles in ten years, notwithstanding that all this time it was seen to be in slow but almost imperceptible motion; during the eruption of this volcano in 1865, I found, however, that at the edge of the current the rate of motion varied from 15 to 120 feet per hour according to local circumstances; in the centre of the stream the lava was evidently still more rapid in its movements.

The entire mass of a lava stream often advances, even when to the eye it would appear to have become quite solid; upon my throwing a heavy stone on to the top of a lava current so far consolidated that the stone merely fixed itself into the surface without sinking deeper, it was seen that the stone moved along with the lava which otherwise looked as if stationary. The surface of this lava consolidated and cooled with almost incredible rapidity, so much so that, notwithstanding the protestations of my guides, I walked over lava currents when, at the same time, the fiery stream still flowing below could be distinctly seen through the cracks in the crust over which I passed.

On this occasion also the stems of the pine-trees in the forest which was destroyed by this eruption were converted into charcoal as high as the lava reached, but the upper portions of the trees then toppled over, and remained in an almost unaltered and uncharred condition on the top of the lava current which had so quickly cooled. The crust which forms on the top of lava when cooling, being an excellent non-conductor, acts so efficiently in preventing further escape of heat, that we find streams of lava requiring many years and even ages to become quite cold. Dolomier relates that the lower part of the Ischia lava of 1301 was still hot in the year 1785.

When, owing to the descriptions of the ground around volcanoes, the water from springs, rivers, lakes, or the sea itself, is brought into contact with the heated mineral matter below, we have the production of the so-called mud volcanoes or of fissures sending forth torrents of heated mud and water, and often, to the great surprise of the inhabitants, throwing out numbers of fishes which had lived previously in these sources. The Geysers of Iceland are somewhat similar phenomena, but on the present occasion time will not permit these subjects being treated in detail.

Whilst some volcanoes like Stromboli, the lighthouse of the Mediterranean, as it was called by the ancients, have continued in incessant activity from the oldest historical periods down to the present day, the eruptions of others are only known to have taken place at long intervals. Vesuvius, although imagined by Strabo to have had a volcanic origin, was not known even by tradition to have ever been in eruption until the year 79, when Pompeii was overwhelmed by it. Since that time, however, up to the present date, it has given ample proof of its volcanic activity, yet its history shows several intervals of a century, and one of more than two centuries, in which no eruption took place. No outbreak of the volcano Sangay in Ecuador is recorded before 1728, since which year it has been in continued activity, and Krabla in Iceland also remained at rest for several hundred years before 1724. In fact, it may be safely affirmed that it is quite impossible for us to know whether any volcano at all is entitled to be regarded as really extinct. Even for ages after the last outburst of lava, it is found that smoke and acid vapours continue to be given off from most volcanic rents, and the extraction of the sulphur found in the craters and sublimed into the fissures around dormant volcanoes, forms in many countries an important branch of industry.

Although, as yet, I have confined my remarks altogether to terrestrial volcanoes, it must not be supposed that the depths of the sea are exempt from such visitations, and in the last few years we have had several prominent examples to the contrary in different parts of the world. Submarine volcanoes were well known to the ancients; Pliny and older writers refer to those in the Mediterranean which threw up the islands of Delos, Rhodes, Anappe, Nea, &c. In the Cyclades very curious examples have occurred, both in very ancient and in the most recent times. Of these islands, Therasia is recorded to have been formed in the third century B.C., as also somewhat later in the same century the island of Thera, now called Santorin; subsequently Hiera, 91 B.C., and then Thea, A.D. 19, appeared, which last two were, in 726, united by an eruption, and together formed the present island of Kaimeni. In 1575 a smaller island called Little Kaimeni showed itself, around which, in 1650, numerous other islets were thrown up, which subsequently became united to Little Kaimeni during the eruptions, which continued from 1707 to 1812, when the island, thus increased in size, became known as New Kaimeni. Finally, the last eruption (still going on), which commenced 28th January, 1866, presented us, on the 2nd February, with a new island, now called King George's Island, from the present King of Greece, which, according to the latest accounts, still continues to increase in size. Numerous other examples might be cited, but I shall only mention the island of Johanna Bogoslawa, in Alaska, which, although it only first showed itself above the water in May 1796, had, in 1806, increased so as to be an immense volcanic island, the summit of which was then elevated to no less than 3,000 feet above the level of the sea.

The volcanic products thus forced out under the sea present, as might be expected, a very different aspect from that of the ashes, scoria, and lava from terrestrial volcanoes; the molten lava coming in contact with the water is at once broken up into fragments, coarser or finer, in proportion to the greater or less cooling power of the water in immediate contact with them, and often in great part instantly converted into fine mud, of a greyish colour when formed from prachytic lava, but more commonly of a chocolate or other dark tint, and much denser when produced from the more prevalent pyroxenic lava. Beds of this character, spread out by the action of the sea, often enclosing shells, fish, and other organic remains, become in time consolidated and upheaved, and as they often present an appearance much resembling ordinary volcanic rocks, they have frequently puzzled geologists, who at first found a difficulty in explaining the presence of such fossils in rocks apparently of igneous origin.

Many writers on this subject hold to the belief that volcanoes are mere local phenomena, each one springing from its own comparatively small reservoir of molten matter, supposed to have originated from the softening or fusion of rocks pre-existing on the spot at some depth below the surface. To me, however, this hypothesis appears altogether untenable when it is remembered, amongst other objections which I have elsewhere considered, that volcanic rocks are encountered in all parts of our globe, often continuous or nearly so, over immense areas, and that all these rocks, without reference to the part of the world in which they occur, are invariably alike in character to one another.

Volcanic rocks may be classified under two heads, viz., the dark-coloured, more dense; and the less heavy, light-coloured lavas, termed, respectively, the basic or pyroxenic, and the acid or trachytic lavas. Both these varieties may proceed from the same volcanic vent in succession—for instance, in Vesuvius, where the mineral matter which buried Pompeii is trachytic, but the later lavas are generally pyroxenic in character. This also was the case in the recent eruption of Santorin, as reported upon by the Austrian Scientific Commission.

The examination of volcanic products, no matter how distant the volcanoes may be from one another from which they are taken, prove them to be altogether identical in general, mineral, and chemical constitution.

Taking all these and other data into due consideration, I cannot arrive at any other conclusion than that all volcanoes are connected with one another in depth, and having one common source, not necessarily situated at any enormous depth below the surface, but in which the molten matter—whilst always containing certain general characters—has undergone considerable modifications in composition, mineralogical and chemical, from time to time in the world's history; for under the term volcanic rocks, I would here include all eruptive rocks without exception, whether called granites, syenites, porphyrites, basalts, or lavas, all of which I regard as but so many members of one series, or simply as the products of the volcanic action of different geological epochs.

So much for the molten products of volcanoes. Now a few words on their gasiform emanations, which consist in greater part of the vapour of water, *i.e.* steam, along with volatile chlorides, hydrochloric and sulphurous acids, nitrogen and sulphuretted hydrogen gases. The sulphur, seen to be sublimed in so large quantities, is probably derived from the mutual reactions of the sulphurous acid and sulphurated hydrogen gases, as they come into contact with one another.

Now if it be true that we have a vast accumulation of molten matter at a certain depth below the surface, which observation further informs us must, in major part, consist of the silicates and sulphides of the metallic elements, then, in my opinion, at least, it only requires the assumption that water from the sea should, by some means or other, find its way down into such a reservoir, to account for all the phenomena of volcanoes, both mechanical as well as chemical. The greater part of the water so introduced would be at once converted into steam, which, in its turn, would become still further expanded by a heat so great as that of molten lava, and would develope an enormous power. Calculations have been made which show that water, even when treated to a much less temperature, would exert an "ejection force," as it has been termed, even exceeding that developed in eruptions of the highest volcanoes known. Another portion of the water with the air carried down along with it, acting upon the highly heated sulphides, would become decomposed, and furnish the sulphuretted hydrogen, sulphurous acid, and nitrogen gases given off, whilst the common salt in the sea water, by its action on the hot silicates in presence of steam, would eliminate hydrochloric acid, and account for the appearances of it, as well as of the volatile chlorides found in volcanic fumes. If we accept this explanation, the chemical reactions would be but the effects and not the cause of volcanic phenomena.

The destructive effects attendant on volcanic convulsions are of two different characters, viz., those arising from the earthquakes which accompany and, as a rule, precede outbreaks; and those caused by the products ejected from the volcano itself. The connection of earthquakes with volcanoes has been noted from the oldest times; the earthquakes which commenced A.D. 63, were but the efforts made by Vesuvius to relieve itself, which culminated in the great eruption of 79; the same was the case in Mexico with Jorillo in 1759, and with the great earthquake of 1834 in Chili, which ended in the outbreaks of Osorno and three other volcanoes of the Andes; and lastly, in 1868, the terrible earthquake which visited the coast of Peru and totally destroyed the cities of Arica and Iquique, was followed by the eruption of Isluga, which, according to the latest news, still continues. There seems little reason to doubt that all earthquakes are of purely volcanic origin, and that volcanoes themselves may be regarded as so many safety-valves for blowing off the surplus steam, gases, and molten products from our great internal boiler; for, as a rule, it has been observed that earthquakes either cease altogether or diminish greatly in violence as soon as a neighbouring volcano has cleared its throat.

Although I have resided several years in what are called earthquake countries, and have experienced numerous and severe shocks, amongst others those which resulted in the total destruction of the cities of Copiapo and Mendoza, on which latter occasion some 20,000 inhabitants perished in the ruins, it seems to me quite impossible to convey in words anything like a true picture of such a dreadful catastrophe; the feeble shocks occasionally felt in England cannot give you even the remotest idea of what a severe earthquake is in reality, for not only are cities destroyed and whole villages swallowed up in an instant, as in the case of Arqure during the eruption of Mount Ararat in 1840, but when situated on the coast, even when they have withstood the shock itself, they may be entirely swept away by the great sea wave which follows close upon it, as happened with the cities of Arica and Iquique, in Peru, little more than a year ago. Equally terrible is the destruction caused by the showers of ashes and torrents of molten rock, as in the well-known instances of Pompeii, Herculaneum, and others, too numerous to mention.

The study of volcanic phenomena presents a wide and interesting field for exploration, for as yet our knowledge of the subject is lamentably defective. To follow it up, however, the student should work out a path for himself, taking advantage of every new means of research placed in his hands by the advance made by the collateral sciences, and steering clear of all schools or preconceived notions. Schools in science are what parties are in politics; the "follow my leader" style will not do in this age, for it does not permit of that perfect independence of thought absolutely requisite to ensure success in the pursuit of science. The study of science is the search after truth, but in its study the persevering and conscientious worker, although sure to attain good results in the end, must always bear in mind that his results, even when proved to be *truths*, are still only fragments of *the whole truth*, and that he therefore should guard himself against overrating their value, *i.e.* the extent of their application, since this can only be correctly estimated when these fragments have been found to fit accurately into their true place in the grand plan of nature.

D. FORBES

SCIENTIFIC SERIALS

THE *Journal of Botany* for July commences with a short account by Dr. D. Moore on a form of *Salix arbuscula* in Ireland, which inclines rather towards *S. myrsinites*. Dr. Seemann proceeds with his "Revision of the Natural Order *Bignoniaceæ*," and Mr. Worthington Smith with his valuable "Clavis Agaricinorum," these three articles completing the portion of the paper devoted to original articles, which we regret to see reduced to so small a space. Then follow the second part of Dr. Braithwaite's "Recent Additions to our Moss Flora," and appreciative reviews of Dr. Hooker's "Students' Flora," and Prof. Babington's "Flora of Iceland."

THE *Student and Intellectual Observer* for July contains several good articles, though none of any striking originality. The longest is by Dr. W. B. Carpenter, on the Deep Sea, its Physical Conditions, apparently a report of a lecture delivered during the winter in St. George's Hall. Dr. Henry White's article on Demonism and Convulsionism gives some interesting details of the epidemic which prevailed in Europe during the 17th century. Dr. Wickham Legg, on Zymotics, discusses the theory of the fungus-germ theory of diseases of this class, which he admits explains a good many of the facts, but demands too great a concession in the outset, in the presence in the blood of nearly twenty distinct and separate substances, which exist only to serve as a nidus for the specific ferment, and to be a source of injury to the individual. Mr. Llewellynn Jewitt contributes an article on Celts and other Implements of Bronze, profusely illustrated; Mr. Barff, a third article on Poisons; and Mr. Henry J. Slack, two short papers on the Juniper Fungus (*Podisoma*), and on the Structure of *Pinnulariæ*. The two publications of the quarter selected for separate reviews are Proctor's "Other Worlds than Ours" and Wallace's "Contributions to the Theory of Natural Selection;" and minor papers and reports fill up the number.

SOCIETIES AND ACADEMIES

London

Royal Society of Literature, June 22.—N. E. S. A. Hamilton, librarian, in the chair. Mr. W. R. Cooper exhibited a Greek Tablet from the Hay Collection, found by the late Mr. Robert Hay in the Aasaseef, Thebes, about 1823. Mr. Cooper stated that the relic was one of peculiar interest, as it was a palimpsest tablet, upon which had been written, in the bold uncials peculiar to the fourth century, a list of familiar Grecian names, and among them that of Athanasius. This circumstance, and the fact that it was found near to the ruins of a Christian church, where a long inscription in honour of Athanasius once existed, seemed to warrant a belief that the tablet had some connection with that famous bishop, the more so as the name was not a common one in Grecian history, and the characters are unquestionably of the period in which he lived. Mr. Cooper was supported in his views by Mr. W. S. Vaux and Mr. Hamilton, who examined the antiquity with much interest, and supplemented his short paper by some very able remarks of their own.

Quekett Microscopical Club, July 22.—Annual general meeting, Mr. Peter le Neve Foster, president, in the chair. According to the annual report of the committee, which was read, the Club still maintains its popularity and success. It numbers over 500 members, and meets for the prosecution of miscroscopical inquiry twice a month throughout the year. Mr. Peter le Neve Foster, in vacating the presidential chair which he had so ably filled during the past year, delivered his valedictory address, in which he called attention to various open questions in microscopical science, and which were fields well worth the labour required for their investigation, and which he considered the members might undertake with pleasure to themselves and advantage to the world at large.—Prof. Lionel S. Beale, F.R.S., was elected president for the ensuing year, and Messrs. Henry Lee, F.L.S., Arthur E. Durham, F.R.C.S., Peter le Neve Foster, M.A., and Dr. Robt. Braithwaite, F.L.S., were elected vice-presidents, while Messrs. Allbon, T. W. Burr, F.R.A.S., Witham M. Bywater, and Charles F. White, were elected to fill four vacancies on the Committee.—The proceedings then terminated in a *conversazione*.

Syro-Egyptian Society, July 19.—Messrs. Bonomi and Simpson attended to exhibit and explain a large collection of water-colour and pencil drawings, mostly by the late Mr. Robert Hay, and now the property of his son, Mr. R. J. A. Hay, of Munraw. The sketches represented Egyptian views and antiquities, the most interesting of which were as follows:—A series of coloured views of *Philol* and *Koum Ombos*, taken about 1833, the more valuable as the latter temple having fallen down is now almost completely buried in the Nile alluvium. A series of very elaborately finished drawings of the palace temple of *Medinet Habou*, by the late C. Laver. The original measured plans, sections and details of the Pyramids of Gizeh, by C. Catherwood (to whom and Bonomi we owe the first accurate map of the *Haram es Shereef*). These were accompanied by notes and details of the now famous Sarcophagus in the king's chamber. A large panoramic view of *Thebes* and a folio of sketches near Karnak, in pencil, by F. Arundale. A view of the singular Purple Lake near Thebes, so called from an unexplained phenomenon, viz., that its waters at a certain period annually assume a purple tint. And, lastly, a collection of miscellaneous hieroglyphic inscriptions and mural paintings from the Tombs at Gourna. Many of these, apart from their artistic merit, are deserving notice as being excellent illustrations of the marvellous accuracy obtainable by the use of an almost forgotten instrument, the camera lucida, by means of which, ere the days of photography, the splendid works of Canaletti, Britton, Roberts, and Hay were produced. At the same meeting were also exhibited, by Mr. T. Christy of Fenchurch-street, seven volumes of beautiful photographs from the East, taken in 1869 by M. Felix Bonfils. They represented the present condition of most of the buildings comprised in the Hay drawings, and exemplified in many cases the wanton vandalism of the celebrated Mahomet Ali, who caused many of the then almost perfect temples to be destroyed for the sake of their materials, with which distilleries, cotton factories, and warehouses were erected about the years 1836 and 1840, in fact until the havoc was arrested by a vigorous "Appeal to the Antiquaries of Europe" (1841), by the late G. R. Gleddon, U.S. Consul at Cairo, to whose energy and the united action of the savans of France and England, the present conservation of the monuments of Ancient Egypt are due.

Zoological Society, June 23.—Prof. Flower, F.R.S., V.P., in the chair. An extract was read from a letter received from Dr. J. Anderson, of Calcutta, containing additional remarks on the dolphin of the Irrawaddi.—Two letters were read from Mr. W. H. Hudson, Corresponding Member, containing remarks on birds observed by him in the vicinity of Buenos Ayres.—Mr. Howard Saunders exhibited and made remarks upon some nestlings of the Booted Eagle (*Aquila pennata*) from Southern Spain.—Dr. J. Murie read a memoir on the anatomy of the walrus (*Trichechus rosmarus*), principally founded upon the example of this animal that had lived for some time in the Society's Gardens in November 1867.—Dr. J. Murie also read notes on a species of *Tænia* from the rhinoceros, which he regarded as probably undescribed; and on a case of variation in the horns of the Panolian Deer (*Cervus eldi*). A third communication from Dr. J. Murie contained remarks on *Phoca groenlandica*, its modes of progression and its anatomy.—Mr. R. Swinhoe communicated a catalogue of the mammals of South China and Formosa, with notes upon the various species that he had observed during his numerous travels in those countries. A second communication from Mr. R. Swinhoe contained a list of birds collected by Mr. C. Collingwood during a cruise in the seas of China and Japan, with notes by the collector. The collection was stated to embrace examples of 33 species, amongst which were several of rare occurrence.—A communication was read from Dr. O. Finsch, C.M.Z.S., containing an account of a collection of birds recently obtained in the Island of Trinidad. The collection included 115 species, amongst which were several new to the avi-fauna of the island.—Messrs. H. E. Dresser and R. B. Sharpe read a paper on the Great Grey Shrike (*Lanius excubitor*) and its allies. The differential characters of the various species were pointed out, and special attention was drawn to the Indian Grey Shrikes (*Lanius lahtora*) which was considered to be identical with the Algerian *Lanius pallens* or *dealbatus*.—A communication was read from Mr. J. Brazier, C.M.Z.S., containing notes on the habits of the Grakle of the Solomon Islands, recently described by Mr. Sclater as *Gracula kreffti*.—Mr. J. Brazier also communicated descriptions of ten new species of land shells, collected by Mr. W. F. Petterd in various parts of the Australian region.—Messrs. Sclater and Salvin read an account of several species of birds recently received by M. Boucard of Paris, in collections from Mexico, which were new to the avi-fauna of that country.—Dr. J. E. Gray communicated a paper on some tortoises in the British Museum, with description of some new species.

Ethnological Society, June 27.—Extra meeting, Prof. Busk, F.R.S., in the chair. Sir John Lubbock, Bart., described the opening of the Park Cwm Tumulus, in the peninsula of Gower, South Wales, and exhibited a plan of the structure.—The Rev. Canon Greenwell read a paper on his explorations in Grime's Graves, Norfolk. These so-called graves consist of a large number of pits and galleries in the chalk, excavated in prehistoric times for the working of flint. The explorations led to the discovery of many neolithic flint implements, picks made of the antlers of the red deer, and curiously-sculptured fragments of chalk. Colonel Lane Fox, Mr. Flower, Mr. Fisher, Sir J. Lubbock, and Mr. Dawkins took part in the discussion.—Mr. J. W. Flower exhibited a large collection of specimens from the neighbourhood of Mr. Greenwell's discoveries, including objects of widely different dates, such as palæolithic and neolithic flint implements, a large British urn, and a fine Roman glass bottle. Mr. Boyd Dawkins then gave a verbal abstract of his paper on the discovery of the remains of platycnemic, or flat-shinned people in Denbighshire. Explorations were made in a refuse-heap in a tumulus, and in two bone-caverns, and the human remains thus obtained were exhibited. These proved that platycnemism was manifest in the ancient dwellers in North Wales, as well as in those who buried their dead in the cave of Cro-Magnon in France, and in those whose remains are found in the caves of Gibraltar.—Prof. Busk exhibited and described the peculiarly-formed tibiæ, and distinguished two forms of platycnemism, but attached no value to this peculiarity as a race-character.—Several other papers were taken as read, this being the last meeting of the session.

Paris

Academy of Sciences, July 25.—M. J. Darboux read a reply to some observations by M. Catalan on his note on the centres of curvature of an algebraic surface. M. Bertrand communicated a report on a memoir by M. Massieu on the characteristic functions of various liquids and on the theory of vapours.—A note was read on the mechanical equivalent of heat and on the electro-chemical properties of aluminium, by M. J. Violle.—Father Secchi communicated some further remarks on the spectra furnished by various types of stars.—M. Bertrand presented a note by M. Laussedat on the restoration of a conical sun-dial, from a fragment brought from Phœnicia by M. Renan.—Remarks on the variations of the magnetic needle, by M. Broun, were read; the author cited the decennial differences observed at Munich from 1841 to 1861, and drew from them the conclusion that the western declination increased up to 1855, remained variable in 1856, and then diminished to about 1860, since when there appears to have been a slight increase.—A note by M. H. Gal on the brominated derivatives of anhydrous acetic acid was communicated by M. Cahours. The compound described by the author was bibrominated anhydrous acetic acid, which was obtained by pouring bromide of monobrominated acetyle upon pulverised fused acetate of soda, and distilling the mixture. Its formula is $C^8H^4Br^2O^6$.—A note was read by M. Guyot on the volumetric determination of the soluble fluorides. The author employs a solution of perchloride of iron.—A note by M. Dobroslavine on the fatty matters of the chyle was presented by M. Wurtz; and M. H. Sainte-Claire Deville communicated a note from Professor Cossa, of Udine, giving an account of some experiments made with an amalgam of aluminium, and stating that aluminium acts upon iodide of æthyle in sealed tubes at ordinary temperatures, and that he has prepared aluminium-æthyle by the action of aluminium upon stannæthyle.—M. Faye presented remarks upon some peculiarities of the soil of the Landes of Gascony, in which he noticed especially the characters of the "alios" or impermeable stratum which exists at a depth of one metre from the surface of the soil, and which, in his opinion, was the main cause of the former insalubrity of the Landes. He considered that it was formed by the infiltration of water holding decomposing organic matter in solution during the winter season, and the evaporation of the water in the summer.—M. H. Sainte-Claire Deville presented a note on a schistose rock impregnated with carbonaceous matter, sent by MM. Ravizza and Colomba.—A note was read by M. Dieulafait on the *Terebratula-diphya* limestones of the French Alps, from Grenoble to the Mediterranean. From stratigraphical considerations, the author confirms the results arrived at by M. Hébert upon palæontological evidence.—An extract from a letter by M. Pissis to M. Elie de Beaumont on mountain-systems and on the formation of the desert of Atacama was read.—M. Daubrée presented a note by M. F. Garrigou on the chemical examination of a metamorphosed cement from the Bayen spring at Luchon. A ball of cement which had remained for eighteen years in the hot water (147° F.) of the spring was found to have gained a considerable quantity of silica, some organic matter, and a little fluorine. It contained some "microzymas."—M. de Quatrefages presented a note by MM. F. Garrigou and de Chasteigner on the contemporaneity of man with the cave-bear and the reindeer in the cave of Gargas (Hautes Pyrénées). The remains discovered consisted of a hearth, with flint implements, split bones, &c.—A note by M. Perez on the generation of the Gasteropoda was communicated by M. Milne-Edwards, consisting chiefly of remarks upon the phenomena of copulation in snails.—An extract from a letter of M. de Vallier stated that whilst the general results of the silkworm cultivation in the department of the Basses-Alpes have been deplorably bad, M. Rayband-Lange, following M. Pasteur's rules, has sold cocoons to the value of 64,000 francs.

BERLIN

German Chemical Society, June 27.—F. Sonnenschein has found the oxide of cerium $Ce_3 O_4$ to give characteristic colours with alkaloids. The oxide, when added to strychnine and sulphuric acid, produces a violet colour more stable than that obtained with bichromate of potassium. The oxygen thus developed is in the form of ozone.—C. Graebe and C. Liebermann have discovered that anthrahydrochinone ($C_{14} H_8 O. OH_2$) is formed when the chinone of anthracene is fused with potash. By treating bromide of anthracene, $C_{14} H_8 Br_2$, with sulphuric acid, bisulpho-anthrachinonic acid is formed, which yields alizarin when fused with potash. They have also prepared alizarin-sulphuric acid and tried in vain to transform it by fusing potash into purpurine.—O. Hesse has investigated opium-wax, consisting chiefly of cerotate of ceryl, and of palmitate of ceryl.—W. v. Schneider, by oxidising diamylene, has obtained an acid, $C_7 H_{14} O_2$, and an indifferent oil, $C_{10} H_{20} O$.—E. v. Priwoznik describes tetracetyl bromo-gallic acid and bromacetyl-gallic acid.—P. Wexlsky communicates an easy way of obtaining bichlorinated chinone by treating trichlorinated phenole with nitrous acid: $C_6 Cl_3 H_3 O + O = C_6 Cl_2 H_2 (O_2)'' + HCl$.—A. Ladenburg describes some chlorinated derivatives of stanno-triethyl.—R. Radziscewsky has obtained nitro- and dinitro-derivatives of phenylacetic acid.—Hugo Schiff has observed that phenylcarbamic ether—

$$CO\begin{matrix} O\ C_2\ H_5 \\ N\ H\ C_6\ H_5 \end{matrix}$$

yields, by heating, cyanurate of phenyl, diphenylated urea and triphenylated biuret.—A. W. Hofmann has obtained, in an easy way, cyanate of phenyl by treating phenyl-carbamic ether with phosphoric anhydride. The cyanate is slowly transformed into cyanurate. The transformation takes place suddenly when triethylphosphine is brought into contact with the cyanate. As phenyl-carbamic ether when distilled by itself also yields a certain proportion of cyanate of phenyl, the reaction just now mentioned by Schiff obtains a simple explanation. The cyanates of tolyl, of xylyl, and of naphthyl have been prepared in an analogous manner.—Prof. Hofmann then drew the attention of the society to some new lecture experiments, apologising that an experiment formerly described by him as new was not so. The demonstration of the development of heat through crystallisation, by pouring ether upon a supersaturated solution of acetate of sodium, belongs to Faraday. He then poured fuming nitric acid into hydriodic acid gas in a test-tube, which inflamed the hydrogen. $H_2 S$ and H_2Se show a similar combustion. A second experiment consisted in heating a watch-glass containing a minute quantity of aniline green. According to experiments instituted by Dove the red copper lustre shown by this substance in reflected light is exactly complementary to the green colour shown in transmitted light. When heated a violet is obtained exactly complementary to the yellow metallic lustre which it shows in reflected light. A third experiment showed the colouring power of aniline red. In one hundred million parts of water added to one part of the colouring matter, the colour may be distinguished, supposing the layer of the liquid to have half a metre's thickness. A white silk thread left in this bath for twenty-four hours exhibits a very decided colour. A fourth experiment was arranged to show the formation of nitrous vapour and nitric acid, by burning hydrogen in air. A balloon of 10 litres capacity was provided with three openings, two of which, opposite each other, were provided with platinum tubes soldered to glass-tubes, and serving to introduce the two gases. The red vapours and the acid property of the water can easily be observed. The fifth experiment, an easy way of condensing cyanogen gas, depends upon a simple apparatus, for the description of which we must refer to the society's reports. Lastly, a pretty experiment to show alternate reduction and oxidation was exhibited. A copper crucible was placed on a triangle, so that it could be heated inside with a strong gas burner. A funnel was placed over it, the tube of which was connected with a hydrogen apparatus. By alternately removing and again approaching the funnel the copper became oxidised and reduced.—N. Limpricht described derivations of meconic acid.—R. Rieth has taken the vapour density of metallic chlorides, arriving at the formulæ of Hg Cl and $Hg Cl_2$, $Sn Cl_2$, and $Sn Cl_4$, dissociation being out of the question, because tin is scarcely volatile.

THURSDAY, AUGUST 11, 1870

SCIENCE SCHOOLS AND MUSEUMS IN AMERICA

AT the present time when we are, as it were, taking stock of our Scientific Institutions, an account of the various schools and colleges in the United States, in which Science is made a chief, if not *the* chief subject, may be welcome to our readers. A paper in the *Canadian Naturalist*, by Prof. Dawson—the result of the Professor's travels through the States, in order to determine by personal visits the practical working of the American Science Schools, and to use the experience so obtained, in the founding of a Canadian School of Science at Montreal—has been largely used.

It was for similar reasons that Prof. Agassiz visited the various museums of the Old World, in order to determine what errors he should avoid, and what precedents he should follow, in founding the magnificent Museum at Cambridge, U.S.

Referring to the various institutions in the various States, we will follow the footsteps of Prof. Dawson, adding whatever has been changed or improved since his visit.

In New York, Science has for some time past been at a very low ebb. Unlike London or Manchester, that busy mercantile community has no time to spend on such apparently trifling matters as the propagation of scientific knowledge, and the acquisition of materials for scientific investigation. The only School of Science in New York is Columbia College; an old-fashioned brick building, in a quaint, old-fashioned square, formerly outside the town, now, by the rapid increase of building, quite enclosed and surrounded. The College-buildings form three sides of a quadrangle, and are long, narrow rooms lighted by windows in the sides. Three rooms are used as laboratories for practical analysis, qualitative and quantitative. Another room is the furnace-room, for assaying purposes; another is used for purposes of drawing, and there are numerous class-rooms and lecture-rooms, but all sadly out of proportion to the size of the town. Two rooms are set apart, one for the mineralogical, the other for the geological and palæontological collections. Among the latter the private cabinet of Prof. Newberry, especially rich in remains from the Carboniferous strata, is the most prominent feature.

The staff of professors, lecturers, and assistants, numbers eighteen in all; and the lectures, practical and theoretical, are purely scientific, embracing mineralogy, metallurgy, chemistry, botany, mechanics, physics, geology and palæontology, assaying, and drawing.

The full course for students is three years, at the end of which they are duly qualified for practical mining work, mineral surveying, and practical chemistry. They have to pass an entrance examination in algebra, geometry, and trigonometry, and at the end of their course most of them attain the degree of "Engineer of Mines," or "Bachelor of Philosophy." The number of students in the last account was from 112 to 120. An important feature of the course is that students are expected in the vacation to visit mines and metallurgical and chemical establishments, and to report on these, and also to make illustrative collections; while, during the session, short excursions are made to the machine shops and the metallurgical and chemical establishments in or near the city.

The practical value of such a course of training cannot be too highly appreciated; it is an example which many of our science schools and colleges would do well to follow. In justice, however, to one of the chief of these in England, it should be mentioned that the engineering and chemical classes in Owens College, Manchester, are in the habit of being taken by the respective professors to the leading scientific and chemical works near Manchester.

Besides Columbia College, New York is now in a fair way soon to possess a very fine public museum. In the beginning of 1869 a bill was carried in the House of Congress to establish in New York a museum, under Government control, similar to the British Museum. This museum is called "The American Museum of Natural History," and it published its first report a little time ago. The fine collection of the Prince of Neuwied, formed chiefly in the Brazils and South America, has been purchased, and communications have been sent to all the United States consuls throughout the world to aid the museum by the collecting and purchasing of valuable natural history specimens in their several localities. We cannot leave the State of New York without noticing how the liberal founder of the Cornell University has made provision for practical and theoretical instruction in natural science. Laboratories, museums, herbariums, libraries of scientific works, have been either presented or bought; and by the scheme by which the students can work out the expenses of their education by their skilled labour, it is now possible for the very poorest artisan or mechanic in America to obtain as valuable a scientific education as any given anywhere in the world.

Proceeding from New York to New Haven, we find here a very important and very fine school of science. The Sheffield Scientific School is a modern outgrowth of the University of Yale College, and was first established in 1847 as a small undertaking, conducted by the elder Silliman, chiefly as a school for applied chemistry and scientific agriculture. In 1860 Mr. Sheffield, a wealthy citizen of New Haven, gave it a building and apparatus valued at 50,000 dollars, supplementing this by a grant of 50,000 dollars to found chairs of engineering, metallurgy, and chemistry. In 1863 it was further enlarged by grants of land from the State of Connecticut in aid of scientific education. It also participates in the benefit which Yale College derives from Mr. Peabody's Museum and his magnificent endowment of 150,000 dollars. The Sheffield School contains some fine natural history collections, one of the most valuable of which is one of Economic Geology, admirably arranged, and which shows the immense mineral wealth of America to great advantage.

The buildings of the school are finer and better arranged than those of Columbia College, and its educational scope is wider. There are six distinct courses of scientific instruction open to the students:—

1. Chemistry and mineralogy.
2. Engineering and mechanics.
3. Mining and metallurgy.
4. Agriculture.
5. Natural history and geology.
6. A select scientific and literary course.

The class-rooms and laboratories are extremely well adapted and arranged; there are small cabinets of specimens of great assistance to the professors in delivering their lectures. It also possesses a fine equatorial telescope, made by Clark, having an object-glass with an aperture of nine inches. For this there is a properly constructed tower, furnished with all the necessary instruments for astronomical observations.

The staff of professors, lecturers, &c., numbers twenty-three, and the number of students is now about 150. Amongst the distinguished men holding appointments here, the names of Dana, Silliman, and Marsh are of European renown.

In Philadelphia we find valuable scientific collections belonging to the Academy of Science, an old and still very vigorous scientific establishment, though sadly wanting more room for its collections. Amongst the treasures of these collections there are several that merit particular notice.

Professor Hawkins has just set up in the museum the skeleton of the Hadrosaurus of the New Jersey Greensand, one of the most gigantic of the immense mesozoic reptiles. Besides this extremely valuable skeleton and other remains, there are portions of the skeleton of a gigantic carnivorous reptile of the same age, with formidable cutting teeth, similar to those of the megalosaurus, and, like it, possessing hooked claws, some of which must have been ten inches long.

Belonging to the Philadelphia Academy of Sciences is a fine scientific library, but both it and the collections suffer from want of space. The museum also contains a fine and very complete collection of American skulls, which Messrs. Morton, Wilson, and Meigs have so elaborately worked out. At Philadelphia two valuable works on palæontology have been undertaken. One of these just published was reviewed in NATURE for June 16, and is an extremely valuable monograph on "The Fossil Mammals of America," by Prof. Leidy. The other work is an equally valuable one, being a monograph on the "Fossil Reptiles of America," by Prof. Cope.

Proceeding from Philadelphia to "the queenly city," Baltimore, we find there an Academy and a band of zealous naturalists, as Tyson, Morris, and Dalrymple. The Peabody Institute here was founded by Mr. Peabody, who was a resident in this city for some time, and who presented to the town the sum of 100,000 dollars for these objects, viz.: (1) to found an extensive library; (2) to provide for the delivery of lectures in science and art; to found (3) an academy of music, and (4) a gallery of art.

The building of the institute was in 1868 being rapidly proceeded with, and is probably now finished. There was then no museum, but the library had already become extremely valuable.

In Washington is located the splendid Smithsonian Institution, of world-wide fame, founded for "the increase and the diffusion of knowledge amongst men," now under the direction of Prof. Henry, the able president of the American Academy of Sciences, and who is now in this country. The chief work hitherto done by the Smithsonian Institution has been in the subjects of geology and natural history, and it already possesses extremely valuable collections, carefully and systematically arranged under the able supervision of Prof. Baird. This institution sets a glorious example to other and much older museums in their treatment of those anxious and willing to make use of the accumulated treasures. Their collections are open to the inspection of any naturalist from any part of the world, who, in some cases, are accommodated with rooms for their work, as well as access to the specimens. Under Prof. Henry's personal superintendence a fine collection of American antiquities is in process of formation, and the number and importance of these objects of early warfare and art make the museum extremely valuable and instructive.

It was in Washington that President Lincoln was so basely assassinated. The building where the event took place, formerly Ford's theatre, has been converted into a museum of a character it is believed perfectly unique. This, the Army Medical Museum, contains a series of excellently mounted preparations of great professional interest, remarkable chiefly for its profuse exhibition of the effects of shot and shell, and other implements of war on the human frame. The materials for this museum were chiefly collected during the American Civil War. It may well be said that the Americans are a wonderful people; there are few other nations which would have been capable of so utilising the results of a protracted internecine war as to make them available in after years towards the advancement of medical science and the alleviation of human pain.

In addition to the purely medical collection, this museum also contains a fine and well-arranged collection of skulls of the various aboriginal American tribes, with a few Mexican and Peruvian. There is also a fine collection of skulls in the Smithsonian Institution.

Before concluding this paper it is necessary to mention two separate munificent gifts, by which the late Mr. Peabody did so much to promote the cause of science in America. The Peabody donation to Yale College has been previously alluded to. One result of this is that Yale College, which was formerly devoted to other subjects, has recently made great progress in science, and bids fair to become one of the leading scientific institutions in America. It still lacks, however, funds towards founding more scientific professorships. Besides this donation, Mr. Peabody in 1867 left 140,000 dollars "for the promotion among the inhabitants of my native county (Essex County, Massachusetts) of the study and knowledge of the natural and physical sciences and their application to the useful arts."

From this gift started the Peabody Academy of Sciences in Salem, Massachusetts, which was inaugurated August 18, 1869. The objects of the foundation are still kept in view by the formation of a museum, which, besides a general collection, shall embrace a complete collection of local specimens from the whole county, and shall keep up and augment the museum of East Indian antiquities collected by the East Indian marine societies, and by the formation of a series of lectures on science, to be yearly delivered.

And, lastly, the nature of the valuable museum which Professor Agassiz is collecting at Harvard College, Cambridge, aided by Government grants and private subscriptions, will have been sufficiently learnt from the article on the Harvard Museum, which appeared in NATURE for June 23.

THE VERTEBRATE SKELETON

SKELETAL archetypes, and "theories of the skull," have of late years gone much out of fashion. The view which made each man a potential Briareus as to limbs, seems itself to be considered as no longer having a leg to stand upon. The fortress of the "Petrosal" has long been carried by assault, and is peaceably and securely occupied; and although we have had lately a brilliant passage of arms apropos of the "auditory ossicles" from which the unlucky Sauropsida retired with broken "hammers" and diminished "anvils;" yet the once widespread interest in skeletal controversies seems to have long subsided. The old war-cries are no longer heard, the question "Is the post-frontal a parapophysis?" falls on indifferent or averted ears, and we fear that even not a few of our anatomists call into daily functional activity a mandible, to the true nature and homologies of which they are comparatively indifferent.

What was the surprise of some, then, who last year witnessed, in the theatre of the Royal College of Surgeons, an unlooked-for resurrection. Some rubbed their eyes—could they have had a long sleep, and was it still the year 1849 instead of 1869? A quasi-vertebrate theory of the skull once more! Again an exposition of cranial hœmal arches!

"Jam redit et Virgo, redeunt Saturnia regna."

But yet in justice it must be said that it was by no means the reproduction of an old or familiar system. The views propounded were in some respects as novel as striking; while in spite of this a careful re-statement of assertions made in the first year of the last Hunterian professorship showed how subordinate after all were the changes made, and how trifling the modifications required as to the statements of that first year. Nor in fact was any new archetypical idea of the whole vertebrate skeleton distinctly proposed for acceptance, though the serial relationship of certain inferior arches was clearly demonstrated, and a striking suggestion made concerning the most anterior of them.

But *some* ideal conception of the vertebrate skeleton as a whole is a necessity for anyone who proposes to extend his osteological labours over several classes, and provided such a conception be a simple "generalised expression of observed facts," no one has a right to complain of its introduction. What best conception then of this kind can be now supplied from the accumulated labours of successive osteologists?

As the points of exit from the skull of the cranial nerves supply the best fixed points for determining special cranial homologies, so probably the arrangement of the nervous system as a whole will supply the handiest key to the explanation of skeletal difficulties.

In the Hunterian Lectures of 1869, the nervous system was treated in a new way, and one by which the sympathetic system lost its isolation, and was called in to take its morphologically important part in the general system of spinal nerves. The embryonic condition being referred to (with ascending dorsal plates and descending ventral-plates—the latter bifurcating to enclose the pleuroperitoneal space between their outer and inner laminæ), each spinal nerve of the trunk was represented as sending one branch upwards into the dorsal plate, another downwards into the outer lamina of the ventral plate (abdominal and intercostal nerves), and another, also downwards, but into the inner lamina of the ventral plate, the collection of these latter internal nerves with their serial homologues forming the sympathetic system. In addition to these, a branch was represented as running directly outward towards the skin, above the external descending branch. Now, such being the condition of the nervous system, what might we *a priori* expect to find in the skeleton? Surely we might expect to find—1st, Parts related to the dorsal laminæ (epaxial); 2nd, Parts related to the external ventral laminæ (paraxial), and 3rd, Parts related to the internal ventral laminæ (hypaxial). To the first category would belong the neural arches, &c.; to the second, the transverse processes, ribs, and steruum; to the third would belong those skeletal structures, if such there are, within the pleuro-peritoneal cavity or medianly situated beneath the vertebral column.

But as to the nerves passing directly outwards above the external descending ones, are there any skeletal structures to answer to them?

Now, fishes present us sometimes with a double series of ribs, whereof the upper strike out towards the skin, while the lower tend to enclose the abdominal cavity. In tailed Batrachians we have two superimposed transverse processes to which a bifurcating Y-shaped rib articulates, and this rib sometimes bifurcates distally also. In mammals we have a rib essentially similar as to its proximal end, but one branch of the Y is diminished into a tubercle which, however, meets a transverse process. Can it be, then, that our own ribs are morphologically double, and that their upper proximal parts together with the fascia ascending from them to bound externally the *erector spinæ*, are homologous with the upper series of the ribs of fishes?

But what are the hypaxial structures, and first, what parts of the skeleton are within the pleuro-peritoneal cavity or are serially homologous with parts so situated? Here an important modification seems necessary in the views given out by Professor Huxley in 1869. He demonstrated unanswerably that the branchial arches are, as Professor Goodsir considered them, thoroughly homologous with the hyoidean and mandibular arches, and not only this, but he also suggested—what was as novel as important—that the *trabeculæ cranii* may be the foremost members of the same group of parts. He considered, however, that all these parts were *costal* in their nature. Now, accepting this view as far as regards the serial homology of the branchial arches with parts more anterior, it is nevertheless here submitted that the branchial arches should be considered parts *within* the pleuroperitoneal cavity, and this because the heart lies *outside* them, and the great vessels (which even in man have reflected on them a continuation of the pericardium) extend along their *outer* sides. It is contended, then, that these arches are hypaxial parts, and, if this is so, then the hyoidean, mandibular, palato-quadrate, and trabecular structures, as they are serially homologous with the branchial arches, must be hypaxial also. If so, the nerves which accompany them (the vagus, &c.) must be serially homologous with the sympathetic nerves of the trunk, and, indeed, this view was put forward by Professor Huxley in the lectures referred to. Are there, then, no true representatives of costal arches in this part of the frame? I think that the external branchial cartilages of sharks and the branchial basket of the Lamprey will be found to be such, and therefore to belong to a quite different category from that to which the branchial arches of osseous fishes pertain.

Again those azygos processes which descend from beneath the vertebral column in the region of the trunk, must be in the line of origin and suspension of the internal lamellæ of the ventral plates of the embryo, and being related to them may be deemed to be hypaxial parts also. Their serial homologues often bifurcate, and are repeated serially in the caudal region by processes or distinct ossicles (chevron bones) protecting the caudal vessels, and which I deem to be hypaxial also. Professor Goodsir has demonstrated that in the crocodile such parts, at the root of the tail, lie within the backward prolongation of the abdominal cavity, and the chevron bones or processes beyond that cavity in the same individual, are clearly the serial homologues of those within it.

According to this view then, the vertebrate axial skeleton in its most generalised expression consists of an antero-posteriorly extended axis, bearing above it (1) a cylinder of *epaxial parts*, for the protection of the cerebro-spinal centres. This cylinder expands anteriorly, and has intercalated three sets of sense capsules, olfactory, optic, and auditory. Everything, whatsoever it be, outside the anterior end of this cylinder (the cranial capsule) is morphologically *outside* the skull, and therefore in such an essentially *external* position is the sella turcica, the anterior communicating artery, &c.

2. From the axis of the skeleton diverge on each side more or less bifid *paraxial parts*, tending to protect or surround the visceral cavity, or homologous with parts which do so tend.

3. From the same axis descend *hypaxial parts*, which parts attain their maximum of size and importance towards the two ends of the skeleton. At the anterior end they by their varied degree of development and coalescence, build up the frame-work of the face, the jaws, and the hyoidean structures.

To this axial skeleton is added, in completely developed forms, two limb-girdles, each consisting of one upwardly and two inwardly and downwardly directed parts on each side. Two limbs, bilaterally symmetrical, are attached to each girdle, and a serial symmetry, bone answering for bone, exists between the anterior and posterior limbs of each side.

Can the skeleton structure of these limbs be expressed in yet simpler terms? Professor Gegenbaur has attempted very ingeniously so to express it, considering the limb bones as differentiations of primitive similar offshoots from a chain of marginal fin bones or cartilages. But much as one would naturally wish to accept so tempting a theory, two obstacles at present oppose themselves. One is the presence of a radial ossicle answering to the pisiforme of the ulnar side. The other is the occasional presence, in fossil forms, of at least one whole chain of such ossicles. So that at present we can hardly in this respect venture upon a more generalised view of the skeleton than the one here adopted.

This conception of the vertebrate skeleton takes little account of the mode of origin of skeletal parts—whether exogenous or autogenous, or of their segmented or unsegmented condition. But such considertaions have been neglected deliberately from a conviction of the completely subordinate importance of such conditions. The views here stated suggested themselves during the study of the skeleton as it exists in tailed batrachians; they have elsewhere been given at length, and their defence attempted, but it has been thought that a brief statement of them here might not be altogether unacceptable to some who are engaged in osteological inquiries.

ST. GEORGE MIVART

HOOKER'S BRITISH FLORA

The Student's Flora of the British Islands. By J. D. Hooker, C.B., M.D., F.R.S., Director of the Royal Gardens, Kew. (London: Macmillan and Co., 1870.)

NOTWITHSTANDING the number of British Floras already in existence, field-botanists have long lamented the want of a text-book combining all the requisites for out-of-door work, unquestionable accuracy, clearly-expressed definitions, a good arrangement, and a portable form. Although the hand-books we have hitherto used have possessed one or other of these features in an eminent degree, no one has yet succeeded in uniting them. For accomplishing this difficult task the best thanks of every British botanist are due to Dr. Hooker. The publication in quick succession of several works with a similar scope, may be taken as an indication of a reviving interest in British botany. Thirty years since, when the Linnean system of classification was still in use, a sufficient acquaintance with plants to enable anyone to give the Latin names of the species of their own districts was a fashionable acquirement, especially with ladies. The knowledge, however, was extremely superficial; it consisted mainly in counting the number of stamens and of pistils, so as to determine the class and order, and of observing the trivial specific characters of the foliage, colour and size of the flowers, &c., and was unaccompanied with the least real acquaintance with structural or physiological botany. An artificial classification like that of Linnæus, must always conduce to this result, and the ease with which plants can be named by such a method, is in itself an evil rather than an advantage. When we advance from an empirical to a natural system, in which the diagnoses of the orders depend on a variety of characters, some of them connected with minute details of structure, the gain, both to the learner and teacher, is immense. The learner is compelled to begin at the root of the matter, and to acquaint himself with the structure and physiological function of every separate organ, and with the different forms it may assume, before he attempts to name a plant; and the teacher can no longer cram his class with that showy surface knowledge which is the bane of popular science teaching. The general adoption of the Natural system of classification was followed by a great falling-off in the ranks of amateurs. The number of real students of botany is now however, we hope, increasing day by day, and the substantial interest and instruction derived from the science are in proportion enormously augmented.

The difficulties of the Natural system must be familiar to all teachers; probably every lecturer has more than once been perplexed by finding that the specimens which have been provided for illustration belong to a species differing in some point of structure from the characters which he has given as belonging to the order under consideration. Teachers will also differ as to the relative importance of certain points of structure, and consequently as to the position of some Natural orders. The uncertainty which still hangs over our classification will be illustrated by the following list of points in which the book before us differs from the fourth edition of Professor Babington's "Manual of British Botany," published as recently as 1856: *Droseraceæ* has been moved from Thalamifloræ to Calycifloræ, the genus *Parnassia* being incorporated with *Saxifrageæ; Acerineæ* undergoes the same change of position; *Balsamineæ* and *Oxalideæ* are abrogated as separate orders, their genera being united to *Geraniaceæ; Portulaceæ, Tamariscineæ*, and *Paronychieæ*, on the other hand, are transferred from Calycifloræ to Thalamifloræ, the tribe *Sperguleæ*, however, of the latter order being relegated to *Caryophylleæ; Grossulariaceæ* is no longer found as a separate order, but is united to *Saxifrageæ; Ilicineæ* or *Aquifoliaceæ* changes its quarters from Corollifloræ to Thalamifloræ; *Loranthaceæ* from Monopetalæ to Apetalæ; *Empetraceæ* from Apetalæ to Thalamifloræ; while the apetalous order of *Callitrichaceæ* disappears, its species being found under Calycifloræ united to *Halorageæ;* the hop, on the other hand, is eliminated from *Urticaceæ*, and appears as a separate order, *Cannabineæ;* and Babington's miscellaneous collection of *Amentiferæ* is divided into the four distinct orders, *Salicineæ, Cupuliferæ, Betulaceæ*, and *Myricaceæ; Trilliaceæ, Colchicaceæ*, and *Asparageæ* are combined with *Liliaceæ.* Although these alterations concern chiefly comparatively small and unimportant orders, there is sufficient change to perplex the student, independently of minor re-arrangements of genera, &c. On the whole it will be seen that the tendency is towards the English practice of "lumping," as contrasted with the Continental practice of "splitting," the number of orders of Flowering Plants being reduced from ninety-seven to ninety-two. We are glad, however, to find that this tendency is not carried to the extent we meet with it in Hooker and Bentham's "Genera Plantarum," where *Papaveraceæ* and *Fumariaceæ* are united; we doubt, indeed, whether the interests of students would not have been better served by keeping apart orders with such clear distinctions of outward structure, as far as British species are concerned, as *Saxifrageæ* and *Grossulariaceæ; Geraniaceæ, Oxalideæ*, and *Balsamineæ; Liliaceæ* and *Colchicaceæ.* The re-arrangements of position are no doubt, in nearly all cases, based on correct botanical principles. The difficulty, however, often experienced in drawing up satisfactory diagnoses of the natural orders may be illustrated by comparing those given by such authorities as Hooker and Oliver. In Hooker's "Student's British Flora," for instance, we find the pistil of *Nymphæaceæ* described as "syncarpous;" in Oliver's "Lessons on Elementary Botany," as "apocarpous." Hooker speaks of the stamens of *Oleineæ* as "epipetalous," Oliver as "hypogynous." In the synopsis of natural orders given at p. xiv. of the book under review, mention of the hypogynous stamens in some genera of *Oleineæ* is omitted.

In his analysis of certain difficult and intricate genera, Dr. Hooker has followed the lead of botanists who have made them their special study, as in the case of *Rubus, Rosa*, and *Hieracium*, where Mr. J. G. Baker's descriptions are adopted. This, no doubt, was a wise course in these instances; we regret, however, to find in the whole work so little of the author's own observations; we are sure that in many cases he could have improved greatly on the method of the "London Catalogue," which has been too implicitly followed. This is especially the case with regard to the plants admitted as "colonists" or "denizens." Why should a place be given, for instance, to *Galinsoga parviflora*, found nowhere, we believe, except within a radius of a few miles from Kew Gardens, from which it has escaped? while, on the ballast hills of the north-east coast and some other localities, many plants have apparently become permanently established, of which no mention is made, or their name is merely given in the Appendix. The time of flowering of plants is also one on which little exact observation appears to have been made; one would judge from our hand-books that the only wild flowers to be gathered in December and January are the groundsel and the daisy; while at least a dozen others could be named that are equally, if not more, perennial. We shall look with eagerness for a work embodying a record of recent physiological and morphological observations on British plants, which Dr. Hooker states, in his preface, it was his original intention to have incorporated with the present volume, and which will possess so great a value from his pen.

The specific descriptions in Dr. Hooker's "Student's Flora" are so admirable, terse, and yet sufficient, the arrangement so excellent, and the size so convenient, that it must rapidly become the work in general use, the companion of every botanist during his summer rambles.

ALFRED W. BENNETT

WATER ANALYSIS

Water Analysis: a Practical Treatise on the Examination of Potable Water. By J. Alfred Wanklyn, M.R.C.S., and E. T. Chapman. Second Edition, edited by E. T. Chapman, Member of the Council of the Chemical Society. Pp. 108. (London, 1870.)

IN the preface to this edition we are told that the whole of the last edition has been transferred almost without alteration, but with slightly different arrangement; and that some new matter has been added, consisting of the tetration of waters; a modification of the process for estimating nitrates; a chapter on volatile organic matter; a method of estimating minute traces of lead; and a chapter on the purification of waters. The tetration of waters is the estimation by standard solutions of the amount of acid present in waters contaminated by the refuse of certain factories or in rain water which has fallen near alkali works. We had thought that the word *tetration*, in the preface, was a misprint for *titration* until we found it so spelt in the text; the latter word (or modification), however, appears on p. 38. The modification of the process for the estimation of nitrates consists in treating the water to which caustic soda has been added with a large excess of aluminium scraps, and pouring off the liquid before distillation, instead of permitting all the aluminium to be dissolved, as in Mr. Chapman's original modification of Schulze's process. In the chapter on volatile organic matter, it is pointed out that on distillation of a water with potassic hydrate, there passes over, together with the ammonia, some combined nitrogen, probably in the form of organic bases, and a process is described for its estimation. The method of estimating minute traces of lead by comparison of the coloration produced by sulphuretted hydrogen water in dilute standard solutions of lead with that obtained by the same reagent in the water under examination is not new, for we remember having seen the experiment illustrated in Dr. Hofmann's lectures at least fifteen years ago. The previous removal of oxidising agents by sulphurous acid is, nevertheless, a useful addition. In the chapter on the purification of water, an ingenious experiment is described to show that separation of suspended matter by filtration through sand and similar substances is really due to subsidence within the interstices of the filter.

As in the first edition, we find no mode of estimating sulphides or the gases dissolved; nor does the treatise contain any indication of the success of the application of the ammonia process in the examination of sea water; it may be answered that the title of the book only refers to potable waters, but then we are at a loss to explain the appearance of some experiments on sewage.

It is much to be regretted that the present editor has thought fit to reprint the preface to the first edition, and also the appendix, which consists of nothing but an attack on Frankland and Armstrong's process. These entail on us the necessity of noticing this treatise at much greater length than the positive information contained in it would justify; for if the statements set forth were passed over without remark, it might seem as if the untrustworthiness of the process were acknowledged by all chemists, and doubt thrown on the accuracy and value of the reports issued by the Registrar General. The authors state in the preface to the first edition that it requires great length of time and great skill to execute it. This may be true, but the vast advantages which it possesses over the old processes amply compensate for the additional trouble. The manipulation, though delicate, is not, we are given to understand, beyond the powers of an average first year's student, at least when he is not influenced by a preconceived distrust in the efficiency of the process, or by a desire to do things with as little trouble as possible. It was not quite fair for the authors to state, two months after the publication of the process, that chemists in general agreed with them as to its invalidity. They should have remembered that "chemists in general" are not such rapid workers as Messrs. Wanklyn and Chapman, and would wish for more time to give a definite decision on the capabilities of a process so entirely new. The appendix consists of a note read by the authors before the Chemical Society. They commence by stating that they do not consider the complete conversion of organic nitrogen into ammonia by their method as being essential to its applicability for determining the relative quality of a water, and that they rely simply on the constancy of the ratio between the amount of albumenoid substance in the water and the quantity of ammonia produced. This is a retractation, though not a very straightforward one; for in their first published account of the process it was stated that all the nitrogen was evolved as ammonia. But it would be well to ascertain if this ratio is really constant, for although this may be the case with white of egg, is it not almost too much to assume that the nitrogenous organic matter present in natural water acts in the same manner as albumen, when we are quite ignorant of its proximate constituents? If the quantity of ammonia always bears a certain relation to the organic matter, and if this ratio is known, the determination of the nitrogenous impurity is merely a matter of calculation; but is it not a fact that some bodies, when treated according to the author's process, evolve more ammonia, in proportion to the amount of nitrogen they contain, than do others? The experiments on strychnine, narcotine, and quinine sulphate, published by Frankland and Armstrong (but not commented on by our authors), show this to be the case. But in their published papers, Messrs. Wanklyn and Chapman admit that the quantities of "albumenoid ammonia" from the following compounds are far from uniformly proportional to the amount they contain, thus:—

Urea and Picric acid gave no albumenoid ammonia

Creatine	gave	$\frac{1}{3}$	of its nitrogen as albumenoid ammonia
Caffeine	,,	$\frac{1}{4}$	,, ,,
Uric Acid	,, about	$\frac{1}{6}$	,, ,,
Albumen	,,	$\frac{2}{3}$	,, ,,
Morphine & 11 other organic substances		$\frac{1}{2}$	,, ,,
Hippuric acid and 7 other organic substances		all	,, ,,

Next follows a list of Frankland and Armstrong's results, in which the differences of the quantities of carbon and nitrogen obtained by experiment and calculations are pointed out. But it should be remembered that in these experiments the substances were weighed instead of being measured in standard solution, and that these solids were first dissolved and the solutions evaporated in order to perform the combustion of the residue. It is afterwards deduced from this same list that the error is inherent in the process, as the results are not better when the amount of organic matter is reduced; but with this reduction the liabilities of error in weighing increase. If this discrepancy were really caused by the imperfection of the process, we should expect to find great variation in the quantities of nitrogen obtained in actual analyses of waters, but in the list of forty nitrogen determinations given in Frankland and Armstrong's paper, the numbers vary from 0·000 to 0·068 per 100,000, or, as our authors would express it, from 0 to 0·68 milligrammes per litre, whereas they accuse the process as being liable to produce an error of no less than 1·29 milligrammes per litre. The following extraordinarily opportune accident has happened during the month of May, and from the results we shall be able to obtain an indication of the concordance of the numbers arrived at by Dr. Frankland's process. In the Registrar General's report it will be seen that the water supplied by the Grand Junction Company was drawn at the cabstand in Woodstock-street, whilst a sample of water was taken at 14, Lancaster Gate, under the impression that it came from the works of the West Middlesex Company. Now, to our certain knowledge, 14, Lancaster Gate is supplied by the Grand Junction Company; thus Dr. Frankland has been analysing two samples of the same water, supposing them to have come from different sources. This mistake could not have been found out till after the report was printed, and the results obtained by the two experiments are as follow :—

	Total solid impurity.	Organic carbon.	Organic nitrogen.	Ammonia.	Nitrogen as nitrates and nitrites.	Total combined nitrogen.	Previous sewage contamination.	Chlorine.	Total hardness.
Grand Junction, collected at the cab stand in Woodstock Street, May 17.	24·7	·135	·020	·000	·184	·204	1520	1·62	19·36
Water collected at 14, Lancaster Gate, supposed to be from the West Middlesex Company; but actually from the Grand Junction, May 15.	24·6	·129	·023	·000	·188	·211	1560	1·60	19·36

It may be objected that even these numbers do not approximate so closely as those of Messrs. Wanklyn and Chapman, but they represent actual quantities obtained from water, and not a theoretical "albumenoid ammonia," which may not be an indication of the quantity of organic impurities.

Since Frankland and Armstrong's paper was published an immense number of analyses have been made with the process, and in his annual report to the Registrar General, Dr. Frankland states that he has seen no reason to be dissatisfied with the results. Probably no one, unconnected with Dr. Frankland's laboratory, knows better than Mr. Chapman that improvements in the details of the manipulations have been made during the last two years; and it is, therefore, with very questionable taste that he has reprinted the appendix to the first edition of the book without a single word of qualification.

It is much to be deplored that two young chemists, with such undoubted abilities as Messrs. Wanklyn and Chapman possess, should have rendered themselves notorious by attacking older workers in scientific investigation. It is, no doubt, very laudable in a young and ardent investigator, when he points out that high authorities may err and frequently have erred, but the manner in which these gentlemen have carried out their corrections has made their matter more distasteful. It would almost seem as if they found an incentive to work in the hope of being able to overthrow the "huge superstructures" which have been raised by men who have been longer in the field of scientific research.

OUR BOOK-SHELF

A Sketch of a Philosophy. Part III. *The Chemistry of Natural Substances.* Illustrated by two folding plates and 150 figurate diagrams of molecules in the text. By John G. Macvicar, LL.D., D.D. (Williams and Norgate, 1870.)

IT is a hard matter to give a just account of this pamphlet. The views propounded by the author are so entirely different from those usually held by chemists, and according to the author's own statement they have been so little studied by others, that it is difficult to know exactly how to treat the subject. We should scarcely be justified in saying that the whole system is mere imagination, though some hold this opinion; but the book, though evidently written with the intensest earnestness, is the work of an enthusiast, which will explain the bitter complaints he makes against modern chemists for not taking more notice of molecular morphology. The author endeavours to explain the formation of all matter by the aggregation of the ethereal element, supposing that all bodies tend to assume a symmetrical, and more or less spherical form. The simplest form of aggregation Dr. Macvicar considers to be the *tetrad*, consisting of four specks of the material element so arranged in space that they form the angles of a tetrahedron, the lines joining them indicating the attracting and repelling forces operating between the units. Two tetrads are also assumed to join base to base producing the *bitetrad*, and from these two forms the tetrad and the bitetrad, all the atoms and molecules of our planet are supposed to be produced. This tetrad by attracting another unit opposite to one of its faces constitutes a group of five units, considered to be the atoms of hydrogen, and with the atomic weight of five. The author proceeds to show the mode of genesis of many other elements and compounds by the juxtaposition of these elemental forms. By calculation he can determine by his system the specific gravities of solids and liquids referred to water as unity, in a manner similar to that by which the densities of gases and vapours may be deduced by the old system. This alone would seem to show that the method deserves more attention from chemists than it has yet received. The non-reception of this molecular morphology may be ascribed to several causes: the diction of the author is peculiar, and he writes in a dogmatic manner, which might be expected in a theological work, but is not usually found in a treatise on natural science; then he pushes his inferences to such an extent (or as some would say, rides his hobby so hard) that his conclusions appear somewhat ludicrous, unsupported as they are by experiment: thus he traces the coincidence between the assumed hexagonal form of the molecule of aqueous vapour and the shape of the minimum snow-flake and ice-flower, and "the inflorescence of plants of the monocotyledonous order, in which an aqueous tissue predominates"; he thinks that one of the forms of aqueous vapour which occupies half the volume of the other, may possibly be converted into the second variety at a high temperature, and thus explain the explosion of steam boilers. Again the dimorphism of water may be the cause of the production of animal heat; for water in the body may be transformed from one of its varieties into the other with evolution of heat; but on escaping from the body as perspiration, the inverse action takes place and cold is produced. But underneath all these extravagances there may be a stratum of truth, and we hope that either the author or some one who understands and accepts his views thoroughly, will so develop them as to ensure their reception by chemists.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Source of Solar Energy

I HAVE not Mr. Proctor's "Other Worlds" by me to refer to, but my impression on reading that book some little time ago, certainly was, that if it did not directly support the *meteoric* theory of solar energy, it at least favoured the idea of innumerable meteors falling into the sun. The principal portion of my letter in last week's NATURE, was not, however, so much addressed against any special views of Mr. Proctor's relative to this *meteoric* theory, as it was against the probability of meteors falling on to or into the sun at all. And whatever be the real value of the arguments I used, I certainly had not before seen them anywhere clearly stated. The question as to meteors being consumed in producing heat by friction in the solar atmosphere, or of their striking the sun's proper surface in a solid form, is of very secondary importance, and would of course be determined chiefly by the size and nature of the meteoric bodies themselves.* The potential or heat result theoretically would be the same either way; though in the former case it might hardly so well explain how whilst heated flames are shot up 60,000 or 70,000 miles from the sun itself, that body is also probably far hotter than the upper regions of this very atmosphere, in which the meteors themselves would be giving out heat.

Prestwich, Manchester, Aug. 5 R. P. GREG

Kant's Transcendental Distinction between Affection and Function

AT page 80 of my "Revival of Philosophy at Cambridge," I ventured to describe a question set by Mr. Mahaffy, at Trinity College, Dublin, as "very oddly worded." I might have said *very improperly worded*, and have justified the sentence; but for the fact that it was the Cambridge examination-papers only that were the subject of my criticism in that work. My boldness in this censure on Mr. Mahaffy has occasioned remark. That gentleman is confessedly a capital metaphysician, perhaps of greater power than the learned professor whose work he translated and annotated. I therefore ask for space in NATURE to assign the reasons on which I asserted that his question was "very oddly worded." Here is the question: "Explain the statement that his [Kant's] doctrine of Space and Time is based on a *transcendental distinction*." I think I cannot be in error in taking this as a reference to the *Kritik der reinen Vernunft*, Transac. Æsth. § 8, *Allgemeine Anmerkungen*, &c., and in particular to the paragraph beginning "Die Leibnitz-Wolfische Philosophie," &c., and that which immediately follows. In the former, and indeed in its immediate precursor, Kant is impugning the view that affection and function (Sense and Intellect) have only a logical difference, as if Sense were only differenced from Understanding by the inferiority of its representations, in precision and clearness. The latter paragraph (the third of those I have referred to) beginning "Wir unterschieden sonst wohl unter Erscheinungen das," &c., may be thus rendered:—

"We otherwise draw a proper distinction, in phenomena, between that which is an essential property of the intuition of it, and is generally valid for every one's sense, on the one hand; and on the other, that which belongs to it accidentally, inasmuch as it is not valid for the faculty of general sensibility, but only for a particular state or organisation of this or that sense."

This, Kant names an *empirical distinction*. To it he opposes what he calls a *transcendental distinction*, viz., that between phenomena and things in themselves, or what is involved therein, that between affection and function. As Kant points out, if we do not make the distinction between affection and function, we cannot explain the transcendental constituents of a phenomenon, and thereby we take it for a thing in itself, *i.e.*, a reality existing independently of our perception of it; and we so lose the distinction between the phenomenon and the thing in itself, of which latter we know nothing whatever.

Now, Mr. Mahaffy's question concerns a certain statement. Whose? Well, probably, it is his own, viz., that which occurs in a footnote to p. 57 of his translation of Fischer's Commentary on Kant's C. p. R. Mr. Mahaffy here says, "We must not confuse the *empirical* distinction between real object and merely subjective appearance with the *transcendental* distinction upon which his (Kant's) doctrine of space and time is based." This I believe to be the topic referred to in the question. It is manifestly open to two objections. Each of the terms "real object," and "merely subjective appearance" is equivocal. "Real object" may be the phenomenal object or the noumenal object. "Merely subjective appearance" may be what Kant calls "blosz Erscheinung" or the impression which the object makes on the particular sense of this or that subject. The actual terms used by Mr. Mahaffy more properly import the distinction between the thing in itself and its phenomenon; yet it is plain he means to follow Kant, and to speak of the distinction between phenomenal object, and particular subjective impression. It is the other matter of the extract with which the question deals; and it is this which I have no hesitation in pronouncing a very improper and misleading statement.

Kant's doctrine of Space and Time is *not* based on this distinction. On the contrary, the distinction is an outcome of that doctrine, and does not, cannot, emerge till that doctrine is established. The fruit of the doctrine cannot be its root; nor can that which is the basis of the distinction be itself based on that distinction. The truth is, that Kant's doctrine of Space and Time is one that concerns Sense only; it is Æsthetic; and as discovering the *a priori* sense-elements of experience, it is called Transcendental Æsthetic. Accordingly it touches but one pole of the distinction, and only so far helps it out! How can such a doctrine be properly said to be based on a distinction between the two poles? The very notion is preposterous, and derives, of course, no countenance whatever from the *Critic of pure Reason*.

The extremely curt and concise manner in which I have dealt with the actual subjects of examination in my book was essential to its brevity and corresponding lowness of price. The above remarks will show how insecure will be any inference of the poverty of my reasons from the paucity of my words.

Ilford, E., Aug. 1 C. M. INGLEBY

Spontaneous Generation

IF there is one thing more curious than another in the "Spontaneous Generation" theory, it is the way in which so-called matters of fact, as proved by careful experiment, are brought forward by the one side to be disproved by the other; one need only instance Pasteur's famous flask experiments, which were thought to be so overwhelming at the time, but which were afterwards refuted, I think by Frémy and others.

I notice with surprise the letters of Prof. Wanklyn and Dr. Lionel Beale in NATURE, with regard to the presence of germs in the air; there is an experiment of Pasteur's, given in his "Memoirs upon the organised Corpuscles which exist in the Atmosphere, 1862," and which I have never seen disproved, and if not disproved it must surely settle at least this part of the question. He passed a quantity of air, taking various precautions to eliminate error, which I need not here detail, by means of an aspirator through a plug of gun-cotton; he then dissolved the gun-cotton in ether, and on examining the sediment which subsided in the course of an hour or two, he found abundant evidence of the presence of organised corpuscles.

Bath CHARLES EKIN

Mirage

I HAVE just returned to England from H.M.S. *Porcupine*, having accompanied the dredging expedition as far as Lisbon. In reading the back numbers of NATURE, I notice in that for July 28 an account of an extraordinary mirage in the Firth of Forth on July 22. A reference to my journal shows me that on the same day we were dredging on the Portuguese coast, within sight of the Ferilhoe and Berlinga Islands, about forty miles north of Lisbon. The bearings of these islands and their exact distance, calculated by the aid of the known height of the lighthouse, gave us, of course, an exact position, which our "dead reckoning" also confirmed. Several solar observations, both for latitude and longitude, were taken by two of the officers during the day, both of whom always arrived at the same result, but this was so widely different from our position as previously determined by two other methods, that we were forced to the conclusion that there was a very false horizon. It was the only instance of the kind during the month I was at sea.

Clifton, Aug. 8 WM. LANT CARPENTER

The Sun's Corona

IF "my mathematical result was based upon data among which the principal point at issue was accepted as proved," it will be easy for you to state what that point is,* and to quote one passage at least in which Mr. Lockyer has associated it with his theory. In this way alone can you justify the assertion in your last editorial note.

So much you are bound in common justice to do. But further, it would be satisfactory if a distinct statement of Mr. Lockyer's

* Suppose the case of a large mass of meteoric iron falling through the solar atmosphere, the first result would of course be a development of heat and light; but if the original or cosmical velocity of the meteoric body was lost through the resistance of the atmosphere (as in similar cases terrestrially happens) *before* the entire mass was consumed, there might possibly result an actual loss of solar energy, caused by the subsequent and necessary melting of the residuum.

* A possible action at the moon's limb suggested by Faye, Gould and others.—ED.

opinion respecting the corona could be made public. At present all that is generally known is, that he regards the corona as "an effect due to the passage of sunlight through our own atmosphere near the moon's place." Those are the words he used (see NATURE, vol. i., p. 14). I imagined that I had understood them. It seems I had not. Will he explain them, and perhaps indicate how the sunlight gets there? I only need to learn how one ray of sunlight can reach the atmosphere near the moon's place, during central totality in any considerable eclipse, and why the atmosphere actually *at* the moon's place (that is, all that cone of air which lies between the eye and the moon) is left free of this sunlight. This being satisfactorily explained, I should waive all other objections and accept the atmospheric glare theory without further question. RICHARD A. PROCTOR

[Mr. Proctor should have quoted the context, in which Mr. Lockyer carefully refers to Dr. Frankland's and his own conclusion (or theory) "against any such extensive atmosphere as the corona had been imagined to indicate." He then states that the "conviction" that the corona is probably an atmospheric effect, "is growing stronger and stronger," if the negative evidence of the new method of observation were alone taken into account; but this is not to elaborate a theory.—ED.]

The Horse-Chestnut

REFERRING to NATURE, No. 37, your correspondent, Eugene A. Connell, has fallen into a mare's nest in the matter of the horse-chestnut.

Country people are well aware of the impression of the horse's foot he has discovered, but the coincidence is quite accidental, and has nothing to do with the name.

"Horse" is a very common prefix, denoting largeness or coarseness, in the same way that the prefix "dog" indicates inferiority and contempt. Thus we have horse-chestnut, horse-bean, horse-radish, horse-mint, horse-parsley, horse-leech, dog-rose, dog-violet, dog-berry (the berry of *Solanum nigrum*), &c.

These prefixes are common to nearly all languages; we have ἱππό-κρημνος, a horse-laugh, "fièvre de cheval," a violent fever, and a host of like terms.

Bath, July 27 CHARLES EKIN

The "English Cyclopædia"

IF the Editor of the "English Cyclopædia," in his letter contained in your issue of July 7, had restricted himself to defending his own handiwork, and had abstained from denying the correctness of my statements, I should not have ventured to ask for space in your columns to reply to him.

In opposition to my statement that I looked in vain for "*Arvicolæ, Crociduræ, Crossopi, Hypudæi, Sorices*, shrews, and voles," the Editor asserts that "all the species mentioned in the Close Time Report are described or noticed in the Cyclopædia." This may be and probably is quite true. I merely asserted that they were not to be found under their respective names. I have stated that I found *Hypudæus* and the voles under the heading *Muridæ*. In return for my information he now tells me that if I wished to become acquainted with *Crocidura* and *Crossopus* I ought to have turned to the article *Sorecidæ*. But how is an unlearned reader like myself to know where to turn? The Editor only confirms the accuracy of my statement as to the great want of cross references. If the Index and the Supplement had contained such references as *Hypudæus* [Muridæ, E.C.], *Crossopus* [Sorecidæ, E.C.], &c., I should probably never have given public utterance to my troubles. In reply to my assertion that I looked in vain for an article on *Rhizocrinus*, I am told, much to my astonishment, that the proper place to find it is under *London Clay*. In my ignorance I had sought for it under its own name, *Apiocrinites*, and *Encrinites*. According to this mysterious system of arrangement, if I had complained that there was no article on *Sparrows*, I should probably have been told that I ought to have looked for a notice of them under the heading *London*.

In my letter I gave a list of twenty-three important subjects on which there were no articles. In defence of these real or apparent omissions the Editor, after making the strange assertion that two of these, *Acclimatisation* and *Deep Sea Dredging*, belong rather to the "Arts and Sciences" than to the "Natural History" division, goes on to say that most of the subjects stated by me to have been omitted "do occur." He must be well aware that I never asserted that they "do not occur." I simply said that there were no special articles on them. He might have had the candour to notice that I unearthed from their hidden recesses the subjects to which he expressly refers in his letter, viz., *Eophyton*, *Eozoon*, *Hyalonema*, and *Protoplasm*.

As I must not trespass further on your space, I will conclude by observing that I fully concur with the Editor in the opinion that "what a Cyclopædia ought or ought not to contain is an open question;" but when an Editor has the moral courage to assert, in illustration of the mode in which he discharged his functions, that "*Meloe* was inserted and *Sphegidæ* rejected, because there was not room for both," and gives no less than twelve columns to the former instead of dividing the space between the two; and when he tells us that *London Clay* is the proper place to seek for information regarding *Rhizocrinus*, the readers of NATURE may draw their own inferences as to what a Cyclopædia, under his superintendence, is likely to be.

I must add that I have not the slightest idea who the Editor of the Supplement is, and that until his letter appeared, I did not believe in his existence.

South Devon, July 8 NEMO

Entomological Inquiries, etc.

I WAS much interested, two nights ago, at finding on the wall of my drawing-room a flattish, dark-grey winged insect, six or seven tenths of an inch in length, which, on being placed in the hand, exhibited two small but brilliant sparks of light towards the extremity of the tail. In the imperfect light in which it was examined, the wings seemed to have elytra and the body to be somewhat like a small caterpillar, with a tapering tail. In size and general aspect it resembled the Italian fire-fly, with which I made acquaintance last summer on the Lake of Como, without, however, a sufficient examination to justify more than the most superficial comparison. My knowledge of entomology is so defective, that I feel unable to form an opinion whether it might be that insect or the male of the common glow-worm (which, however, is not common in my neighbourhood). If so meagre a description may enable any of your readers to give me satisfactory information as to this point, I shall feel much obliged to them.

There is adequate evidence that some kind of fire-fly has been seen during hot seasons in England. Kirby and Spence give a reference, which I have no opportunity of verifying, to Phil. Trans. 1684, as to their appearance in Hertfordshire, and their having been considered the genuine *Lampyris italica*. The following unpublished account may be interesting as having come to me from a perfectly reliable source: "In 1822—the year is pretty certain—during the month of June or July, the weather being very hot, on at least two evenings a number of fire-flies were seen at a village near the Thames, between Reading and Henley; they were flying about the fields and the lawn before a gentleman's house, and some of them came into the house; three or four or more might be seen at a time, like little flying lamps. The insect was brown [reference is then made to a sketch from memory thirty-two years afterwards, from which it must have greatly resembled my specimen], and seems to have had opaque elytra and network wings; the light was in the tail, like that of a glowworm, as bright, but probably not as large. A very intelligent gentleman who was upon the spot, an acquaintance of Dr. Wollaston's, who had been in America and the West Indies, was greatly astonished; he caught some of them, and considered them identical with the West Indian firefly. He said he had heard of their being in England, but never seen them."

A lady, whose experience must be referred to a later date than the foregoing account, has informed me that she once observed them for a single day in Wiltshire.

The newspapers of 1868 or 1869—I am not certain which—spoke of them as abundant in some places; particularly, I think, at Caversham in Kent, where they were even considered "nuisances!" if I recollect right. Some of the readers of NATURE may perhaps be able to furnish information as to this alleged fact.

There is something very remarkable in the occasional appearance of these beautiful insects in our climate. They can hardly be thought to reach us by direct migration. Can it be supposed —as it has been ingeniously suggested to me—that their ova are frequently being imported from warmer countries, but are only fully developed in the temperature of our hottest summers?

While speaking of entomological matters, allow me to mention that in the month of August last year the small blue lobelias in my garden were the favourite resort not only of my hive-bees, but of a species of wild bee so singularly resembling them in every respect (excepting, perhaps, a barely perceptible amount of greater firmness and roundness of form), that they could only be distinguished by the presence of a tuft of lemon-yellow hairs in the front of the head between the eyes. I thought at first that this might have resulted from a lodgment of pollen, but it soon became evident that it was a specific distinction. These pretty insects were very numerous, but I never found any nest. Will some apiarian reader oblige me with an identification?

To turn to a somewhat different subject. In a little book called "Flowers of the Year," published by the Religious Tract Society, is the following passage: "An interesting phenomenon is sometimes exhibited by red and orange-coloured flowers, and also, in a less degree, by yellow-tinted blossoms. It is that of a light of their own colour playing about the plant. This is not the result of an inflammable vapour igniting on the approach of a candle, but seems rather, as Sharon Turner has remarked, 'an actual secretion of light additional to their usual show.' The cause of this phenomenon has not been discovered, but it seems dependent on an electrical state of the atmosphere. It has not been seen during the bright sunshine, but has been observed after sunset in several flowers, as the marigold, the different species of poppy, the scarlet geranium, and even in the heartsease." I have several times met with a similar statement, and much wish to know what trustworthy foundation there may be for it. I have repeatedly tried to verify it by observation, but in vain.

Since penning the above remarks, the yellow-visored bee has again appeared on the blossoms of a Linaria Alpina, the descendant of a plant brought by my wife from Switzerland seven years ago, and now blooming profusely with us. I have seen several specimens of my old friend, but cannot as yet satisfy myself that the yellow tint is due to hair of that colour, as I supposed last year.

Hardwick Vicarage, July 12 T. W. WEBB

The Solar Spots

I HAVE been much interested of late in observing the solar spots, and especially in the greatly-increased numbers which have lately made their appearance. I have counted from 100 to 200 spots, through a six-feet telescope, with a power of 100, quite frequently in the past few months. On the 22nd ult., with a power of 200, I counted 675 sun spots, and on the 27th saw 470 with the 100 eyepiece. In general, I think the number of spots visible is about in proportion to the power used when the atmosphere is favourable for high powers. During the month several spots were visible to the naked eye.

I feel quite desirous to learn what our spectroscopists find about the sun's margin, also if observations indicate a terrestrial magnetic force corresponding with the sun's activity.

Would not many readers of NATURE be much interested with results from Huggins and Lockyer and the Kew observers?

Spiceland, Indiana, July 6 W. DAWSON

DARWIN BEFORE THE FRENCH ACADEMY

THE discussion on the claims of Mr. Darwin for election into the Zoological Section of the Paris Academy was continued at the meeting on August 1 in *comité secret*, and the *Revue des Cours Scientifiques* gives a report, of which the following is an abstract, of M. de Quatrefages' brilliant and able reply to M. Blanchard:—There are two men included in Mr. Darwin, a naturalist observer and a theoretical thinker: the naturalist is exact, sagacious, and patient; the thinker is original and penetrating, often just, sometimes too rash. That the theory with which his name is connected, that of Natural Selection, has in it at least something seductive and plausible, is shown by its having been worked out by such men as Darwin, Wallace, and Naudin, labouring independently and in different paths. If the ideas and the works of Darwin are such as some of his opponents represent, how can they have obtained the support in less than ten years of such men as Lyell, Hooker, Huxley, Karl Vogt, Lubbock, Haeckel, Filippi, and Brandt himself, who has just been elected correspondent in opposition to Mr. Darwin? In Darwin's great work there are certainly some things which are found in Lamarck, the laws of heredity, and the transmission and progressive development of characters. The point of departure of Lamarck is an incessant spontaneous generation, that of Darwin is a unique archetype which he supposes to pre-exist, and the origin of which he does not seek. That which belongs to Darwin alone is the laws of variation which he has established, and the law of correlation of growth. His error has been the confusion between the laws which regulate the foundation and propagation of races and of species; substitute the former for the latter and his theory is incontrovertible. Without defending Mr. Darwin's theories, some of which he has indeed publicly combated, M. de Quatrefages then proceeded to enumerate the various branches of scientific inquiry in which Mr. Darwin has made original observations, and concerning which he has contributed works of great importance to science. In geology we find seven great memoirs—1. On coral islands; 2. Geological observations on volcanic islands; 3. Geological observations in South America; 4. On the connection of the volcanic phenomena in South America; 5. On the distribution of erratic blocks in South America; 6. On the geology of the Falkland Islands; 7. Origin of the saliferous deposits of Patagonia. In botany the speaker invoked the testimony of Dr. Hooker that the most beautiful discoveries made during the last ten years in vegetable physiology belong to Mr. Darwin. Finally, in zoological literature we have the report of the voyage of the *Beagle*; and the monograph of the Cirrhipedes, one of the most important monographs ever published. After speaking of his more popular works on the origin of species and the variation of animals and plants under domestication, M. de Quatrefages referred to his important and laborious investigations of the strange variations in fowls, pigeons, and rabbits; and summed up his eloquent address as follows:—"En résumé, M. Darwin est un naturaliste éminent qui veut écarter de la science l'invocation de la cause première, et chercher l'explication des faits naturels du monde organisé dans les causes secondes, comme on le fait depuis longtemps en géologie, en chimie, en physique. Mais il ne va pas au delà, et il ne faudrait pas juger Darwin sur la parole de quelques disciples qui semblent parfois ne pas avoir lu ses ouvrages. Il y aurait injustice à le rendre responsable des exagérations et des aberrations de ceux qui s'abritent sous son nom."

M. de Quatrefages was followed by M. Ad. Brongniart, who attacked the Darwinian system, denying the existence of variation in plants. The appearance of species is a fact which can only be explained by a supernatural cause, and Darwinism is nothing but a fairy tale. M. Ch. Robin considered that in respect of proved facts which he had introduced into science, there would be a hundred zoologists who should have precedence over Darwin. M. H. Milne-Edwards replied to M. Brongniart, that the sea sometimes discloses fairy tales, and spoke of the very great value of the monograph of the Cirrhipedes. Although himself opposed to Darwinism, he strongly supported his nomination. M. de Quatrefages, in reply, denied the charge against Darwin made by M. Blanchard, that he had declared that man was descended from the apes. In deciding Mr. Darwin's claims, we ought not to be influenced by those points in which we have to combat his views, any more than Lamarck was judged in this manner. In spite of his errors, he will be none the less one of the glories of science and of the Academy. His nomination will not make the Academy Darwinian. Men of science know that the Institute appreciates work independently of doctrine, and men of the world know that the supporters of Darwin in the zoological section, MM. Milne-Edwards, and de Quatrefages, have always professed themselves opposed to his ideas. The discussion was then adjourned to last Monday evening.

TRANSMISSION OF POLARISED LIGHT THROUGH UNIAXAL CRYSTALS

THE appearances presented by the transmission of polarised light through crystals, have long been known as the most magnificent in Optics. It is our intention in this paper to give an account of the more recent observations which have been made respecting the phenomena exhibited by uniaxal crystals, accompanied by such an explanation as will, we hope, render them intelligible to persons very slightly acquainted with science. We shall therefore avoid as much as we can the use of technical terms, and assume as little as possible to be previously known to the reader.

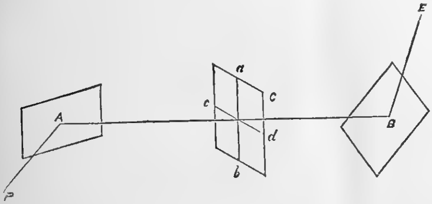

FIG. 1.

Common light consists of undulations of the supposed ætherial medium, in which the vibrations of each particle are perpendicular to the direction of the wave's motion, and in every conceivable direction which this condition admits.

Suppose now a ray of sunlight reflected from a plate of unsilvered glass. The principle of the composition and resolution of forces plainly enables us to regard it as made up of two sets of vibrations, one in the plane of reflection, and the other perpendicular to it. Now for reasons which cannot be explained to a reader unacquainted with mathematics,* it is found that the vibrations of the reflected ray in the plane of reflection, when the angle of

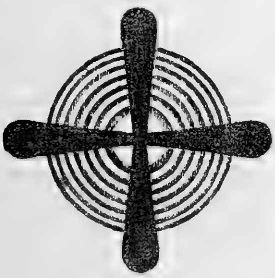

FIG. 2.

reflection is equal to 56° 30′, wholly disappear, so that the reflected ray consists entirely of vibrations perpendicular to the plane of reflection, and is said to be polarised. The reader will carefully remember the distinction between common light and polarised light. Common light is light in which the vibrations occur in every conceivable plane passing through the ray; polarised light is light in which the vibrations occur in only one plane of fixed inclination passing through the ray.

Now let a ray of sunlight fall upon a plate of unsilvered glass at an angle of about 56°, let the reflected ray be received by another glass plate at the same angle, and be thence reflected to the eye. Suppose the position of the mirror to be such that the planes of first and second incidence and reflection are perpendicular to each other. Then remembering what we have just stated, we see that the vibrations of the ray reflected from the first mirror lie altogether in the plane of second incidence. These vibrations, therefore, will all be destroyed by the second reflection, therefore nothing but a dark spot will be perceptible to the eye.

* The mathematical reader is referred to Green's "Memoir on the Reflection of Light," Cambridge Philosophical Transactions, vol. vii.

If now the position of the second mirror be shifted, so that the planes of first and second incidence coincide with each other, while the angle of second incidence remains unaltered, the vibrations of the incident ray will all lie perpendicular to the plane of second incidence, and therefore a bright spot will be visible to the eye.

FIG. 3.

Let now the second mirror be gradually turned round an axis situated in the direction of the ray incident upon it from the first position into the second, then the angle of second incidence will remain unaltered during the revolution, while the plane of second incidence will revolve with the mirror, and, as might be expected, light will begin to be visible to the eye and continually increase, till it attains its maximum in the second position of the mirror. It is usual to call the first mirror the polariser, the second the analyser.

Let a plate cut from a transparent crystal be interposed between the polariser and analyser thus arranged, luminous

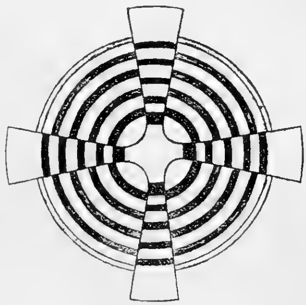

FIG. 4.

curves of varying colours intersected by dark bands will be visible to the eye. Before describing these gorgeous appearances, we must say a few words on the modification light undergoes in passing through a crystal.

When a ray of light passes through a crystal, it is in general divided into two, so that if a plate of crystal be interposed between the eye and a luminous point, the point will appear doubled. But in all crystals there is one, and in some two fixed directions in which no bifurcation of the ray takes place. If we look along one of these lines, called the optic axes, we shall see only one image of the object of vision. Crystals with one axis are called uniaxal crystals; those with two axes are called biaxal crystals, and in this paper I shall confine myself to the former.

We observe that a plane drawn through the direction of the ray or pencil and the axis of the crystal is called a principal plane. It is found that one of the two rays into which the incident ray is divided is refracted according to the ordinary law, and is therefore called the ordinary ray, the other according to a more complicated law, and is called the extraordinary ray. But we especially remark that the vibrations constituting the ordinary ray lie wholly perpendicular to the principal plane of the crystal, those of the extraordinary ray parallel to the principal plane. Consequently both rays will consist of polarised light, according to the definition we have just given of polarisation, and this polarised light will arise from the vibrations of the incident ray being resolved perpendicular and parallel to the principal plane.

Of all uniaxal crystals the best known is Iceland spar, which possesses the power of double refraction in an eminent degree. It occurs in the form of a rhombohedron, and the axis of the crystal corresponds with the shortest diagonal.

Now suppose a plate of this crystal, cut perpendicular to its axis, is interposed between the polarising and analysing plates, when the first and second planes of incidence are perpendicular to each other.

The colour of light depends on the length of the wave. The length of a wave of violet light is ·0000167, and that of a wave of red light ·0000266 of an inch. The wave-lengths of the other colours lie between these. White light is a compound of all colours, and therefore its vibrations are of all lengths lying between these extremes. It will therefore manifestly simplify the explanation we are going to submit to the reader, if we commence by assuming the light to be monochromatic, and its vibrations of the same length. Let a small pencil of monochromatic light, P (Fig. 1), be reflected from a plate of glass, A, at an angle of about 56°, pass through the crystal C, and then be reflected a second time from the plate B at an angle of about 56° in the direction B E. The plane P A B is supposed to be perpendicular to the plane of the paper, the plane A B E to coincide with it. The crystal is supposed to be bounded by parallel surfaces perpendicular to its axis, and in a position perpendicular to the line A B. Let *a b*, *c d*, be two straight lines drawn in the crystal, one in the plane of the paper and the other perpendicular to it. The eye is supposed to be placed at E.

The vibrations of light proceeding from A will all be parallel to the plane of the paper. In general, each ray as it enters the crystal will be resolved into two, and thus will arise two sets of waves which will interfere with each other. Hence a succession of dark and bright curves will be visible to an eye placed at E. Moreover, as the crystal is symmetrical round A B, it may be expected that these curves will be circular. It may also be expected that the diameters of the bright circles will depend on the length of the wave, and therefore on the colour of the light.

We have already defined the principal plane of the crystal for a given ray, to be the plane passing through the ray and through the axis of the crystal, which in this case coincides with A B. As therefore the vibrations of the rays incident on the crystal are all parallel to the plane of the paper, those which enter the crystal along *c d* are all perpendicular to a principal plane of the crystal, and those which enter it along *a b* are all parallel to a principal plane. Therefore every ray which enters the crystal along *a b* and *c d*, will be transmitted to the second plate unresolved, and unchanged, and will therefore be incapable of being reflected to an eye situate at E. Consequently a dark cross will appear to the eye at E, corresponding to the lines *a b*, *c d*, intersecting the system of rings we have just described. Now suppose white light to be substituted for monochromatic light. White light is composed of light of all colours, and we have seen that the diameters of the bright rings are different for each colour. Consequently, instead of dark and bright rings, we shall have a series of coloured rings intersected by a dark cross. This phenomenon is shown in Fig. 2.

If the second plate be turned round an axis in the direction A B, till the first and second planes of reflection coincide, the reader who has followed this investigation will perceive that the dark cross intersecting the rings will be changed into a white cross. This bright cross is shown in Fig. 3.

If the second plate is turned round the same axis into any position intermediate to those we have just described, the rings will be intersected by two crosses, inclined to each other at an angle equal to that between the planes of first and second reflection. There will be coloured arcs between the crosses, but those distances which give a maximum light for the arcs outside the crosses will give a minimum light for the arcs inside the crosses. This phenomenon is shown in Fig. 4. These are the appearances observed when the surfaces of the crystal plate are perpendicular to the axis of the crystal, and to the axis of the incident pencil. Dr. Ohm has investigated the phenomena which occur when the axis of the crystal is inclined at any angle to its surface, and the crystal itself is placed in any position between the polarising and analysing plates. His mathematical investigations will be found in the seventh volume of the "Munich Transactions," and the following are the principal results which he has obtained.

We shall suppose the light monochromatic. There will be a succession of dark and bright curves which are either parabolas, ellipses, or hyperbolas. For a given position of the crystal, the ellipses and hyperbolas are concentric; but the centres are never in the centre of vision, unless the axis of the crystal is either perpendicular or parallel to its surfaces. When the bright curves are parabolas, their vertices are equidistant from one another. When the bright curves are ellipses or hyperbolas, the difference of the squares of the semiaxes of two consecutive curves is a constant quantity. We have seen that when the axis of the crystal is perpendicular to its faces, the bright curves are circles. As we cut the plates so that the axis may be inclined at angles more and more acute to the surfaces, the bright circles become ellipses, which elongate continually till they become parabolas.

Suppose two plates of crystal, with parallel surfaces of equal thickness, and with their axes inclined at the same angle to the parallel surfaces, be placed in contact, so that their axes may lie in the same plane, but not in the same straight line, and then introduced between the polarising and analysing plates, a succession of dark and bright ellipses and hyperbolas, with their centres in the centre of vision, will be seen. It was this experiment which led Dr. Ohm to the results we have endeavoured to lay before the reader.

W. H. L. RUSSELL

NOTES

TWELVE months ago the Erdington Orphanage, founded, built, and endowed solely by Mr. Josiah Mason, at a cost of nearly 250,000*l.*, was opened at Birmingham. Mr. Mason, exactly following the example of Mr. Peabody, has now in contemplation another public work of even greater ultimate importance, namely, a college and schools for scientific and technical instruction, open to all classes, and if the hopes of the founder should be realised, capable of expansion into one of the noblest institutions in the kingdom. As yet the plan is only broadly formed, and some time must elapse before it can be carried into effect; but the *Birmingham Daily Post* states that a beginning has been made, and that for the purpose above mentioned, Mr. Mason has agreed to buy a large block of land in Edmund Street, exactly facing Ratcliff Place, between the Town Hall and the Institute, and reaching back to Great Charles Street. The purchase money, we believe, is more than 20,000*l.*, a magnificent earnest of the ultimate scheme which Mr. Mason has in contemplation. We make this announcement with the greatest pleasure, and ask—Why are citizens who thus consecrate their wealth to such noble and enlightened purposes so rare when their reward is so great?

THE following are the arrangements for the approaching fortieth annual meeting of the British Association for the Advancement of Science, to be held in Liverpool, commencing on Wednesday, Sept. 14. President-elect—Professor Huxley, LL.D., F.R.S. Vice-Presidents-elect—The Right Hon. the Earl of Derby; Right Hon. W. E. Gladstone, M.P., D.C.L.; Sir Philip G. Egerton, Bart., M.P., F.R.S.; Sir Joseph Whitworth, Bart., LL.D., F.R.S.; S. R. Graves, Esq., M.P.; J. P. Joule, Esq., LL.D., F.R.S.; Joseph Mayer, Esq., F.S.A. Chairman of Local Executive Committee—The Mayor of Liverpool (Joseph Hubback, Esq.) Local Treasurer—Henry Duckworth, Esq., F.G.S. The sections are—(A) Mathematics and Physics; (B) Chemical Science; (C) Geology; (D) Biology; (E) Geography and Ethnology; (F) Economic Science and Statistics; (G) Mechanical Science. These will meet each day from eleven to three o'clock, in St. George's Hall, the Town Hall, Free Public Library, and other places to be duly announced. General and Evening Meetings—Wednesday, Sept. 14: The first general meeting will be held in the Philharmonic Hall, at 8 P.M., when Professor Stokes, M.A., D.C.L., will resign the chair, and Professor Huxley, LL.D., F.R.S., will assume the Presidency and deliver an address. Thursday, Sept. 15: The Mayor's First Reception at the Town Hall. Friday, Sept. 16: Lecture in Philharmonic Hall, at 8.30 P.M., by Professor Tyndall, LL.D.; the Mayor's Second Reception at the Town Hall. Saturday, Sept. 17: Address to Working Men, in Concert Hall, Lord Nelson-street, at 8 P.M., by Sir John Lubbock, Bart., M.P., F.R.S. Monday, Sept. 19: Lecture in Philharmonic Hall, at 8.30 P.M., by Professor Rankine, LL.D., F.R.S. Tuesday, Sept. 20: Soirée in St. George's Hall, at 8 P.M. Wednesday, Sept. 21: Concert in St. George's Hall, at 8 P.M. Thursday, Sept. 22: Excursions to several places. Members requiring further information should apply to any of the following Hon. Local Secretaries—Wm. Banister, B.A.; Reg. Harrison, F.R.C.S.; H. H. Higgins, M.A.; A. Hume, D.C.L., LL.D., Municipal-buildings, Dale-street, Liverpool.

PROFESSOR WINLOCK is now engaged in photographing the sun on a plan which, so far as we know, has not before been put into practice. He uses a single lens object-glass, 4½ inches diameter, 40 feet focal length, of crown glass, made by Clark, and corrected for spherical aberration by means of an artificial star of homogeneous (sodium) light in the focus of a 5-inch collimator. The image of the sun is 4¼ inches in diameter. The tube of the telescope points to the North, and the image of the sun is thrown in by means of a reflector of plate glass. This glass is *not* roughened or blackened on one side, because when that was done the heat of the sun distorted the plane surface. The slit is at the object-glass end of the telescope, and that position has the advantage that when it is thrown across no dust is shaken down on to the plate, as is apt to happen in the usual way of working. It is Mr. Winlock's intention to photograph the sun every fair day now. It seems also probable that this mode of photographing might be of advantage for the partial phases of an eclipse.

MR. H. POWER, M.B. (Lond.), and Mr. B. J. Vernon have been appointed ophthalmic surgeons to St. Bartholomew's Hospital.

DR. LAPEYRERE insists in the *France médicale*, on the desirability of disposing of the bodies of the slain during the Franco-German war by incremation rather than sepulture. Although there is a feeling against this mode of obsequy during present times, he points out that it was practised by the most civilised nations of antiquity. The burial of the dead after a battle is always a difficult task; it is probably never done so completely as to destroy the probability of the tainted air giving rise to all kinds of infectious diseases; and when we recollect the enormous masses of men concentrated in a small space in the present conflict, and the season of the year, the matter becomes one of very serious moment.

THE fearful destructiveness of so-called "natural" causes of death, as compared with even the most sanguinary battles, is shown by the fact that during the siege of Sebastopol, the French army lost 20,240 men by death in the field or as the result of their wounds, 75,000 from epidemic and other diseases. During the Italian campaign of two months, the French losses were 3,664 killed or mortally wounded, 5,000 from disease.

THERE was a shock of earthquake on the 12th July at Smyrna. It was not very strong, but lasted a considerable time. The previous shock was on the 24th June, and was felt at different parts of Asia Minor and in Cyprus, Crete, and Egypt. Of the July shock there were only particulars at the last advices of its having been felt at Aivali and some other inland points of Asia Minor. We learn further that the earthquake of the 24th June was felt at Damascus at 6^h 15^m P.M. It was felt also in the town of Zebedani in the Anti-Lebanon, N.W.

THE Geological Survey of Italy will begin its regular definitive work next August. Commencing with Florence, it will first of all complete the study of a portion of that province. As the Ordnance map on the scale of 1 to 50,000 is not yet completed, the Geological Survey will make use of the map made by the Austrian Ordnance surveyors on the scale of 1 to 86,400, enlarged by photography to the scale of 1 to 50,000.

WHATEVER claims Sir Christopher Wren may possess to be considered the originator of the Thames Embankment, it is hardly fair to leave out of sight those which belong to Sir John Kiviet. The latter gentleman was a refugee from Rotterdam who came to England in 1666, and possessed some of the ingenuity of his brother-in-law Admiral Van Tromp. It does not appear how soon after the Fire of London it occurred to Sir John to propose a river embankment, but as early as 2nd December, 1666, we find him examining the soil of the foreshores with a view to discovering whether it was suitable for making clinker-bricks. On the 6th of March following Evelyn definitely proposed to the Lord Chancellor "Monsieur Kiviet's undertaking to warfe the whole river of Thames, or Key, from the Temple to the Tower, as far as the fire destroied, with brick, without piles, both lasting and ornamental." We may presume it was favourably received by Lord Clarendon, as upon the 22nd of the same month Evelyn had audience of the King with reference to building the Quay, and a few days later Sir John Kiviet and the Diarist "went in search for brick earth in order to a greate undertaking." No further mention is made of the scheme, and we may perhaps conclude that it was abandoned ei[illegible] on account of the unpopularity of the inventor (whose Dutch extraction would at that time have been a natural bar to success), or of the fall of Clarendon at the ignominious close of the war with Holland. At any rate, Kiviet has some right to divide the honours with Wren, though, in view of the work just completed, we cannot regret that its execution was reserved for our own times.

THE *Food Journal* for August, which contains some excellent articles, thus sums up the possible influence of War on our food supplies:—"*Free trade in live-stock* is by no means synonymous with *free trade in meat.* France will now get meat whence she cannot get live-stock. Her soldiers and sailors will eat the salt beef and pork of Cincinnati, Chicago, and St. Louis.

Prussia will probably suffer—she will certainly suffer if the war be prolonged—from her native animals being stricken by contagion; and England, that has hoped so long and so much from the resources of the East, will be left to seek for plenty in her own evergreen fields, and trust that some day her pre-eminence over the seas may render her independent of the transportation of a few hundred bullocks and sheep weekly from shores nearest her, by securing the produce—dead, not alive—of healthier, though more distant lands."

THE *Pharmaceutical Journal* (which now appears weekly) states that the plans for the erection of a Pharmaceutical Institute in connection with the University of Marburg have been approved, and the work was to have been commenced at once, but will now probably be delayed by reason of the war.

A COMMITTEE, appointed by the Royal Medical and Chirurgical Society to investigate the hypodermal method of administering injections, has just presented its report, on which the *Medical Times and Gazette* remarks:—"We may safely take, as a broad guide in practice, the rule that the physiological activity of nearly every substance which can thus be used, is three, if not four times greater when it is given by the skin than when it is swallowed." The proper commencing dose of strychnine is $\frac{1}{120}$ grain of the sulphate. The dose of atropine is also $\frac{1}{120}$ grain at first. The dose of morphia is $\frac{1}{10}$ grain to $\frac{1}{6}$ grain.

A TRANSLATION of Professor Huxley's Elementary Lessons in Physiology has just been brought out in Paris, edited by Dr. Dally, who introduces it as "*La Science sans Phrases.*"

THE following parliamentary papers have been recently issued:—Second Report of the Rivers Pollution Commission (discussing the A B C process of treating sewage); report of the Meteorological Committee of the Royal Society for the past year, an important document to which we shall return; and Volume VII. of the Irish Primary Education Commissioners' report.

SOME standard photographs and directions for measurement have been received by the Colonial Office from the Ethnological Society, through Prof. Huxley, the president. These are intended for the measurement and descriptions of aborigines in our Colonies.

THE Statistical Society has under consideration the means of promoting the study of political economy and of the numerical and statistical mode of investigation by granting prizes in our public schools. The first step will be to obtain the opinions of the head masters. The success of the Royal Geographical Society's examinations is an encouragement for this new effort.

OIL seeds having proved such a valuable branch of commerce in India, the Government is trying to promote the gum trade. The plants of the Australian gum tree, the *Eucalyptus*, introduced into the Punjaub, are taking well. It is hoped the gum will be of equal quality to the fossil *Damara Australis*, or New Zealand *Kauri pine.*

COAL containing 68 per cent. of carbon is reported to have been discovered near the town of Darjeeling, in the hill district of the Himalayas. Valuable copper and iron have also been discovered, so that important English settlement has the chance of other resources beyond tea and cinchona. The development of the minerals promises in time to give further employment for English settlers. At present in the hill regions the only metal working is in the iron mines of Kumaon. The hills can supply fuel for working charcoal iron. Our newly-annexed Bhootan territory is supposed to contain iron.

NOTWITHSTANDING the financial raid, the Lieutenant-Governor of Bengal has directed that nothing shall be done in the way of disbanding the establishment assigned for the survey of the Khasi, Naza, and Garrow hills, but, on the contrary, that the survey operations shall be taken up whenever the reduced strength of the staff will admit of it. The Government of India has confirmed this decision.

THE last scientific curiosity is a "Statement of a recently claimed discovery in Natural Science, incentive to mining enterprise," compiled by "Research," who endeavours to prove that geologists are entirely wrong in teaching that the changes in the ocean-line are due to continuous slow elevation or subsidence of the land. It appears that these changes are really due to shiftings of the mass of water in the ocean resulting from "a change of the centre of gravity of the earth's volume;" though how a knowledge that we are at any time liable to a sudden overflow of the waters of the ocean can be "an incentive to mining enterprise" is not clearly shown.

AMONG the novelties in the Exhibition at Paris in 1867 was the American Gatling gun, which, it was asserted, was to revolutionise the art of war. Like the mitrailleuse, the Gatling has as many locks as it has barrels. But whereas in the mitrailleuse the barrels are fixed and the locks have only a horizontal motion, in the Gatling both locks and barrels revolve. The locks have also, when the gun is at work, a reciprocating motion. The cartridges are kept in "feed-cases" side by side, and transferred to a "hopper," or shoot, when they are to be used. A handle is turned, and a process goes on analogous to that of the bullet-making machines, well known to visitors of the Royal Arsenal at Woolwich. When a ten-barrel Gatling is being fired, five of the cartridges are in process of loading and firing, five in process of extraction after discharging their bullets. The locks play backwards and forwards in the cavities where they work, and if one becomes disordered the action of the others is not stopped, provided that everything acts as it ought. Three sizes of Gatlings are generally made, the largest throwing a projectile of about half a pound weight. Case shot are made for the large-sized Gatling as well as solid bullets. It is, however, too heavy, and requires four horses. The chief defect of the Gatling, of all sizes, is that it cannot, like the mitrailleuse, fire volleys, but only single shots, always in the same line.

TWO experiments have recently been tried with a gunpowder invented by M. Pertuiset—the first by the Austrians against iron plates at Pola; the second recently in London. The former were made last September, in continuation of a series commenced some time before. The target was intended to represent the side of a first-class ironclad ship. There were two plates, one of 4·5 inches thick, the other 4·75 inches, English measure. The backing was 10 inches of hard wood, then an iron skin 1·5 inches thick, and behind it 12 inches of oak. The gun was of 8 inches calibre; the charge was 12 kilogrammes of common powder. The projectiles were of cast iron, made in Austria. They weighed 90 kilogrammes, and those intended to explode contained 1,500 grammes of Pertuiset powder. Two solid shot were first fired at the target, and only indented the face of it. The first of M. Pertuiset's shells not only broke the front plate and damaged the backing, but dislodged a mass of iron 22 inches by 15. The second round struck on a sound plate, and not only destroyed the iron, but so smashed the backing as to render the target unfit for further experiments. The opening in the front plates was this time far more considerable than after the first round. The experiments in London were made on horses. The skull was split, and on handling it large pieces of bone came away easily. The surface bones were removed, and the brain beneath was found to be utterly destroyed—a mass of gray and white matter devoid of consistency. When the loose material was lifted out there was a hole like the crater of a mine, 7 inches long by 6 broad. Part of the bullet had been driven up to the back of the head. And this work was done by a weapon that a man can carry in his pocket!

THE FLAGSTAFF OBSERVATORY AT MELBOURNE

ALL earnest workers in science must often have felt the extreme labour attaching to a complete reduction of an extended series of experiments. To derive some portion of truth from such a series may be a comparatively easy task, but to bring out the truth, the whole truth, and nothing but the truth, is a very difficult one. Yet how much more is this difficulty increased, when the experiments are made by Nature herself; so that while on the one hand the scale has become cosmical, we have, on the other hand, lost all control over the apparatus and the experimenter. Thus it happens that our progress in those sciences, which are strictly observational, is more slow than in those which are experimental, and truly we are yet in the infancy of Cosmical Physics.

In Dr. Neumayer, the late director of the Flagstaff Observatory, Melbourne, we have a most earnest observer of the highest type, and those who are aware of the difficulties with which he had to contend, must feel astonished at the very great and valuable work which he has successfully achieved. In the volumes of his results now before us, we have meteorological and magnetical observations of lasting value.* In meteorology we have a very complete set of elements extending throughout the years 1859 to 1863, and including, besides the usual phenomena, observations of the Zodiacal light, meteors, hailstones, atmospheric electricity, and the Aurora.

Not the least interesting of these are the observations of the Zodiacal light, and we may here note one or two remarks rather puzzling to those who assign an exclusively celestial origin to that phenomenon.

1859. Sept. 19.—The upper portion appeared to be much broader than the base.

Sept. 24.—It did not terminate in a point, but in a diffused edge of considerable breadth. The axis of the phenomenon was decidedly not in the ecliptic, but there was a particularly bright line about or in the ecliptic.

1860. March 20.—No regular column of light, but a broad patch of light towards W.; sky clear.

July 18.—A column of light much resembling the Zodiacal light was visible in S., 70° E. The column showed great change.

August 8.—The lower part of the phenomenon appeared of a rosy tint, which at times disappeared and returned.

1861. June 29.—A most extraordinary appearance of light in S.E. It descended in straight, well-defined lines. The light was white, and better defined than the Zodiacal light, and it appeared to be slightly bifurcated. Magnets perfectly quiet during the phenomenon.

The nautical observations form another important division of Dr. Neumayer's labours. These consist of the logs of various vessels which agreed to work in conjunction with the observatory, and from these logs results are derived of much practical benefit to the navigator, and of much interest to the ocean meteorologist. In them the usual method of dividing the ocean into five degree squares has been adopted.

A system of hourly observations in meteorology and terrestrial magnetism was carried on day and night, without interruption, for five years, after which a more simple system of observations was organised.

Another important task undertaken was the magnetic survey of the colony, in pursuing which Dr. Neumayer had frequently to be absent for three or four months at a time. The aggregate number of miles which he travelled over in the survey was 11,000, and the number of stations he examined, 230, situated at all elevations.

But this labour—great and Herculean as it is—represents only a portion of that which Dr. Neumayer has done, and merely denotes the work spent in obtaining raw materials. These have now to be tabulated, reduced, and discussed—a process not unlike that by which the sheaf of the reaper is made into good, wheaten bread. This reduction and discussion have been made by Dr. Neumayer in one of the volumes now before us, and, in obtaining his final results, the most approved scientific methods have been adopted. The magnetic observations are very completely discussed after the method of Sir E. Sabine, and many valuable results have been obtained. In particular, allusion may be made to a connection, traced by Dr. Neumayer, between the magnitude of the lunar-diurnal variation, and the moon's declination, forming a paper which has been published in the Transactions of the Royal Society.

These remarks would be imperfect without alluding to one point for which Dr. Neumayer deserves very great credit. While he has reduced his observations according to the most approved methods, he has, nevertheless, exhibited to his readers, as far as possible, the *actual observations* themselves, so that in future, if other methods of reduction should be followed and other objects sought, we can fall back upon actual facts, capable of being moulded anew into the form required. This is a point which ought surely to be borne in mind in all similar discussions.

THE MANUFACTURE OF TAR PAVEMENT *

IN most provincial towns there are two important bodies of men, the paving commissioners and the gas directors. The one is pledged to keep the rates low, and the other to keep the price of gas as low as will enable them to provide the statutory dividend. As one means of ensuring a cheap supply of gas is to create a greater demand and obtain a better price for the residual products, it is of advantage to consider a subject the adoption of which would be advantageous to both of these bodies. It is not a new one, but has hitherto been a neglected source of revenue to gas companies, and will also be a great benefit to the public. That subject is tar pavement. In some counties, such as Yorkshire, where stone is as abundant as brain is said to be, tar pavement will receive but little attention; but in the eastern and some other counties where the same conditions do not exist, but where York flag costs 7*s*. per yard laid, tar pavement is a desideratum. In such districts there is a scramble for pavement; and, on account of the high price, unless a paving commissioner reside in the street, it remains unpaved.

Tar pavement may be made of the ordinary cinder-dirt produced in gas-works, of shingle, or of a mixture of both. The material is burnt in heaps like ballast, and when hot is mixed with hot tar. In practice a small fire of coke is made on the ground, and covered with cinder-dirt or shingle. When this layer is hot another is added, and so on in succession until a large enough heap has been provided. The tar is now boiled in an iron copper, and taken when hot and mixed with the hot material from the heap already described, in quantities of two bushels at a time, in about the proportion of one gallon to every bushel of cinder-dirt, and slightly less than a gallon for the gravel. It is turned over and over with the shovel until every part of the material has got a covering of tar. Then the whole is passed through a sieve with $\frac{5}{8}$-in. mesh, and part of it through another with $\frac{1}{4}$-in. mesh, and put in heaps until required. Indeed, it may be kept for months before being laid down.

Before the pavement is laid, an edging should be provided about 2 in. thick, and projecting 2 in. above the surface of the ground to be covered, which should

* Paper lately read before the British Association of Gas Managers, by Mr. T. H. Methven.

be tolerably even. It is advisable to have the ground next the curb well trodden on and rammed before the pavement is laid, otherwise there will be an unseemly hollow next the curb. In laying, the rough stuff is put down first and rolled tolerably firm, then the second quality is put on, then the third, and when the whole has been raked level, a little of the finest material is sifted on through a sieve with ⅛-in. meshes, and a little fine white shingle or Derbyshire spar is sprinkled on the top. The whole must now be well rolled. The best roller is a water ballast roller, which at first is used without ballast, and well wetted to prevent adhesion of the material, and, when the pavement is slightly consolidated, the full weight should be applied.

For heavy cart traffic the material should be made of shingle only, heated and mixed as above, and well rolled. Both descriptions of pavement are laid best and most easily in warm weather, and should be rolled when the sun has warmed it well. Those parts in angles should be well rammed and trimmed off with a light shovel.

Though apparently a simple manufacture, there is a little difficulty in ascertaining the proportion of tar to gravel or cinder-dirt. A little experience will only be necessary in this, as well as in all other manufactures, to enable anyone to carry it out successfully.

This pavement cannot be spoken of too highly, as it is cheap, wears well, and can be easily repaired. The colour, which never can be made to equal York flag, and the smell for some time after it is laid, are the only objections to its use; it can be laid with a good profit in any district at 1*s*. 4*d*. per square yard; and besides being a boon to the public, who must otherwise walk on gravel, is a great advantage to gas companies. To them it provides a remunerative outlet for their tar, which often otherwise must be sold at a low price to distant distillers.

A late paragraph, which appeared in the daily press, states that it is proposed to pave the streets of London with stone laid in asphalte instead of lime grout. This is just a more systematic application of the above-described plan; for the tar, by being boiled and thrown on hot stones, becomes an elastic asphalte.

INDIAN BARRACKS

RECENT discussions regarding the new Indian Barracks have shown the necessity for an adequate knowledge of physical science on the part of all engineers who have to cope with great natural forces.

These costly structures have been described as "sun traps," meaning thereby that the materials and details have been so selected, that instead of the interior of the rooms being as cool as, if not cooler, than the outside, it is cooler for the men to be in the open air under the sun. It is true that this objection has been raised at very few stations, but with adequate knowledge on the part of the architects, it ought never to have been raised at all. The barracks complained of are stated to be brick structures of the usual dark colour, with verandahs supported not on light easily heated and easily cooled columns, but on massive piers and arches like a bridge. The roofs have been constructed almost as they would have been at home, and no adequate means have been adopted for protecting the walls from sun-radiation. Of course the great mass of brickwork becomes heated during the day, and heats the air outside and inside the rooms at night, while the structure of the roof is such that the interior is heated both by direct conduction and radiation. Now surely such mistakes might have been avoided. There are such things as non-conducting materials to be had, and double walls with a ventilating air space between are not an uncommon expedient in this country for keeping out both heat and cold. Again, there is such a thing as white plaster or whitewash for outside walls, which reflects a large portion of the solar heat. Double roofs are not unknown, we believe, in India, and it is possible to construct such a roof as to interpose not only an air current between the outer and inner layer of the roof, but to prevent the radiation of the inner surface of the outer layer passing through the inner layer. These are very elementary applications of physical laws to Indian house construction, and how little they have been attended to may be inferred from a fact which has been stated—viz., that these barracks have been roofed with slate. The ordinary laws of conduction and radiation of heat appear to be at a discount in the Indian works department.

THE PROVINCE OF MINERAL CHEMISTRY

PROFESSOR KOLBE has recently succeeded to the directorship of the *Journal für Praktische Chemie*, rendered vacant by the decease of Erdmann, its original founder; and in his hands this periodical will doubtless become the recognised organ of the modern Leipsic School of Chemistry. Dr. Kolbe, in the first number o the new series of this work, has signalised his succession to the office of editor by an introductory essay, setting forth his opinions upon what he considers must be the future aim of the student of Inorganic Chemistry. Organic Chemistry, once the neglected sister of Inorganic Chemistry (to use the Professor's phraseology), has become so courted and honoured since Liebig introduced her as a young science into the chemical world, that little by little her relative has sunk into comparative obscurity. But the time has now arrived when, in Kolbe's opinion, it is evident that Inorganic Chemistry has not merited this neglect, but that she has it in her power to bestow rewards not less precious than those of Organic Chemistry, upon those who devote themselves to her service.

Much of the attractiveness of Organic Chemistry must, according to Kolbe, be traced to the zeal with which the origin of the almost numberless cases of Isomerism in organic compounds is being searched out; indeed, this zeal has nearly displaced the lively interest in Inorganic Chemistry created by the discovery of Isomorphism. This cause can never actuate the investigator in the domain of Inorganic Chemistry—at least not to the same extent—and for the reason adduced by Kolbe, that Isomerism cannot possibly occur in inorganic compounds to anything like the same degree as among organic substances, owing to the greater simplicity of constitution possessed by the former class. That so few cases of Isomerism have been discovered in Inorganic Chemistry is undoubtedly due to the fact that hitherto we have neglected to investigate mineral substances with special regard to their chemical constitution.

In order to prove the truth of this latter assertion Kolbe asks how can we frame anything like a reply to any question respecting the chemical constitution of the naturally-occurring silicates—felspar, for example? What are the proximate constituents of this compound, and what are their respective functions?

In half a dozen brief sentences Kolbe disposes of all our knowledge upon this subject, beginning with the views of Berzelius, by whom felspar—the typical silicate—was regarded as possessing a constitution analogous to that of dehydrated alum—that is, as a double salt of neutral silicate of alumina and silicate of potash; and ending with Gerhardt, who thought to explain the constitution of this and all bodies by his theory of types, or, in the expressive language of Professor Kolbe—"mit dei mechanischen Handhabung eines todten Schematismus."

The greater portion of the paper is devoted to Kolbe's theoretical views upon the nature of felspar, and he suggests a number of structural formulæ to explain its constitution according to our present opinions upon the quantivalence of the component elements. Whether, however, any of these formulæ represent the actual constitution of felspar, or if, indeed, its true nature can be represented by such formulæ, is a question which Kolbe leaves untouched, for the simple reason that the necessary experimental foundation from which alone valid arguments can be drawn, is entirely wanting.

Professor Kolbe concludes this remarkable paper by defining what should be the future aim of the student in Mineralogical Chemistry. He must not now rest content with a mere quantitative analysis, or with the empirical deduction of rational formulæ from the results of such analysis. Such a process can never fully elucidate the chemical constitution of inorganic compounds. This can only be accomplished by a careful and systematic study of the decomposition, syntheses, and substitutions; in other words, by the application of methods of research similar to those which have yielded such splendid results in Organic Chemistry. T. E. THORPE

NEW OBSERVATORY IN THE SOUTHERN HEMISPHERE

THE following statement with regard to the Cordova Observatory, to the foundation of which we have before referred, is extracted from the last number of Silliman's *American Journal of Science and Arts.*

"The Argentine Congress voted to establish a national observatory at Cordova, at the instance of President Sarmiento, and through the exertions of the present Minister of Public Instruction, Dr. Avelleneda, who invited me to organise and take charge of it, knowing my desire to extend the catalogue of the southern heavens beyond the limit of 30° to which the zones of Argelander extend. Bessel went through the region from 45° N. to 15° S. with systematic zone observations at Königsberg, which have since been reduced and published in two catalogues by Weisse of Cracow. Argelander carried the same systematic scrutiny with the Meridian Circle, from Bessel's Northern limit to the pole, and afterwards from Bessel's Southern limit to 30° S.

"Since then Gilliss has observed a series of zones for 30° around the south pole; but the reduction of these, although very far advanced, was not completed at the time of his death, and the MS. is now stored somewhere in Washington. Let us hope that it may at some time be recovered, the work completed and given to the world.

"My hope and aim is to begin a few degrees north of Argelander's southern limit, say at 26° or 27°, and to carry southward a system of zone observations to some declination beyond Gilliss's northern limit, thus rendering comparisons easy with both these other labours, and permitting the easy determination of the corrections needful for reducing positions of any one of the three series to corresponding ones for the other. It is of course impossible to arrange in advance the details of such an undertaking, but my expectation is to go over the region in question in zones 2° wide (except in the vicinity of the Milky Way where the width would be but one-half as great), up to a declination of about 55°, after which the width would be gradually increased as the declinations became greater. Within these zones all stars seen as bright as the 9th magnitude would be observed, so far as possible, moving the telescope in altitude when no bright star is in the field until some one becomes visible, according to the well known method of zone-observations.

"For reducing the observations, differential methods will probably be employed, inasmuch as the time now assigned for my absence from home would be inadequate for proper discussion of the correction required for nice determinations of an absolute character. Still, it is my present purpose, so far as possible, to make such subsidiary determinations as might hereafter be needed in any attempt at computing the observations absolutely. But as I hardly venture to anticipate any opportunity of making a thorough determination of the constants of refraction, or of the errors of graduation, it seems best to arrange for a differential computation at least at first.

"It is improbable that a sufficient number of well-determined stars will be found available even for this differential reduction, and the necessity may thus be entailed of determining the comparison-stars myself, this determination, however, itself depending upon standard star places. So far as possible I propose employing those heretofore determined by me, and published by the Coast Survey, which form the basis of the star places of the American Nautical Almanac.

"With these observations of position it is my hope to combine others of a physical character to some extent; but in the presence of a plan implying so much labour and effort, it would be unwise to rely upon the possibility of accomplishing much more than the zone-work.

"The meteorological relations of the place are very peculiar, but I dare not undertake any connected series of observations bearing upon these, without self-registering apparatus, which is beyond my means.

"Cordova is one of the oldest cities, and contains the oldest university, of the Western hemisphere. It is situated in $31\frac{1}{2}$° S. latitude, on the boundary of the Pampa, where the land begins to rise toward the group of mountains known as the Sierra de Cordova. It is connected with Rosario, on the Parana, by the Central Argentine Railway, which has probably been already opened to travel through its entire length of about 250 miles, although information to that effect has not yet reached this country.

"The two largest instruments will be a Repsold meridian-circle of 54 inches focal length and $4\frac{1}{2}$ inches aperture, and an equatorial by Alvan Clark and Sons, provided with the 11-inch object-glass, by Fitz, lately in the possession of W. Rutherfurd, who has supplied its place by one of 13 inches. A photometer by Ausfeld of Gotha, according to Zöllner's latest form, has been constructed under the supervision of Prof. Zöllner himself; a spectroscope will be furnished by Merz of Munich, and a clock by Tiede of Berlin.

"The Scientific institutions of the U.S. have afforded the expedition every possible assistance. The Coast Survey lends a circuit-breaking clock, a chronograph, and a portable transit; the Smithsonian Institution lends a zenith telescope; the American Academy of Arts and Sciences of Boston (probably) a photometer and spectroscope; the Washington Observatory and the Nautical Almanac have greatly aided the undertaking by gifts of books and by a manuscript copy of Gilliss's catalogue of Standard Stars; and from the astronomers of England, Germany, and Russia important assistance has been freely and effectively contributed, in the order and supervision of instruments and apparatus, and by the gift of books, as well as by important and valuable suggestions.

"Four assistants will accompany me, Messrs. Miles Rock, John M. Thome, Clarence L. Hathaway, and William M. Davis, jun. We hope to reach Buenos Ayres not later than the middle of August.

"The building is now under construction in Boston. The means available proved inadequate for its construction according to the original plan, which was in the form of a cross, with four square rooms about its centre, and turrets at its four extremities. One half of it will be first erected, and it is hoped that the remaining portion will speedily be added." B. A. GOULD

SCIENTIFIC SERIALS

THE greater part of the *Revue des Cours Scientifiques* for July 23, is occupied by the commencement of a very able paper read before the Anthropological Society of Paris by Prof. Broca, on the Transformation of Species. Commencing with the pre-Darwinian theories of transformation of Blainville and Lamarck, he then proceeds to give a *résumé* of the theory of Darwin, and the arguments in favour of or against the permanence of species, drawn from the observation of living species and from palæontology. Following this we have, *à propos* of the war, an article on field ambulances and hospitals, by Prof. Champouillon. In the number for July 30, we have the rectorial address of von Littrow to the University of Vienna, on the backward state of science among the ancients, and the conclusion of M. Broca's paper on the transformation of species, in which the subject is treated from a philosophical point of view, and the professor sums up strongly against the idea of permanence. The hypothesis of Natural Selection is then discussed, but a much less certain conclusion arrived at. The number for August 6 opens with a report of the discussion on the nomination of Mr. Darwin as corresponding member of the Academy of Sciences, to which we have referred in another column. This is followed by a singularly able and exhaustive review by M. Claparède, of Geneva, of Mr. A. R. Wallace's Essays on Natural Selection, in which he points out that while Mr. Wallace demands the intervention of a superior force to explain the foundation of the human races, and to guide man in the path of civilisation, he altogether denies the existence of such a force as assisting to produce the inferior races of animals and plants, which he attributes entirely to the operation of Natural Selection. In the same remarkably interesting number of the *Revue*, we have also Mr. Marey's extremely important paper on the Flight of Birds.

THE current number (No. XXXIX.) of the *Quarterly Journal of Microscopic Science* is an unusually rich one, containing several papers of great importance. Amongst them we may draw attention to one of considerable length by Dr. Beale, entitled "Bioplasm, and its degradation," with Observations on the Origin of Contagious Disease. He introduces and defends the use of the term Bioplasm, which we think is admissible enough, and serves very well as a distinguishing appellative for actually living matter, as opposed to protoplasm, which has been rather vaguely used to designate organic matter whether dead or alive. The application, however, of the new term is sufficiently wide, since Dr. Beale appears to consider them in a special form for each separate structure in the body originating in the primary mass of bioplasm of the egg. From each subdivision of the latter "in pre-ordained order, and with perfect regularity more are produced, no doubt according to laws, but laws which we know nothing about, except that they are not physical." This last assertion indeed seems open to question, for if we know *nothing* about them, how can it be said with certainty that they are not physical, as it is certain we are not acquainted with all the physical laws of the world. Dr. Beale proceeds to describe the Bioplasm of the Amœba, the principal forms of that of man, and its relations to such morbid products as pus and infectious poisons. An interesting paper follows, by Dr. Macdonald, of H.M.S. *Fisgard*, on the minute anatomy of some of the parts concerned in the function of accommodation to distance. Dr. Caton describes the means he has found best adapted for studying transparent vascular tissues in living animals. To this succeeds a capital *résumé* of Prof. Stricker's "Studien aus der Institut für experimentelle Pathologie in Wien aus dem Yahre 1869," and the part devoted to original communications terminates with two essays, one by Mr. E. Ray Lankester, on the Migration of Cells, and one by A. M. Edwards, on *Diatomaceæ*.

The *Transactions of the Linnean Society*, vol. xxvi., pt. 4, is entirely occupied by two papers on Fossil Cycads. The first, by Prof. W. C. Williamson, is descriptive of the remarkable *Zamia gigas* Lindl. and Hutton, or *Williamsonia gigas* Carr., found in considerable abundance in the Lias at Whitby. He believes it to have borne a strong resemblance to existing Cycads with diœcious flowers. In Mr. Carruthers's valuable monograph of Fossil Cycadean stems from the Secondary rocks of Britain, he shows that these fossils are, as far as is at present known, entirely confined to Secondary strata, the so-called *Cycadeæ* of the coal-measures and other palæozoic strata being rather referable to cryptogamic *Lepidodendra*, and the few specimens reported from Miocene beds being very imperfect and uncertain. In his description which follows, Mr. Carruthers describes four new genera from British rocks, *Yatesia*, *Fittonia*, *Williamsonia*, and *Bennettites*. Both papers are illustrated by excellent plates.—Vol. xxvii., part 2, is of more varied interest. Mr. John Miers contributes two botanical papers; a description of three new genera of *Verbenaceæ*, *Rhaphithamnus*, *Phelloderma*, and *Diostea*, from Chile and the adjacent regions; and a paper on the anomalous genera *Gœtzia* and *Espadea*, the position of which is very unsettled, and which he proposes forming into a new order. Dr. Birdwood describes and figures three new species of *Boswellia*, natives of the Soumali country, all of which yield frankincense, and one of them, he believes, the bulk of the olibanum of commerce. Dr. J. B. Hicks points out a singular resemblance between the genus *Draparnaldia*, and the confervoid filaments of mosses. We have descriptions of new Agarics and Lichens from Ceylon, the former by the Rev. M. J. Berkeley, the latter collected by Mr. Thwaites, and named by the Rev. W. A. Leighton, who also contributes notes on the Lichens of St. Helena, and a description of a new British Fungus, *Sphæria tartaricola*, Nyl. The longest paper in this part is an important monograph by Messrs. Henry Brady, Parker, and T. Rupert Jones, of the genus *Polymorphina*, an attempt to rescue this difficult genus of Foraminifera from the almost inextricable confusion into which it has fallen. Dr. A. Rattray contributes a paper on the anatomy, physiology, and distribution of the *Firolidæ*, forming the section of Heteropoda with a straight and elongated form, and either wholly naked or furnished with a very small shell, and including the genera *Carinaria*, *Carinaroides*, *Firola*, and *Firoloides*. Sir John Lubbock proceeds with his Notes on *Thysanura*, part iv.; and from Dr. Edward Moss we have an account of the genus *Appendicularia*, with its remarkable appendage, or "haus," the object of which in the vital economy has not been ascertained.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, July 4.—Mr. Alfred R. Wallace, president, in the chair. The Rev. F. A. Walker and Mr. Edward Mackenzie Seaton were elected members. Numerous objects of interest were exhibited by or on behalf of Mr. Meek, the Hon. T. De Grey, Mr. F. Moore, Mr. Blackmoor, Mr. Albert Müller, Mr. Jenner Weir, Sir J. C. Jervoise, Bart., Mr. Tegetmeier, and others.—Prof. Westwood made some observations on a group of very minute four-legged *Acari*, and the President mentioned instances of protective mimicry in insects, recently observed by Mr. Everitt in Borneo.—The following papers were read:—"Further observations on the Relation between the Colour and the Edibility of *Lepidoptera* and their Larvæ," by Mr. J. Jenner Weir; "On a Collection of butterflies, sent by Mr. Ansell from South-Western Africa," by Mr. A. G. Butler; "Contributions to the Insect Fauna of the Amazons" (continuation, *Coleoptera longicornia*, Fam. *Cerambycidæ*), by Mr. H. W. Bates; "List of the *Hymenoptera* captured by Mr. J. K. Lord in Egypt and Arabia, with Descriptions of New Species," by Mr. Francis Walker.

EDINBURGH

Scottish Meteorological Society, July 21.—Half-yearly general meeting, Mr. Milne Home in the chair. The following report from the Council was read:—"The Council have to report that the number of the Society's stations is now ninety-one, there being an additition of one since the last general meeting, in consequence of the services of an observer having been obtained for Leith. At the last half-yearly general meeting, reference was made to a renewed application by the Council to Government for pecuniary aid. The application was so far favourably received that the Board of Trade a second time recommended the Council to prefer to the committee of the Royal Society their claim, with a view to an allowance being made from the annual Parliamentary grant of 10,000*l*. for meteorological purposes, of which grant that committee have charge. The Council regret to say that the Royal Society committee have stated that they are unable to make or promise any allowance out of the grant, as the whole of it has been appropriated to other objects; for which objects the grant is, as the committee state, even too small in amount. The Council have in these circumstances been induced to renew their application to Government for a special grant to the Society. The Council have requested Mr. Buchan to prepare a report on the monthly temperature of the British islands, and to state to this meeting a few of the results obtained by him. The subject is one which it is believed has not been thoroughly investigated by any other society, or indeed by any meteorologist except Professor Dove; and Professor Dove's charts, which are now ten years old, were based on observations not only necessarily scanty, but in several cases unavoidably incorrect. The first chart which this Society prepared of the temperature of the British Isles was published in the Society's journal in January 1864, and it has been frequently referred to by meteorologists as the only one existing. That chart was constructed on returns obtained during a period of five years; the new charts which Mr. Buchan is now constructing are founded on observations for thirteen years, ending December 1869. These charts, besides giving the mean temperature of the year for the whole British Islands, give also the mean temperature of each month. The Council anticipate that, when these charts are published, with the tables explanatory of them, they will be found to afford valuable aid in the discussion of many important questions of a practical nature."—Mr. Mohn, Professor of Meteorology in the University of Christiania, and director of the Norwegian Meteorological Institute, who was at the meeting, presented a work entitled the "Storm Atlas," referring to various storms which had passed over the north of Europe. The Swedish returns were from twenty-five stations, where the observations were made three times a day, and were sent gratuitously by the Swedish Institute.

A paper "On the Temperature of the British Islands," by Mr. A. Buchan, was read; thirteen charts illustrating the temperature of the British Islands in each month of the year being exhibited. The author said that the investigation, the results of which were now exhibited on the walls, was one of the most important of all that the Society had undertaken. An early attempt was made to partially solve the problem about seven or eight years ago, and a chart was constructed showing the mean temperature of different parts of Britain in July and in January. These observations had two inherent defects. They were based only on five years, evidently too short a period to yield such results as were quite trustworthy. They were also defective in respect of number of stations, there being some parts of the country very badly represented. Now, however, an investigation had been completed for thirteen years, which must be a very close approximation, indeed, to the solution of the problem. The real temperature of the various months could differ very slightly from what was now exhibited. Further, the number of stations now brought under review was four times what the Society had at first. The observations were upon a mean of thirteen years of 68 Scotch stations, 54 English stations, and 11 Irish stations—Ireland being yet very badly represented. To enable him to draw the lines on the outskirts of the British Isles with greater accuracy than could otherwise have been attempted he had calculated the mean temperature for Faroe. Several Norwegian stations he had obtained from Professor Mohn's publications, and he had also ascertained the mean temperature of places in Belgium and France. The temperatures had been reduced to sea level by the ordinary method of allowing a degree for every 300 feet of elevation, and the lines were drawn upon the charts to show each difference of a degree of Fahrenheit. Among the results brought out, it appeared that in January there was as high a temperature in the north of Shetland as there was in London. As soon as the westerly winds crossed the high mountain ridge that was on the west of the British Isles, they deposited their vapour, radiation took place, and the temperature rapidly fell. In the same way, in Ireland, the lower temperatures were found inside, the higher temperatures outside. Another very marked result was the effect of Ireland upon Britain in increasing the summer temperature and lowering the winter temperature opposite to that island. In regard to the influence of the Irish Sea, Mr. Tennent, a member of Council of the Society, who had for a year or two given a good deal of attention to the direction of winds in different parts of the British Isles, is of opinion that the winds of the Irish Channel were not so much westerly as in Scotland and Ireland, but flowed to a great extent through the centre of the Channel. Now, on looking at the charts, it would be seen that the effect of this current in the winter months was to push up the isothermal lines over the Irish Sea. Through the whole of the months, the observations all showed the marked effect which that open space of water had upon the temperature of the British Islands, as clearly as the effect which Ireland had upon the part of Britain opposite. Questions of temperature had an important bearing upon agriculture. Many agriculturists believed that if the night temperature fell to 40°, there was no growth for twenty-four hours. If the night temperature fell to 40°, the mean temperature might be expected to be about 46°. Thus, then, by observing the charts for the various months, and taking note of those parts of Britain whose temperatures were less than 46°, one would ascertain the places where during certain months there was little growth, a very important question in discussing the crops of the British Islands. The next important temperature for agriculture was that required to ripen cereals. It had been proved by observations made by persons competing for prizes offered by the Marquis of Tweeddale, President of the Society, that for the purpose in question, with the ordinary range of temperature in Scotland, there must be an average of 56°. If it fell below that, there was a deficiency in the crop; if it rose, the crop was so much the better, provided there were rain and other necessary conditions. Accordingly, with the charts for the different months, one could point to those parts of the British Islands where there was some hazard in rearing cereal crops—the places, namely, where the necessary temperature was scarcely to be expected, or where it occurred so seldom that the risk was too great. It was generally supposed that the temperature fell one degree for every 300 feet of elevation, so that supposing at the sea level there was a temperature of 58°, at an elevation of 600 feet the temperature would be 56°, or a temperature sufficient to ripen cereals. In reference to this point, however, it was interesting to compare the station of Braemar on the Dee-side with that of Wanlockhead in the Leadhills, which were among the best equipped stations of the Society. It was well known by experience that on Deeside oats could ripen up to about 1,500 above the sea; but at Wanlockhead, which was only 1,300 feet above the sea, oats were sown only for the straw. Here, then, were very marked differences in the effects of temperature, as shown in the growing crops. Taking the month of June, he found that, adding a degree for every 300 feet of elevation, he got a mean temperature at Wanlockhead of 54·9°, while at Braemar, applying the same correction, he got a temperature of 56·8°. The cause of the difference between the two places he was not prepared to hazard an opinion upon, but it had an important bearing on the produce of the country. He thought that if this question were a little inquired into at some other stations, they might get some general law for guidance in reference to such matters.

Dublin

Royal Irish Academy, June 23.—The Rev. Professor Jellett, B.D., president, in the chair. Mr. Frith read a very interesting paper on arterial drainage in the west of Ireland. Mr. W. Andrews mentioned the second occurrence on the coast of Ireland of the rare Cetacean *Xiphis sowerbii*; it had been found in May last, in Brandon Bay, Co. Kerry. It was seventeen feet in length, the back of head and fins were of a velvety black colour with lines of white. Although sadly mutilated by the fishermen, yet several important parts had been obtained sufficient to enable him to supplement his (Mr. Andrews) provious paper on this very rare whale.—A paper was read by the secretary on the Book of Clonenagh.—The last part of the proceedings was laid on the table, and the receipt of a MS. index to the volume from the Rev. Dr. Reeves was acknowledged with many thanks and ordered to be printed.

Paris

Academy of Sciences, August 1.—A note was read by M. G. Rayet, on the spectrum of the solar atmosphere, in which the author noticed the variability of the bright lines, in confirmation of Mr. Lockyer's observations. M. Berthelot communicated some thermo-chemical investigations upon the sulphurets, in which he described the action of the alkaline sulphurets upon metallic salts in solution, the action of acids upon the alkaline sulphurets, that of sulphuretted hydrogen upon various metallic salts, and of acids upon the metallic sulphurets. A note by M. L. Henry, on the action of pentachloride and pentabromide of phosphorus upon various æthers, was read. M. F. Pisani presented an analysis of nadorite, a new mineral from the province of Constantine. This mineral was supposed to consist of one equivalent of oxide of antimony, and two equivalents of oxide of lead; the author gave as its formula $(Sb^2 O^3, Pb O) + Pb Cl$. A note by Mr. F. C. Calvert, on the evolution of pure nitrogen from nitrogenous organic matters was communicated by M. Chevreul. The author described the evolution of nitrogen from animal matters, by the action of hypochlorite of lime, and gave a tabular view of the quantities produced from gelatine, albumen, calcine, wool, and silk; these amounted in each case, to rather more than one-third of the whole quantity contained in the substance operated upon. A note was read by M. Contejeau, on the maximum of temperature at Poitiers, on the 24th July, 1870. The maximum observed was at $1^h 10^m$ P.M. when the thermometer suspended under the shadow of a tree showed

$41^{\circ} \cdot 2$ C. (= $106^{\circ} \cdot 16$ F.).—A note by M. V. Raulin on the rain-fall of the French Alps was communicated by M. Leverrier. It included tables of mean, annual, seasonal, and monthly rainfalls for sixteen stations.—M. C. Saint-Claire Deville communicated an extract from a letter of M. Chassin on a severe earthquake felt in Mexico on the 11th May of the present year. This earthquake destroyed the town of Pochutta, in the State of Oaxaca, in twelve minutes; it continued until the 19th.—A note was read by M. Marès on the corpuscular disease of the silkworm, and Marshal Vaillant contributed some extracts, showing the advantages which have been obtained in various places by the adoption of the processes of selection of silkworm's eggs recommended by M. Pasteur.—M. Decaisne presented a note by MM. Planchon and Lichtenstein on the specific identity of the *Phylloscera* of the leaves and roots of the vine.—A note by M. E. Roze on some mycological experiments, was communicated by M. Brongniart. The author confirmed the results obtained by M. Oersted as to the production of *Rœstelia penicillata* on the hawthorn by means of *Podisoma clavariæforme* from the juniper, and described some important experiments on the relation of *Claviceps purpurea* (Tul.) to the *ergot* of rye and other grasses.—A note by Mr. F. C. Calvert on the employment of phenic acid as a disinfectant, was presented by M. Chevreul. The author claimed the first application of phenic acid in this way for Dr. D. Davis, of Bristol, in 1867. The perpetual secretary states in a note that it was used on a large scale in Paris in 1865.

BERLIN

German Chemical Society, July 11.—Alexander Müller, having been engaged in analysing the waters of Berlin, stated the principles which he thinks necessary for procuring good analyses, as follows:—The bad property of water depends upon the organic matter contained in it. Water should therefore be evaporated *in vacuo* and submitted to dialysis, the colloid portion to be examined with the microscope. The organic matter should be determined by elementary analysis. Another portion should be evaporated with a weighed quantity of carbonate of soda, to separate silicic and phosphoric acids. The residue should be heated to redness; the loss corresponds to the nitric and nitrous acids and organic matter. The remaining weights, minus the carbonate of soda added, is that of the salts contained in the water, with the exception of phosphates and silicates.—Dr. Schwarz related his experiments instituted to obtain the homologues of isothionic acid with methylic, amylic, and butylic alcohols. Working with large quantities of sulphuric anhydride, he was unable to remark the two modifications which have been lately observed by Schultz Sellac. The boiling point of his anhydride (prepared by distilling Nordhausen acid with phosphoric anhydride) was 26° C.—M. Jaffé in describing an experiment concerning the constitution of rufigallic acid established the mode of the formation of colouring matters in plants. Gallic acid $C_7 H_6 O_5$, a derivation of benzol, when heated with sulphuric acid, yields rufigallic acid, until now considered as $C_7 H_4 O_4$. By treating this compound with zinc powder M. Jaffé has obtained anthracene $C_{14} H_8$. He therefore doubles the formula of rufigallic acid, and thinks it probable that the complicated vegetable colouring matters are derived from the tannic acids which are a constituent ingredient of most plants.—A. Oppenheim described experiments on the action of sulphuric acid on oxygenated organic chlorides. This he found to be analagous to the action of sulphuric acid on the corresponding chlorinated hydrocarbons. The chlorhydrine of glycol yields glycolsulphuric acid, just as chloride of ethyl yields ethylsulphuric acid. Epichlorhydrine, C_3H_5ClO, yields the mixed ether of glycerine, $C_3 H_5 Cl OHSO_4 H$, just as chloride of allyl yields a mixed ether of propylic glycol. Acid chlorides yield sulphuric acids in which the organic acid radical replaces one atom of hydrogen. These compounds are decomposed by water into the acids entering into their composition. Thus we have acetyl-sulphuric acid, phthalyl-sulphuric and benzoyl-sulphuric acid. The latter, however, is gradually transformed into sulphobenzoic acid. By heating, this molecular transposition takes place at once, and thus a good method exists for preparing this acid free from any secondary product. The same chemist, conjointly with M. Ador, established the identity of this acid with that discovered by Mitscherlich. It yields the same salts and is transformed into isophthalic and oxybenzoic acids by fusion with formiate and hydrate of potassium.—L. Carus communicated observations on the temperature necessary for his method of organic analysis in sealed tubes. P. Griess established the formula of benzo-creatine, $C_8 H_9 N_3 O_2$, obtained by the action of potash on the cyanide of amidobenzoic acid.—L. Henry reported on the action of PCl_5 on the ethers of diatomic monobasic acids.—MM. Merz and Mülhauser described the properties of naphthoilic or naphthylcarbonic acid—T. Thomsen described experiments on specific heat. In order to arrive at a standard quantity of heat he heated liquids by burning a certain volume of hydrogen. He arrived at the conclusion that mixtures of sulphuric acid and water have the specific heat of the water entering into the mixture. C. Rammelsberg communicated experiments on the specific weights of the different modifications of tin.

THURSDAY, AUGUST 18, 1870

MR. DARWIN AND THE FRENCH INSTITUTE

THE judgment of foreign nations gives the best clue to that of posterity; and it is therefore with peculiar interest that the countrymen of Mr. Darwin have watched the reception of his works in France and Germany. In the latter country his theory of the origin of species has been more or less completely accepted by those best qualified to judge, including men like Gegenbaur and Haeckel; and it has produced a complete literature of arguments and facts "für Darwin," without encountering any very serious opposition. In France, the truth of the theory is far less extensively admitted, and has been lately the subject of prolonged discussion in the Academy of Sciences. The debate on Mr. Darwin's claims has now been adjourned for three months, but so far as it was reported in our last number it furnishes much ground for reflection.

At the present time, Imperial France is, perhaps, the most conservative in science of any country in Europe. It is not, therefore, surprising that, with a few exceptions like M. Claparède, French naturalists refuse to accept the theory of Natural Selection, and do not see (as others, and notably the Germans do) that it has already made a new epoch in human knowledge. Some, like M. Robin, object that it is not "demonstrable," and therefore not scientific at all; as if gravitation or the atomic theory had been, or could ever be, demonstrated like a proposition of Euclid. The Darwinian theory offers an explanation of acknowledged facts by the help of others equally indisputable, and it will only be "disproved" when it ceases to furnish an adequate explanation, or is superseded by a more simple and equally sufficient hypothesis. Meanwhile it fulfils, at any rate, one object of every theory, by stimulating research in all directions, and awakening new interests for the fresh investigations which it suggests. The speeches of MM. Milne-Edwards and de Quatrefages are especially worthy of note; though opposed to the conclusions of "The Origin of Species," both these distinguished men discuss them with the intelligence and clearness of Frenchmen and the tolerance of philosophers: and both accord to the earlier works of Mr. Darwin the hearty praise which they deserve.

Two points come out very clearly in the course of this debate. First, that the wide extent of a scientific man's labours may hinder them from being properly appreciated. Geologists, who know well the value of Mr. Darwin's writings on the formation of coral islands, are ignorant of his admirable series of observations on the fertilisation of orchids; and many who are startled by the boldness of his speculations in zoology would feel more confidence in his judgment, were they acquainted with his work on barnacles—"ouvrage, selon M. Milne-Edwards, qui depuis sa publication suffit à tous les besoins de la science." The field of natural history is now so cut up, that a great dipterist may be almost ignorant of many orders of insects, and quite so of other animals. Few professed geologists have an adequate knowledge of physiology, botany, and geology, and thus we fear science often loses in breadth what is gained in minuteness. One cannot, of course, hope even to touch upon all the provinces which Aristotle "ruled as his demesne," and the extent of Hunter's or of Cuvier's range is probably too great for modern times; but, after all, the theory of natural selection would scarcely have been framed by one who had studied nature in a less comprehensive spirit than Mr. Darwin.

Another remarkable point, which was brought forward in the Academy as a reproach to the English naturalist, is that his researches are those of an amateur. M. Milne-Edwards met the accusation in the best possible way,—by admitting it: "Si l'on entend par amateur un homme qui aime passionnément la science, et qui s'y consacre tout entier sans en attendre aucune rétribution—oui, M. Darwin est un amateur, un grand amateur." But for us in England it is a serious consideration how far it is wise to rely so exclusively as we do upon a continued succession of such amateurs. The result upon the English character of our entire disregard of science as a pursuit of national importance is what might have been expected. When with us a man by his own independent energies comes to the front rank, he is pretty sure to make an epoch in science, be he never so much an amateur in French eyes. Such were Hunter and Faraday. Of such men we can boast at the present moment among the greatest living historians, philosophers, and political economists of Europe.

But, on the other hand, we have never had a continuous "school" in any branch of learning, and as a distinct result the mass of our scientific work is much below the standard of average excellence abroad. Nowhere, probably, are text-books so slovenly and imperfect as in England; nowhere are even good workers in the rank and file of science so narrow and unenlightened; and nowhere does the attainment of equal results so little affect the character of the nation. Whether we shall ever succeed in uniting the discipline and organisation of French science with the freedom and individuality of our own is hard to say, but unless something be done in this direction, we must be content every now and then to see a whole branch like Physiology become almost extinct in this country. The success which has attended the efforts made in Germany (chiefly within this century alone) to establish scientific research in a durable manner, and as a part of the national organisation, may at least encourage us to forward the attempt here. In the meantime, as we have no system of establishing and fostering schools, we must hope for men who cannot be repressed.

Another point introduced by M. Robin was, that considered in respect of demonstrable facts which Darwin had introduced into science, there would be a hundred zoologists who should have precedence over him. "Si des publications de M. Darwin, on élimine les vues dont ni la réalité ni la fausseté ne sont démontrables, et qui dès lors ne sont plus objets de science, il lui reste un ensemble de titres qui est inférieur à celui que représentent les données scientifiques bien démontrées introduites dans la science par M. Bischoff; il lui reste même moins de titres à nos souffrages qu' à quelques-uns des savants qui sont placés *ex æquo* avec lui sur notre liste de présentation. Ce sont là les raisons qui m'ont conduit à ne pas porter M. Darwin au premier rang, et il m' a paru qu'elles ont influé sur le vote des autres membres de la majorité de la section."

THE ICE AGE IN SWITZERLAND*

IF one might venture to use the word "romantic" in reference to the history of any past geological period, it would certainly with most fitness be applied to that time, so recent and yet so remote, which we know as the Ice Age. The story of the old glaciers, like that of the living ones, has a perennial interest. We listen to it over and over again without wearying, much as we used to do with some of the standard tales of childhood. For even though we are now familiar with the evidence which proves that, at no very distant date, the northern parts of Europe and America, including nearly, if not the whole, of our own country, lay buried under a vast sheet of ice, the fact is so strange that every fresh presentation of it comes even yet before us with not a little of the charm of novelty. Hence every description of new facts which tends to elucidate the history of the Ice age in any one locality possesses a more than local interest and importance. More particularly is this the case when the description relates to Switzerland. The Swiss glaciers of to-day have become in a manner the common property and fighting-ground of the geologists of all countries; and all fresh observations which bear on the ancient extension of these glaciers are welcomed as additions to the common fund of geological knowledge.

But there is a peculiar interest attaching to the publication the title of which is given below. It is not only a most meritorious contribution to geological literature, showing in great detail the history of glacial phenomena in one of the Swiss cantons, but it may be taken by all local scientific societies as a model of what enthusiasm and industry, well directed, may accomplish. Its origin and growth may be briefly stated. In December of 1867 the Natural History Society of Aargau determined that the year 1869, being the fiftieth of its existence, should be marked by some fitting celebration. It was suggested that, besides the usual festivities, it would be well if the society would engage in some piece of scientific work, so as to present the result at the anniversary; and it was finally resolved to make an extended and detailed survey of the erratic formations of the canton. General attention had been roused to this subject by the Swiss Naturalists' Society in 1867. That body had issued a circular inviting all authorities and private individuals throughout Switzerland to preserve the erratic blocks which were rapidly disappearing before hammer and gunpowder. MM. Favre and Soret, of Geneva, had likewise pointed out the desirability of having an accurate map made of the distribution of erratics in the country. Accordingly communications were entered into with the federal and cantonal authorities, who cheerfully lent their assistance. A circular was sent out inviting all and sundry to give their aid towards the ascertaining and mapping of the erratic blocks in the canton Aargau. In that document were likewise given directions as to the nature of the observations to be made. Each of the fellow-workers was requested to note in a schedule the erratic blocks (or *foundlings*, as they are happily termed in German) of his neighbourhood, with an exact record of the locality of each block, its local name, height above the sea, proprietor, the nature of the rock of which it consists, the legends, if any, connected with it, such human marks as might have been carved on it, and any other remarks that might seem important. To conduct the whole inquiry a reporter or secretary was appointed. His duties were to receive and reduce into connection and order the reports of the various volunteer surveyors; and that he might the better perform this task, he was authorised at the public cost to visit the more remarkable localities, to mark those blocks which he considered it desirable to preserve in the interests of science, and to preserve two type specimens of all the more important blocks, the one specimen to be deposited in the Aargau Museum, the other to be sent to M. Favre at Geneva. The blocks lying on State property were to be considered thenceforth inviolable, and for the conservation of those resting on other lands the secretary was authorised to treat with the proprietors with a view to the acquisition of the blocks by the State. By thus taking advantage of the general movement the Aargau Society not only aided in a work of national interest, but gained an opportunity of celebrating in a singularly excellent way its own anniversary.

The result of the undertaking is now before us in the form of an octavo volume of upwards of 200 pages, with a map showing the distribution of erratics and the extension of the old glaciers over the canton. A more admirable piece of work has not been done in glacial geology for some time. The society deserves the warmest thanks, and more especially the reporter, Herr Mühlberg, who first suggested the task, and on whom the main share of the labour has fallen. The course of each of the ancient glaciers is traced by the lines of "foundlings" which it has left in its path. The evidence furnished by the Canton Aargau as to the retreat of the ice is carefully collected. The limits of the second glaciers are mapped out, and abundant details are furnished as to their moraines. It has long been familiar knowledge that the great glacier of the Rhone, after abutting against the Jura mountains, pushed an immense body of ice eastwards over the lowlands of Switzerland as far as the district round Soleure. But we now learn that rocky *débris* borne along by the huge glacier has been traced even up to the Rhine at the confluence of the Aar. Swelled by the numerous streams of ice which came down from the Bernese Oberland, the united glacier of the Rhine and Rhone must have poured an enormous mass of ice down the Rhine valley, between the Black Forest and the Jura.

The sequence of events in Switzerland since the close of the Tertiary period is thus epitomised by Herr Mühlberg:—

1. Close of the Tertiary period, elevation of the Alps, &c.
2. Erosion of the valleys in the area of the molasse.
3. Renewed elevation of the Jura, formation of the barriers at Aarburg, Wildegg, &c., and consequent lake-basins.
4. First and greatest extension of the glaciers even to the highest crests of the Jura and over the whole canton. Northern limit of the ice unknown; accumulation of bottom moraines (Grundmoräne, *moraines profondes*) upon the "Stoss-seite" of the hills.
5. Retreat of the glaciers, with deposit of earthy rubbish, angular blocks, scratched stones, sand and gravel; filling up of the lakes behind the above-named barriers (save

* Ueber die erratischen Bildungen im Aargau, &c. Ein Beitrag zur Kenntniss der Eiszeit, von F. Mühlberg. (Aarau: H. R. Sauerländer.)

the still-existing lakes over which the retreat of the ice, if it took place at all, was rapid); erosion of the river terraces.

6. New advance of the glaciers to a line drawn from Dagmersellen to Baden; overlaying of the older glacial deposits with fresh erratic materials; formation of large moraines; origin of the small cross-valleys in the molasse hills outside of the ice-covered region.

7. Periodic retreat of the glaciers (with perhaps an occasional renewed advance) until the ice had finally retired from the canton; newer deposits of moraines, &c., and formation of lakes and marshes where the moraines were laid down across valleys.

8. Changes which are still going on.

There is nothing, indeed, which is novel in this synopsis, but it is satisfactory to find that it is borne out by so large an array of evidence as the author has here brought together. On one or two points we could have wished for information. There is no record given of the direction of the striæ on the rocks. No doubt the molasse is not well adapted for the preservation of such markings, though they would remain even on that rock when protected by superficial clayey deposits. We can hardly doubt that if looked for, striated rock surfaces would be found in Aargau as good as those in the adjoining canton of Solothurn. Herr Mühlberg says nothing of any warmer interglacial epoch, as indicated by lignites lying between the deposits of the first and second glacier periods. Is it that no such evidence exists in Aargau, or that the attention of the observers was not specially directed to this subject?

We cordially commend this little volume to the notice of local scientific societies in this country. Such societies often fail of success, either because on the one hand they are too ambitious and seek to emulate the greater societies in such a manner as to ensure certain failure; or, because, though they possess the will and the ability to work, they lack the strength and the enthusiasm which spring out of well-directed and hearty cooperation. Let them take a lesson from the way in which the Aargau Natural History Society has celebrated its fiftieth anniversary. ARCH. GEIKIE

PRIMITIVE MAN

Primitive Man. By Louis Figuier. Revised Translation. 8vo. (London: Chapman and Hall, 1870.)

M. FIGUIER has been singularly fortunate in the mode in which his books have been received by the French public. "Le Monde avant le Deluge" had a large circulation, and even in England the translation revised by Mr. Bristow met with considerable favour. It is almost needless to remark that it reproduces the wild catastrophic doctrines that were given up in England some thirty years ago, with a grace and elegance which lead the *dilettante* reader to believe that he is learning at the feet of a modern Gamaliel. "L'Homme Primitif" takes up the narrative where it was dropped by the preceding work, and tells the story of the early races of men that have lived in Europe, with that vivacity and idealism which is only to be found in perfection among the people for whom it was written. It is undoubtedly true that M. Figuier's works give a faithful outline of the present state of science in France; but it is none the less true that in England catastrophism is practically extinct, and that many of the inferences of French Archæologists are received by English *savants* with a considerable amount of reserve. We, therefore, hold that Science is not really advanced by these books being put before the non-scientific English reader. Of the two books the latter is by far the best, but it is disfigured by many and grave mistakes. There can be no doubt that it will become almost as popular in England as in France, although the elegance of style cannot be preserved in plain straightforward English.

"Primitive Man," the English editor tells us, is intended to "fill an open place in the literature of Prehistoric Archæology," although it covers precisely the same ground as Sir John Lubbock's "Prehistoric Times," and rivals that work in size. If this means that "the Raffaelesque idealism" of the illustrations is intended to find its way to the hearts of a British public that is given to sensational literature, we think that the editor is right. The frontispiece, representing a family of the Stone age, is admirably adapted to arrest the attention of the mother of a family; and the feasting during the Stone and Bronze ages is fitted to strike gourmands, the pictures of the chase, sportsmen; while the cultivation of gardens during the Bronze epoch is a touching scene of rural happiness. A man is hoeing the ground, while a woman is sowing seed, and hard by stands Phyllis with a basket on her head, and leading a favourite goat that is reaching forward to eat a tempting vegetable (also of the Bronze age), while Corydon up an apple tree is shaking its riches into Galatea's lap, and behind are the sheep tended by a shepherdess, and kine and long-snouted pigs are looking on from the palings. All this is extremely pretty, and will doubtless attract many readers. We doubt, however, whether an appetite for archæological knowledge created by such stimulants would be satisfied with the sober logic of the English standard works on the subject. In the letterpress we have failed to detect any fact of high importance which is not to be found in "Prehistoric Times," or in "The Antiquity of Man." The English edition of "Primitive Man" has been corrected and altered from the French original, and therefore may be treated as a purely English work. In his preface the editor is so anxious to give reasons for translating the book, that he seems conscious that he holds a bad brief. We shall proceed to point out some of the more glaring mistakes.

M. Figuier gives an account of the celebrated controversy about the Moulin-Quignon jaw, in which he states that Dr. Falconer, Dr. Carpenter, Professor Busk, and Mr. Christy "unanimously agreed in recognising the correctness of the conclusions arrived at by the indefatigable geologist of Abbeville," viz., that the flint *hâches* and the human jaw were of the same Quaternary age as the extinct mammalia found in the same gravel pit. So far from this being the case, Dr. Falconer stated in the *procès-verbaux* that "the character which the jaw presents, taken in connection with the conditions under which it lay, are not consistent with the said jaw being of any very great antiquity," while Prof. Busk wrote that "the internal condition of the bone is wholly irreconcileable with an antiquity equal to that assigned to the deposits in which it was found." Mr. Evans also afterwards came to the conclusion that the suspected flint *hâches* are modern fabrications, and that an ingenious and successful fraud had been practised by the workmen. The editor, however, allows M. Figuier's version to stand, feebly qualified by a note in small print, that "it should rather have been said that the ultimate and well-considered judgment of the English geologists was against the authenticity of the Moulin-Quignon jaw." Why, then, let M. Figuier's error be allowed to mislead the English public? The high antiquity of man is amply proved by the genuine flint *hâches*, without involving the apocryphal Moulin-Quignon jaw, which throws a certain degree of doubt on the whole question.

In 1823 Dr. Buckland advocated the theory of a great diluvial flood which swept over the earth, destroyed the extinct mammalia, and conveyed large blocks of stone far from their parent rock. This he shortly after withdrew. From that time down to the present no attempt has been made in England in any scientific work to account for facts which the author could not understand, by the hypothesis of a deluge. The glaciers and ice-bergs are supposed to have transported the blocks of stone, and the presence of the remains of men and animals in caves is accounted for either by the fact of their having lived and died in them, or by their having been swept in by the action of water. Now, however, M. Figuier brings again the old exploded theory to the front. He speaks of the "cataclysm of the European deluge of the quaternary epoch," as if it were an article of geological faith; "the European diluvial inundation was, as we know, posterior to the glacial epoch, a great catastrophe, the tradition of which is preserved in the memory of all nations, marked in Europe the end of the quaternary epoch." In the first place there is not the slightest proof to be adduced of anything of the kind having ever happened in Europe, and in the second there is proof direct that it did not happen at the end of the so-called quaternary epoch. And the proof direct is furnished by the fact that the quaternary mammalia die out one by one, gradually and not all at once. There is an unbroken sequence of animal life in Europe from the Pliocene to the present day. This old diluvial theory runs more or less throughout the first part of the book, and leads the author very frequently astray. There are also minor points which require correction. The little globular sponges, with a hole in the middle, washed out of the chalk, and found in the gravel at Amiens, which are supposed by Dr. Rigollot to have formed necklaces, are figured as "fossil shells." If the author will refer to D'Orbigny he will find that it is figured as *Coscinopora globularis*. That it is a protozoon and not a shell there can be no doubt. It is indeed hard to understand how the mistake could have occurred, for the arrangement of M. Figuier's woodcuts is the same as that given by Sir Charles Lyell ("Antiquity of Man," p. 119) by whom it is rightly described. Again, why does the editor allow M. Figuier to call Professor Huxley "Hippocrates Huxley," Professor Vogt, "Galen Vogt," and Sir Charles Lyell "Celsus Lyell," because the first says that the Engis skull might have belonged to a philosopher, the second, that it belonged to a degraded savage, and the third offers no opinion whatever? It is a piece of wit too subtle for ordinary minds. The latter is certainly not a Doctor, nor has he written, like Celsus, on agriculture, rhetoric, or military affairs. The only possible point of resemblance between the three couples is that each was at the head of his own particular profession in his own time.

The portion of the book relating to the Neolithic Bronze and Iron ages is much better than the earlier part, but it contains little or nothing of importance that has not been published by Sir John Lubbock. We have done our duty by calling attention to the leading blunders. The book is the work of a remarkably skilful compiler, and is written altogether for effect. W. B. D.

OUR BOOK SHELF

An Elementary Course of Plane Geometry and Mensuration. By Richard Wormell, M.A., B.Sc. Second Edition, revised and enlarged. Fcap. 8vo., pp. 276. (London: T. Murby.)

THIS book is the work of a reformer, not so much of geometry, as of the mode of presenting it to the young. Sciences begin in practical applications, and tend by a universal law to become more and more abstract; and the doctrine of the reforming school is that whatever the science may have developed into, it is necessary in teaching it to go back to practical applications, and to seek for a sure foundation for abstract notions in the familiar experience of common objects. Teachers need to be incessantly reminded of this necessity. In teaching physics or chemistry or botany it is perhaps admitted, though not always obeyed; but in mathematics it is generally not admitted; and when admitted, it is rarely followed out to its logical consequences. Geometry, arithmetic, algebra, must alike be presented first in their applications; and then alone, in most cases, can definition and soundness be given. In most cases, we say, because where mathematical talents of a moderately high order exist, as in the generality of mathematical teachers, this necessity is not felt. And for this reason mathematical teachers who are not also observant of mental phrases, may be slow to believe what has just been pointed out as a necessity in their art. Many of them, we suspect, have a secret sympathy with the mathematician who proposed the health of "The prime numbers, the only branch of mathematics that has not been defiled by contact with the concrete."

The aim of Mr. Wormell's book is to teach scientific geometry, the logical dependence of truths on one another being shown, and to make the teaching sound by giving familiar illustrations of all the conceptions involved, and applications of the result attained. The book is interspersed with examples, geometrical and arithmetical. Among the subjects mentioned—we turn to the index, as giving a good idea of the book—are star polygons, axis of symmetry, graduation, land-surveying, spirals and volutes, transmission of motion by cogs, &c. Considering what the aim of the writer seems to have been, the illustrations and applied part of the book have been well done. It is generally clear, moreover, and accurate in style, and is interesting. In form it is adapted for a school book; and for certain schools it may be a success. But it fails as a scientific geometry intended to replace Euclid, in three respects; want of clear statement of axioms and exhibition of the science as rigidly deductive; the avoidance of the difficulty of incommensurables; and a degree of undefinable inelegance of treatment throughout. The book is too long, and is too nearly scientific, to use as an introduction to Euclid or to any of its modern substitutes; and, though it would replace them with advantage if the mathematical education of the student were to end with the reading of this book, it is not easy to see how the student proceeding to higher mathematics could do so without previously mastering another more complete geometry. It seems to me, therefore, a successful contribution to "technical education," and a valuable and suggestive attempt, but not altogether a successful one, to teach scientific geometry on true principles. The book is well adapted for middle-class schools. It is scarcely worth while to notice minor faults, either of the printer, which are very few, or of style. But it is really to be regretted that a degree should have been defined thus:—"Suppose we have a circumference sufficiently large to be divided easily into 360 equal parts, each part is called a degree." A degree is an angle, and this conception ought to be prominently brought forward.

J. M. WILSON

THE *Sitzungs-Berichte* of the Isis Natural History Society of Dresden for the first three months of the present year contains, as usual, a great number of short communications of more or less interest, and among them a few longer notices. Of the latter we may mention a note on the "Occurrence of Precious Stones in Saxon Switzerland," by M. A. Stelzner; a paper on "Diatomaceæ," by Dr. Eulenstein; a notice by Count Pourtalès on the "American Deep Sea Explorations;" a paper on the "Course of the Boomerang," by Professor Schneider; and, especially, a paper (illustrated) by Dr. Geinitz, on some "Fossil Fruits from the Zechstein and Coal Measures." The society has established a section for prehistoric archæology, the first meeting of which is here recorded; its proceedings consisted chiefly in the delivery of a long opening address by the President, Captain Oscar Schuster.

WHETHER the inhabitants of Rhenish Prussia and Westphalia are at the present moment devoting much of their attention to Natural History may fairly be doubted, but hitherto they have shown great activity in this department, and the publications of their Natural History Society generally contain much valuable matter. We have lately received the volume of their transactions for 1869 (*Verhandlungen des Naturhistorischen Vereins*, vol. xxvi.), in which we find several important papers. Kaltenbach contributes the continuation of his valuable "Natural History of the German Phytophagous Insects," consisting of an alphabetical list of the principal plants growing in Germany, either in a wild or cultivated state, with an account of the insects feeding upon each of them. Dr. C. Schlüter gives descriptions of numerous fossil Echinodermata from North Germany, with good illustrations on three large plates; whilst from Mr. F. Winter we have a contribution to the knowledge of the cryptogamic flora of the Saar district, now the scene of military operations. Another important botanical paper is a contribution to the flora of the Rhine by Dr. P. Wirtgen. In the section of the work denominated the "Correspondenzblatt" we find a note by Dr. Mohr on the "Theory of Coal," and in the "Proceedings of the Natural History and Medical Society of the Lower Rhine," a great number of notices upon scientific subjects of all sorts. This latter part is published separately for the present year. We have received the first number for 1870, including the proceedings during January and February.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

School Natural History Societies

IN your notice of the various School Natural History Societies, you have omitted one, which has been established for more than a year, and is now in a very flourishing state. I allude to the Clifton College Scientific Society. Unfortunately, no one is here to give me any statistics, but I understand that it has seventy members, with about twenty more waiting for admission. Mr. Percival has built a museum at a cost of 1,500*l.*, which will, I believe, be opened next September.

T. B. PRESTON

4, Lanesfield Villas, Durdham Down, Bristol
August 1

IN the leading article of NATURE for July 28 (which I have just received), you name some of the chief public schools in which Natural History Societies exist. I am sorry you have omitted to mention Cheltenham College as among that number, and conclude the omission arose from ignorance of the fact. Perhaps it may be interesting to some readers of NATURE to hear that last March, a society consisting of members of that College, was founded under the presidency of the principal (Mr. Jex-Blake) to whom the college is much indebted for the encouragement of Natural Science as a part of the general education of the place.

The Society numbers about fifty members, the department chiefly worked at present being botany, at which several of the boys are becoming tolerably proficient, with a small sprinkling of devotees to geology and zoology.

Our difficulty lies in making meetings sufficiently attractive. Original papers, containing original observations, are scarcely to be expected from the boys themselves till they have been educated to observe; and in our case the number of masters who take an active part in the society is too few to keep interest alive. I cannot, however, doubt, in spite of such difficulties, which have been felt (and in some instances overcome) by others as well as ourselves, that these societies are sowing good seed of which it is not too much to hope the world and science will reap the fruit by-and-by.

Our Dublin Correspondent and the Parturition of the Kangaroo

ON my safe delivery, after a good deal of labour, from the perils of war, and on my arrival in London from Germany, I found your letter, enclosing a copy of Dr. J. Barker's communication as printed in your issue of the 14th ult. Dr. Barker has, apparently, no fault to find with my report, which, as a matter of necessity, could not be otherwise than imperfect. But he somewhat loftily criticises the writer of the comments on my report, who, in spite of the facetious title given to him by Dr. Barker, I believe to be a gentleman of considerable merit, and one whose comments on my correspondence appear to be always most just. Dr. Barker is right when he states that the late Earl of Derby's father did not observe the facts about the Kangaroo which he records; these were observed by the keeper of his collection, but they were placed on record by the Earl and hence the mistake. Dr. Barker seems annoyed that he should be made to appear as if he adopted the views, the absolute nonsense, of the writer whose paper he permitted to be read. Those who know Dr. Barker know what absolute nonsense it would be to believe him capable of adopting them. Yet, ought he not, as chairman, to have repudiated and refuted them? Would it not have been well if he had given the members of the learned societies, on the occasion in question, the information which he now offers to the readers of NATURE, and instead of telling them "that the actual passage of the fœtal kangaroo from the uterus to the pouch was not yet proved," he had told them that the fact of there being such an actual passage had long since been proved; though how the actual transit, whether with the help of the mother's paws or lips, takes place, is still regarded as a matter for further observation; and so, instead of appearing to justify the reading of such a paper as the one referred to, he would from the extent of his knowledge on the subject, have reflected credit on his position, and on the societies to which he belongs, and have made, at least, an effort to advance the science he is so zealous for.

August 13 YOUR DUBLIN CORRESPONDENT

The Horse-Chestnut

I SAW to-day in the last number of NATURE, a letter on the meaning of the word horse-chestnut. As I do not see NATURE regularly, I do not know whether any of your correspondents have called your attention to the similar use of ἵππος in composition. In case this should have escaped them, I send the following extract from Liddell and Scott:—

"ἵππος, vi., in Compos.; it expressed anything *large* or *coarse*, as in our *horse-chestnut, horse-laugh*; v. ἱππό-κρημνος,-μάραθρον, -σέλινον, -τυφια, -πορνος; cf. βου-."

Long Ditton, Kingston, Aug. 5 M. W. MOGGRIDGE

The Rotundity of the Earth

WE have seen the statement signed "Parallax," at page 236 of No. 38 of NATURE, and shall be obliged if you will afford us an opportunity of briefly saying in reply, that when we tried the "flag experiment," the person calling himself "Parallax" was not present.

The experiment was conducted in his absence, as he did not come at the time appointed. He did not come at all that we know of; we did not see him.

Cuckow's Eggs

A SHORT time ago I addressed you on the subject of Cuckow's eggs, giving you some experiences of my own. I now have much pleasure in forwarding to you a portion of a letter on the same subject from an esteemed and observant correspondent, Mrs. Barber, of Highlands, near Graham's Town, to whom I communicated the substance of my letter to you. Mrs. Barber's name is well known in the botanical world as a most accurate scientific observer; of her ornithological acuteness my work on the Birds of South Africa amply testifies, and you may place full confidence in the statements she has made in this communication.

Cape Town, June 1870 ED. LAYARD

"Your remarks on the eggs of the cuckow tribe are very interesting. I confess that I am a believer in natural selection, and Darwinian in my opinions, but nevertheless in this matter I do not see the necessity for the intervention of natural selection; however, I hope you will bear in mind that I am speaking only with regard to the cuckows of my own country (South Africa), and as far as my observation extends, the eggs of these birds bear no resemblance to those of the birds upon which they are parasitic.

"Many of the different species of the cuckows of this country lay white eggs; the whole of those included in the genus *Chalcites* produce white eggs, the birds upon which they are parasitic are the various species of *Fringillidæ*, they do not, however, confine themselves entirely to this tribe.

"I have frequently seen the eggs of the 'Dedric' (*Chalcites auratus*) and the 'Metje' (*C. klaasii*) in the nest of the Cape canary (*Fringilla canicollis*) and the 'Streep Koppie' (*Fringillaria vittata*), where they were conspicuous not only for their pure white unspotted appearance, but for their size also, which is nearly twice that of the Cape canary, and considerably larger than the eggs of the 'Streep Koppie.'

"I have also found the egg of the 'Dedric' in the nest of the green Sun-bird (*Nectarinia famosa*), where it was also much larger than the grey speckled eggs of the sun-bird, and likewise dissimilar from its pure white colour.

"The egg of *Cuculus solitarius* is of a dark mahogany brown, and this egg I have seen in the nest of the wood robin (*Bessonorius phœnicurus*), when its difference was obvious both in size and colour, my son (F. H. Barber) found one of these dark brown eggs in the nest of the Cape canary! and despite its great dissimilarity compared to the small white speckled eggs of that bird, the work of incubation was quietly going on.

"The birds upon which the 'Honey Guides' are parasitic are *Laimodon leucomelas* (vel *L. unidentatus*). I have frequently seen them at the nests of these birds, where great conflicts occasionally take place between the *Indicators* and *Laimodons*, the latter being fully aware that the 'Honey Guide' is an intruder, the egg of the *Laimodon* is speckled, that of the *Indicator* white.

"The 'October bird' (*Oxylophus edolius*) deposits her white eggs in the nest of the large woodpecker; my brother (Bertram Bowker) once met with *three* of the young of this cuckow in the nest of that bird; it is not a common occurrence, I believe, that so many eggs should have been deposited in a single nest; the large woodpecker is, however, equal in size to the 'October bird;' when the birds upon which they are parasitic are smaller, the cuckow deposits but one egg, as the food and space required will in that case be only sufficient for a single individual.

"In the nest of the green sun-bird (*Nectarinia famosa*) I once observed a young 'Dedric,' which nearly filled the nest. It was not quite full fledged, and its frequent calls for food induced the sun-birds (both male and female) to exert themselves to the utmost, and in fact they had to work hard to satisfy the cravings of this greedy intruder; however they did it with a good will, and apparently without any suspicion that they were being imposed upon. Birds in general have no suspicion on this score, they suspect no trickery, and are therefore willing to incubate any kind of egg, provided it is not too large to fill up the nest. I think I told you how I had occasionally changed the eggs of various species of birds from one nest to another, making fearful confusion in consequence, yet the owners of the nests never suspected that anything was wrong, but proceeded quietly with their work. With regard to eggs, the discriminating power of birds is very obtuse, in fact they have none at all, and therefore in this case the agency of natural selection would not come into play; it would not be required. In nature there is no waste, no failure, no useless expenditure of time and ingenuity, every arrangement is sufficiently perfect to work out its own end without being overstrained or overwrought.—M. E. BARBER."

Special Modification of Colour in the Cushat

IN reading the chapter on "Mimicry," in Mr. Wallace's valuable collection of essays lately published, I was struck by a remark there made in regard to the special modification of the colour of the wood-pigeon. It is stated (p. 53), on the authority of Mr. Lester, that "the wood-dove, when perched amongst the branches of its favourite fir, is scarcely discernible, whereas, were it among some lighter foliage, the blue and purple tints in its plumage would far sooner betray it." This description may be accurate enough in regard to *Columba œnas*, but our experience is against its application to *Columba palumbus*. It was a common pastime of our boyhood to stalk the cushats in a mixed wood of the usual Scotch trees, and while familiar enough with their habit of making their nests in the spruce, unquestionably their favourite perches were on beeches and other hard-wood trees. Even after surmounting the somewhat delicate task of approaching the roosting-place of a cushat, it was no easy matter to detect the bird, except by its note, so closely did its general colours blend with the smooth, lichen-covered boughs of the beech, even where no leaves intercepted the view. The bird appears to build its nest especially in the spruce, not because its general colour agrees therewith (which it does not), but because the thick nature of the foliage and branches gives it, the eggs and young, sufficient privacy. Under all other circumstances it prefers to perch on the beech and other hard-wood trees, where its colours so adapt it for concealment. Of course the casual alighting on the pinnacles of the spruce during the breeding season is of little moment in the present question.

W. C. MCINTOSH

Colour Blindness

ALTHOUGH I have no intention of discussing the theory of colour-blindness propounded by Mr. Monck in NATURE of July 28, it may not be inopportune, while the subject is under the notice of your readers, to call their attention to a peculiarity with respect to the perception of colour, of which I have been able to discover no instance.

Some years ago I was sitting in a chapel opposite to a stained glass window, a portion of which (towards my left) was hidden from me by a pillar, and I observed that, as I moved my head to the right, the window flashed out into brilliancy where it had appeared dull before, while the contrary effect was produced as I moved my head to the left. On examining the conditions of the phenomenon carefully I found that it was due to the fact (which I had not the least suspected before) that my right eye is distinctly less sensitive to colour than my left. This I have since verified in various ways, though the difference is not very easily perceived unless the colours are brilliant, as in stained glass, bright coloured flowers, many of Turner's pictures, &c. The difference consists in this, that all colours appear less bright, or, as I should say, *greyer*, when seen with the right eye, and the more delicate gradations of colour cease to be perceived, while in many cases of even strongly contrasted colours, I should find it difficult to distinguish them with certainty with the right eye, especially if I had not previously seen them with the other eye. I have found too that the central part of the retina of my right eye is more defective as to the perception of colour than the lateral portions, since in looking at an extended surface of a single bright colour, scarlet for instance, a kind of shadow appears to come over any part of the surface to which I direct the eye.

With respect to my absolute power of perception of colour, I believe that though I cannot be said to be colour-blind, my eyes are less sensitive to colour than the average of those who have equally good general sight. For instance, scarlet and green do not appear to present to me the same degree of contrast that they do to most persons with whom I have made the comparison. Close at hand the contrast is sufficiently vivid, but a scarlet uniform seen at some distance in a green field would not attract my attention by contrast of colour, though I could make out the difference under a favourable light when my attention had been called to it; so also the scarlet berries of the mountain ash would at a little distance attract my notice rather by their form than by their colour, especially if seen against the sky or a bright object. Again, I can never pronounce with certainty as to the colour of distant bright lights; the colours of the lights, for instance, used for railway signals, though distinctly enough perceived by me when close at hand, puzzle me much when seen at a distance, while I am quite incapable of assigning with certainty a colour to a star or a meteor.

I should add that my ordinary power of vision is good; though here my right eye has a slight, but unmistakeable, advantage as to distinctness over my left. Hence, in looking at a brilliantly-coloured picture I have found that I could appreciate the drawing best with my right eye, the colour with my left, while in using both eyes each appears to remedy the defect of the other.

I think that the facts which I have here stated cannot fail to be of interest to those who are inclined to theorise on the nature of colour-blindness; but apart from all theory it would be satisfactory if the statement of my case should induce others to examine their own perceptions of colour with each eye separately, and in the event of their observing anything confirmatory of, or contrasting with, my observations, to send an account of them to NATURE. I think it quite possible that such cases may not be very uncommon, since the defect is one which may easily escape the notice of the subject of it.

Harrow, August 1 ROBERT B. HAYWARD

The Source of Solar Energy

MR. GREG still misses my meaning. I do believe that meteors supply a portion of the solar energy, and I also believe that they fall in enormous quantities into the sun; what I do not believe is that the whole solar energy is derived from meteors, or that any meteors fall in a solid state upon the sun (whose surface is also certainly not solid, even if any part of his mass be).

Mr. Greg's reasoning only proves what I have already pointed out, that none of the meteor systems our earth encounters can supply a meteoric downfall on the sun. This is, however, so obvious as to need no enforcing.

The reasoning by which I show that enormous quantities of meteors must fall upon the sun is wholly untouched by Mr. Greg's arguments, and is, so far as I can see, simply incontrovertible.

Surely Mr. Greg is not in earnest in saying that there would be a loss of solar energy if a large mass of iron fell on the sun before it was quite melted (any conceivable mass would, by the way, be vaporised), *because the sun would have to melt the portion which remained solid.* That solar energy would be consumed in the process is true enough; but if Mr. Greg supposes that the total solar energy would be diminished, he altogether misapprehends the whole subject he is dealing with. If the action of the solar energy in changing the condition of matter forming (as the imagined meteorite would) part of the sun's substance had to be counted as loss of energy, the sun would be extinguished in a very short time indeed. Such processes involve exchange, not loss.

If the earth could be placed on the sun's surface, the action of the sun in melting and vaporising the earth, and producing the dissociation of all compound bodies in the earth's substance, would involve an enormous expenditure of energy, yet the solar energy, considered as a whole, would be recruited, even apart from the fact that the earth would serve as fuel. The absolute temperature of the sun would, I grant, be diminished in this imaginary case, though quite inappreciably, but his total heat would be increased by whatever heat exists in the earth's substance.

Apart from this, however, if the minimum velocity with which a meteor or other body can reach the sun, is such as would—if wholly applied to heating the body—completely melt it, then the size of the body makes no difference whatever in the result. The meteor might not be melted if enormously large, but in that case the balance of heat would be communicated to the sun. In reality, of course, the heat correspondining to meteoric motion near the sun is very far greater than is here implied.

But I really must apologise for bringing before your readers considerations depending on the most elementary laws of the conservation of energy. RICHARD A. PROCTOR

Müller's Physics and Meteorology

FROM Prof. Jack's Review of Müller's "Physics and Meteorology," in your issue of August 4, I infer that he is not aware that an earlier edition of that valuable book was translated into English more than than twenty years ago, and formed one of the volumes of Baillière's *Scientific Library.* M.A. Cant.

Aug. 7

Colour of Water

MR. E. R. LANKESTER, in his letter in NATURE on 21st July, does not mention what is certainly one of the most remarkable known instances of a decided colour in water, I mean the Blue Lake near the road from Frutigen to Kandersteg in Switzerland. It is very small, not a stone's throw across. I think it is fed by springs. Its blue tint is so decided as to give the idea of some colouring stuff mixed with the water—not that it can be really so.

The Lakes of Neufchâtel and Bienne are of the same light-green tint as those of Lucerne, Brientz, and Thun, although the latter are fed by glacier streams and the former are fed by the streams of the Jura, where there are no glaciers. This appears to prove that the solid matter which glacier streams contain in suspension can have nothing to do with causing the green tint of most of the Swiss lakes. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Aug. 5

Water Analysis

YOUR article entitled "Water Analysis" consists of a review of a book, a commentary on a paper, and the reviewer's opinions of the character of Mr. Chapman and myself.

I shall not trouble you with any rectification of the statements contained either in the review or in the commentary on the paper; inasmuch as both the book and the original memoirs are accessible to the readers of NATURE, and the entire subject has already been very fully discussed.

In giving his opinion on the character of the authors of the book, the reviewer "deplored that two young chemists, with such undoubted abilities as Messrs Wanklyn and Chapman possess, should have rendered themselves notorious by attacking older workers in scientific investigation."

Perhaps you will allow me to say, that in rendering ourselves notorious in this manner, we have committed no crime, and that I cannot see why it should be deplored.

I believe that a great deal of the work which these older workers have done is unsound, and have endeavoured to sweep away some of that which I believe to be unsound. In this sweeping I have been to some extent successful, successful to an uncomfortable and alarming extent, I suppose your reviewer would say. But, if the rottenness of much that passes current in science is appalling, it is surely matter for congratulation that there are young men who will undertake a crusade against it, even at the risk of incurring the disapprobation of the older men, and of suffering every wrong that the possession of place and power enables these older men to inflict.

London, Aug. 14 J. ALFRED WANKLYN

[Mr. Wanklyn omits the sentence following his quotation:—"It is, no doubt, very laudable in a young and ardent investigator, when he points out that high authorities may err, and frequently have erred, but the manner in which these gentlemen have carried out their corrections has made their matter more distasteful."—ED.]

Suckers from the Apple Tree

MOST of the orchards in the west of Herefordshire have had their herbage injured during the present season by the extraordinary profusion of suckers thrown up by the apple-trees. In many places it looks like a miniature plantation, and is a serious detriment to the pasture. In an equal degree the elms have exhibited the same tendency to throw up an infinite number of shoots, and I am curious to know whether I am right in considering it to be due to the great heat of the surface of the soil.

C. J. ROBINSON

A Natural Fernery

NEAR where I am writing, in this parish (East Woodhay) is a deep hollow lane, with high sloping banks, which are abundantly clothed with the following ferns (nomenclature and arrangement from Dr. Hooker's new "Flora"):—*Pteris aquilina*, *Lomaria spicant* (rare), *Asplenium Adiantum-nigrum*, *A. filix-fœmina*, *Scolopendrium vulgare*, *Aspidium aculeatum*, *A. angulare*, *Nephrodium filix-mas* (with several pretty barren varieties), and *Polypodium vulgare*. Although the ferns are of the most common species, yet from the sloping nature of the ground, and the intermixing of a few other plants, such as *Equisetum sylvaticum*, *Lactuca muralis* (very fine), *Digitalis purpurea*, *Campanula Trachelium*, *Hypericum pulchrum*, *Juncus glaucus* and *compressus*, with a few pretty *Rosæ* and *Rubi*, tend to make it the most charming bit of fern scenery that I have ever fallen in with.

HENRY REEKS

The Science and Art Department

IN your impression of the 4th you have touched upon a point which has of late interested me much, viz., the science teaching of the "Science and Art Department."

At the commencement of the article you say that the work done is so little known that you have ventured its history. If you will allow me a small portion of your valuable space, I will put before your readers a few facts concerning the said "Department."

The teachers in the employ of the Department have no fixed salary; payments are made upon results to those persons who have passed in the first or second class (advanced stage) in the subject or subjects in which they give instruction, or who have passed in "Honours."

Now, a teacher's certificate is by no means difficult to obtain (advanced stage), provided Honours are not tried for, and consequently there is a large number of low-class teachers in the ranks, or those who are only grounded in elements of the subject which they are certificated to teach. For instance, a pupil on entering in 1869 for the examination and taking a second class in the advanced stage is entitled to teach and earn payments on results; such a teacher may only be grounded in the elements of the subject (say chemistry), and when he is applied to for the solution of a problem governed by physical laws he is at a loss and the pupil gets no answer to his query. It is my opinion that the teachers' examinations are much too easy. I think a certificate ought not to be granted unless the candidate has shown that he is familiar with the subject he intends to teach, and also with the cognate sciences. A chemistry teacher should know, at least, light and heat, magnetism and electricity; but at present such knowledge is not required.

I am not speaking specially for chemistry; geometry I may instance. There are many teachers at present engaged in giving instruction who know not a jot of Euclid's elements, nor can they work out the simplest algebraical problem. Should not a *teacher* know the theory as well as the practice, so as to give a definite and true answer to a pupil's inquiries. Machine drawing is the same; the examination consists of mere copying, and I can safely say that there are many teachers of mechanical drawing who would not be able to answer a single question of the paper set by the Society of Arts' examiner.

Science-teaching is daily becoming more and more appreciated, in some districts, however, only but very slowly; and I think it is only right that those teachers who do take an interest in science should endeavour to keep up the standard of the teacher. I should like to see every teacher obliged to pass in Honours—then the chemist would not pass without a thorough knowledge of physics, neither would the teacher of plane and solid geometry escape so easily, nor the pseudo-machinist obtain a certificate in a subject he was not competent to teach. But we must look at science as now taught from another point of view. It is for the encouragement of science among artisans (designated in the *Science Directory* as "the industrial classes") that the payments are made to teachers, the teachers not being able to claim any sum upon those which do not *strictly* come under that denomination.

Now, in the branch of chemistry some important rules have lately been made: candidates for the advanced stage are to be taught qualitative analysis, and each is to be supplied with a 2*l.* set of apparatus, the artisan cannot afford to supply it himself; the institution, or other place where the class meets, has only just enough funds to enable it to keep its head above water—who is then to supply it? The teacher; but often he will not see his way clear, for if he supplies it, 50 per cent. only is allowed him if the candidate obtains a first class. The pecuniary result to a teacher then is—for passing a student in the first class 1*l.*, and in the second a loss of 1*l.*, so therefore it will be advantageous for a teacher to keep his pupils out of the advanced stage altogether. If the authorities continue to let the rule stand, I should think payments would be allowed on middle-class students, as they are the only ones who probably could provide them with the apparatus.

It is all very well to say that an artisan, if he take sufficient interest in the science, *will* provide himself with the apparatus, but it generally happens that the willing ones are those who have the least opportunity of doing what they wish.

The past session has been a trying one for all teachers, for not only have the payments been reduced, but, to make up the list of evils, the standard has been raised, and consequently fewer have passed. The current session seems to be attended by as many drawbacks, which, if not withdrawn or somewhat modified, will, in the opinion of the majority of teachers, produce injurious results.

AN "HONOURS CERTIFICATED SCIENCE TEACHER"

The Intended Engineering College

WILL you allow me a small space in NATURE to call attention to a subject which seems to me to require the serious consideration of everyone who is interested in the progress of science in this country?

In reply to a question put to him in the House of Commons by Mr. Plunket, on the 9th instant, Mr. Grant Duff is reported to have said that it is the intention of Government to establish an engineering college for the Indian service, to be entered by competitive examination. Mr. Grant Duff does not appear to have entered into any detail with regard to the instruction to be given in the intended college, but it is fair to assume that Government would not think it worth while to take the education of engineers for India into its own hands, except with the intention of giving them a thorough and systematic training, at least as complete as what is already supplied by existing institutions. In this case, the instruction to be given in the new college will embrace at least a three years' course of study devoted to pure and applied mathematics, mechanics, physics, chemistry, geology, and the principles of engineering, in addition to the actual practice in the drawing office and workshop. That is to say, the Government school of engineering will be, on this supposition, what the Government School of Mines has become, in the main, a school of pure science.

Now, in view of this probability, the question suggests itself—whether it is fair and just that institutions like University College and King's College in London, and Owens College in Manchester,* which, without Government support or help of any kind, offer precisely the kind of training which we suppose the new college is intended to impart, should have to compete with an institution supported by Government prestige and Government money. The answer to this question affects not merely the interests of private institutions, such as those which have been mentioned, but, so far as the existence of these institutions is a benefit to the general public, it affects the interests of the whole nation; for in the case of colleges which depend for all or much of their income upon the general demand for education, their efficiency and their power to supply teaching of the highest kind, cannot but be seriously interfered with, if they are to be deprived of all share in the training of a class of pupils numerous enough to induce the Government to found a separate college for them alone. The course which Government proposes to adopt would, it seems to me, be justifiable only if the existing colleges were inefficient, and it had a clear prospect of establishing a more successful institution. As I have the honour to be connected with one of the Colleges in question, I do not intend to discuss their merits further than

* The Universities of Glasgow and Edinburgh might also be referred to although they do receive some amount of aid from the public funds.

to say that the quality of the teaching in any institution must depend upon the qualifications of the teachers, and that none of the three Colleges I have named need shrink from a comparison in this respect with any Government school at present in existence.

In answer to these considerations it might perhaps be urged that it is the duty of Government to secure efficient public servants, and that they are not called upon to consider how far private institutions are benefited or injured by the means that appear necessary for this purpose. To this I reply that, even adopting for the sake of argument this point of view, it is the imperative duty of Government not to spend public funds in doing what is already well done by private effort; and that, if anything was required which is not already supplied, public money would be far more productively expended in helping existing institutions to supply the defect, than in founding a new institution which will have to be supported entirely at the national expense. The obviously proper plan is for Government to test the qualifications of candidates for the public service with any degree of strictness they may think proper, but not to burden the country with the expense of educating them.

Perhaps, however, the assumption with which I started may be entirely wrong, and the proposed Engineering College may be intended to supply only a purely professional training. If this be so, there is even less to be said for it than before. In this case it will be merely a "Technical School," attempting to impart the knowledge and experience which can only be really acquired by actual practice under a working engineer.

In any case it seems strange that Government should announce its intention of establishing an Engineering College at the very time when a Royal Commission is making "inquiry with regard to Scientific Instruction, ... and the aid thereto derived from grants voted by Parliament."

University College, London, Aug. 15 G. C. FOSTER

OUR SALAD HERBS

THERE is perhaps no country in the world so rich as England in native materials for salad-making, and none in which ignorance and prejudice have more restricted their employment. At every season of the year the peasant may cull from the field and hedge-row wholesome herbs which would impart a pleasant variety to his monotonous meal, and save his store of potatoes from premature exhaustion; and there can be no question that in hot seasons a judicious admixture of fresh green food is as salutary as it is agreeable. Much has been said lately about the advantage which the labouring man would derive from an accurate acquaintance with the various sorts of fungus, and he has been gravely told that the *Fistulina hepatica* is an admirable substitute for beef-steak, and the *Agaricus gambosus* for the equally unknown veal cutlet. But deep-rooted suspicion is not easily eradicated, and there will always be a certain amount of hazard in dealing with a class of products in which the distinctions between noxious and innocuous are not very clearly marked. There is not this difficulty with regard to salad herbs, and we conceive that the diffusion of a little knowledge as to their properties and value would be an unmixed benefit to our rural population.

The first place must be assigned, on the score of antiquity, to the sorrel plant (*Rumex acetosa*), which in some districts still preserves the name of "green sauce," assigned to it in early times when it formed almost the only dinner vegetable. Its acid is pleasant and wholesome, and more delicate in flavour than that of the wood-sorrel (*Oxalis acetosa*), which, however, is used for table purposes in France and Germany. Chervil (*Anthriscus cerefolium*) is often found in a wild state and is an admirable addition to the salad bowl; and it is unnecessary to enlarge upon the virtues of celery (*Apium graveolens*) when improved by cultivation. John Ray, writing in 1663, says that "The Italians use several herbs for sallets which are not yet, or have not been used lately, but in England, viz., *selleri*, which is nothing else but the sweet smallage; the young shoots whereof, with a little of the head of the root cut off, they eat raw with oil and pepper;" and to this we may add that the alisander (*Smyrnium olusatrum*) is no bad substitute for its better known congener. The dandelion, which in France is blanched for the purpose, affords that *amari aliquid* which the professed salad maker finds in the leaves of the endive, and the same essential ingredient may be supplied by the avens (*Geum urbanum*), the bladder campion (*Silene inflata*), and the tender shoots of the wild hop. Most people are familiar with the properties of the water cress (*Nasturtium officinale*), and the garlic hedge mustard (*Erysimum alliaria*); but it may not be generally known that the common shepherd's purse (*Capsella bursa-pastoris*) and Lady's smock (*Cardamine pratensis*) are pleasant additions, whose merits have long been recognised by our foreign neighbours. In fact there is scarcely a herb that grows which has not some culinary virtue in a French peasant's eyes. Out of the blanched shoots of the wild chicory (*Cichorium intybus*), he forms the well-known *Barbe des Capucins*, and dignifies with the title of *Salade de Chanoine* our own neglected corn salad (*Fedia olitoria*). It would be very easy to extend the dimensions of our list of native salad herbs, for there are, perhaps, some palates to which the strong flavours of the chive (*Allium schœnoprasum*) and stone-crop (*Sedum reflexum*) may commend themselves, but enough has been said to show that Nature has not dealt niggardly with us, and that only knowledge is needful to make the riches she offers available. If the British peasant can be taught to discover hidden virtues in these plants with whose outward forms he has had life-long familiarity, we do not despair of his acquiring the one secret of salad-making, viz., the judicious employment of oil so as to correct the acid juices of the plants and yet preserve their several flavours unimpaired. C. J. ROBINSON

TESTIMONIAL TO PROF. MORRIS, F.G.S.

THE presentation of a testimonial to Prof. Morris on July 14, was the occasion of the meeting of nearly one hundred gentlemen, occupying prominent positions in connection with geology and the allied sciences.

Sir Roderick I. Murchison, Bart., K.C.B., occupied the chair, and, in opening the business of the day, expressed the sincere gratification he experienced in having been requested by the subscribers to this Testimonial to act as Chairman on an occasion when it was sought to do honour to Prof. Morris, whom he highly esteemed as a geologist, and whom he loved as a friend. He then gave a sketch of the career of Prof. Morris as a geologist, showing that in his earlier researches he was among the first to make most valuable communications upon the structure and fossil contents of the Tertiary formation of the South and East of England; and how he next threw much new light upon various members of the Oolitic formation and the Lias, describing the fossil contents with great acumen and ability. These were followed by his *opus magnum*, the "Catalogue of all British Fossils," which had gone through two editions, and was a work which would for ever hold a high place in science, as a truthful record of the succession of all classes of known animals from the earliest traces of life to those of the youngest Tertiary formations connecting ancient with existing nature.

The address was then presented, as follows:—

To John Morris, Esq., F.G.S., Professor of Geology in University College, London.

We, the undersigned, Friends and Cultivators of Geology, taking into consideration the degree in which this science has been advanced by your long and successful labours, are desirous of offering to you a Testimonial of the high estimation in which they are held. Always working in the field, and classifying public and private collections, you have for many years been among the foremost and most diligent of the Students of

Geology and Palæontology; your careful publications have their places among those of the Masters in every geological library; and your thoughtful lectures live, and will live, in the minds of your scholars. We shall be happy if by this Testimonial you may be encouraged to persevere in a course alike honourable to yourself and advantageous to the public, and that it may be pleasant for you in future years to remember that among the names to be submitted to you are many of those who have known and shared and been instructed by your labours.

"*Forsan et hæc olim meminisse juvabit.*"

Mr. Prestwich said: I have known Prof. Morris now some 35 years, and I can truly say that a more earnest geologist, and one more ready to impart to others the great and varied information he himself possesses, there cannot exist. His aim has ever been to spread a knowledge of that science which he has cultivated with so much pleasure and so much success. Often, too, regardless of other considerations, his first object has always been the free, and, if possible, the gratuitous diffusion of geological science—possibly too much so. Still, if he has failed often to secure his reward in *£ s. d.*, he has always secured the respect, esteem, and affection of his friends, and of all with whom he has worked. With most men the prospect of a good fee would be an incitation to work, but with my good friend Morris the surest way, I believe, to get him to work was too often to say that no fee or remuneration would attach to it. His first introduction years ago was by a valued mutual friend, Mr. Lonsdale, who suggested that a work on the Tertiary Geology of the London Basin was needed, and he thought that Prof. Morris might undertake the palæontological and I the stratigraphical part. I am inclined to believe that Mr. Morris must have considered the work as likely possibly to be remunerative, as, though taken up warmly at the time, the first chapter still remains unwritten. This testimonial is, I feel, but a small earnest of our feelings towards Prof. Morris. For the opportunity thus afforded of expressing our good wishes towards our friend, we have to thank the *Mining Journal* for the publicity it has given to the matter, and for an active part in the management we are, I believe, indebted to Mr. Hearn, whilst Mr. Milnes has kindly acted as treasurer for the fund, which for Prof. Morris's sake I only wish had been doubled.

The meeting was then addressed by Mr. Hearn, and Prof. Tennant, and a letter was read from the venerable Prof. Sedgwick; and Prof. Morris made an eloquent reply, in the course of which he said: It is with deep and sincere feeling that I thank you and the members of the Geological Society, and other friends, for the handsome testimonial which I have received at your hands this day. I not only thank you for the kind manner with which you have expressed yourself, but I recall with pleasure the encouragement to pursue my labours you gave me more than 25 years since from that chair when President of the society, in 1842, and still more so when in after years your kind suggestion induced me to become a candidate for, and your strong recommendation placed me in, the position I now hold at University College, the duties of which, during the last 15 years, I have earnestly endeavoured to fulfil, so that I trust you have had no cause to regret the confidence you then placed in me.

Prof. Sedgwick's letter was as follows:—

"The infirmities of old age make it impossible for me to attend the public meeting at the rooms of the Geological Society. This is to me a great sorrow, for no one can value Prof. Morris's most laborious and most useful palæontological works at a higher price then I have done. And I honour him not merely as a man of science but also as a kind personal friend, who has for many years taken his place in the first rank of practical English geologists. Pray present to him my heartfelt congratulations, which the load of 85 years, and a great infirmity of sight and hearing, will prevent me from offering personally."

The meeting then separated.

WHEAT RUST AND BERBERRY RUST

THE theory has long been prevalent among practical agriculturists that the proximity of berberry trees produces rust in wheat. Men of science, unable to trace herein the sequence of cause and effect, long derided the idea, and placed it among the prejudices of the agricultural mind. The facts of the farmer have, however, been too strong for the science of the botanist, and experience has won the day over theory. Let us trace for a moment the history of the inquiry. The first reference to the injurious influence of the berberry on corn appears in Krünitz's Encyclopædia, published in 1774. Marshall, in 1781, speaks of the berberry having been extirpated in Norfolk for this reason, and Schöpf, in 1788, mentions the same idea as prevalent in New England. Other writers of the same period give similar testimony; and in 1806 Sir Joseph Banks writes thus in the *Annals of Botany*:—"It has long been admitted by farmers, though scarcely credited by botanists, that wheat in the neighbourhood of a berberry bush seldom escapes the blight. The village of Rollesby, in Norfolk, where berberries abound, and wheat seldom succeeds, is called by the opprobrious appellation of 'Mildew-Rollesby.' Some observing men have lately attributed this very perplexing effect to the farina (pollen) of the flowers of the berberry, which is in truth yellow, resembling in some degree the appearance of the rust, or what is presumed to be the blight in its early state. It is, however, notorious to all botanical observers that the leaves of the berberry are very subject to the attacks of a yellow parasitic fungus, larger, but otherwise much resembling the rust in corn. Is it not more than possible that the parasitic fungus of the berberry and that of wheat are of the same species, and that the seed is transferred from the berberry to the corn?" The acute suggestion thrown out by Sir Joseph Banks, at a time when so little was accurately known of the structure of fungi, was not followed out for half a century; it was reserved for the German fungologist, De Bary, within the last few years to establish the truth of his theory, and to prove the existence of the

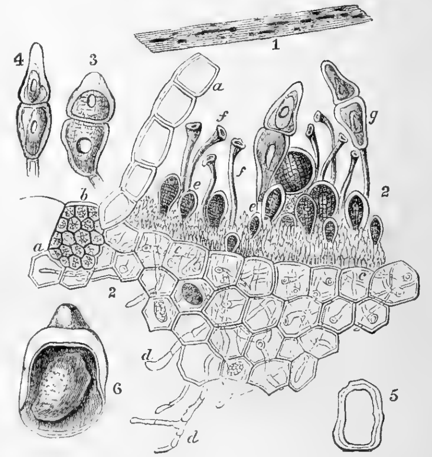

FIG. A.—*Puccinia graminis*, Pers. 1. Leaf of grass, with mildew, natural size. 2. Section of the leaf, with a patch of mildew and rust; *a*, epidermis of the leaf; *b*, bast-cell nerves; *c c*, outer layer of cells of the leaf, on which the parasite rests; *d d*, mycelium; *e e*, young and old spores of *Cæoma lineare*; *f f*, stalks from which the spores have fallen off; *g*, spores of the *Puccinia*. 3, 4 Spores. 5. Section of the wall of the lower spore-cell. 6. Longitudinal section of the upper spore-cell with the spore-nucleus. (2 - 6 magnified.)

phenomenon of Alternation of Generation among Fungi. The researches of Steenstrup and others have made us familiar with this remarkable phenomenon among the lower forms of animal life, but had hardly prepared us to meet with it in the vegetable kingdom. It appears probable, however, that the phenomenon is by no means uncommon here also,—affording another instance of the law that it is in their lowest forms that the animal and vegetable kingdoms approach one another most nearly,—and that whole tribes of fungi hitherto considered distinct are but different phases of one another. This remark applies especially to the two genera of minute parasitic fungi, *Æcidium* and *Puccinia*, to which the rusts in question belong, both belonging to the family *Uredineæ*. The well-known orange-red spots so common on the leaves of the berberry are produced by the *Æcidium berberidis*, while the rust of wheat and other cereal crops, but found equally on some other species of grass, as the common couch-grass or *Triticum repens*, is the *Puccinia graminis*. In the volume for 1865 of the *Monatsberichte der kön. preuss. Akademie der Wissenschaften zu Berlin* is a paper by Dr. De Bary, giving an elaborate account of his experiments on the propagation of these two fungi, in which, if his experiments are reliable, he clearly proves the correctness of Sir Joseph Banks's suggestion that they are one and the same species. The experiment was tried, with due precautions, of inoculating the leaves of the berberry with the spores of the *Puccinia*, the result being the production, not of the same fungus, but of the *Æcidium*, while the sowing of the spores of this latter fungus on the leaves of couch or wheat produced conversely the *Puccinia*. By sowing the spores of either fungus on the plant on which it was itself parasitic, he failed altogether to reproduce the same plant; and this alternation of generation may serve to account for the fact which has often been noticed, that rust is apt to appear not in successive but in alternate years on the same crop.

It is unfortunate to find that in a work bearing a considerable amount of scientific authority among agriculturists, and published in the same year, 1865, Prof. Buckman's "Science and Practice of Farm-cultivation,' the theory which thus appears to have been proved on the Continent was scouted in the following terms: "*Æcidium berberidis* is here referred to, from an opinion prevailing

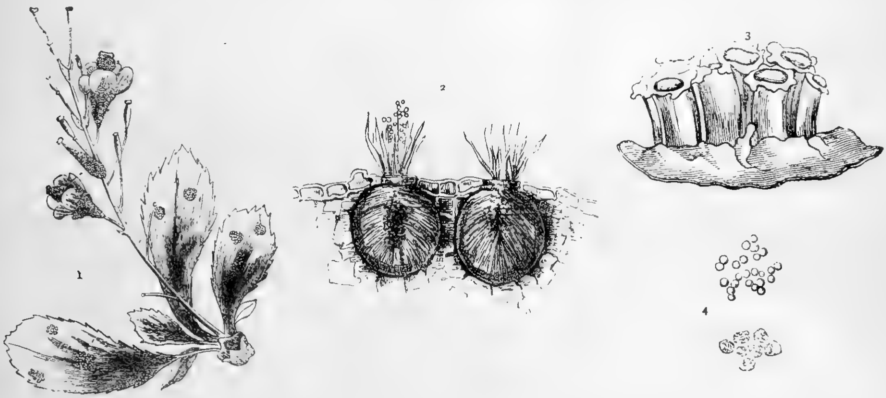

FIG. B.—*Æcidium berberidis*, Gmel. 1. Branch of berberry with spots of rust, natural size. 2. Spermagonia. 3. A group of Peridia with their orifices dentated. 4. Sporidia. (2, 3, and 4 magnified.)

that it is the cause of rust or mildew in wheat. We can no more believe that the berberry rust would produce rust in wheat than the rust of any other plant would do so. Still that wheat growing under a berberry hedge may be more blighted than in the rest of the field is quite true, and so it is with wheat growing under any kind of hedge." Mr. Buckman fails entirely to grasp the argument, which is not that wheat "growing under a berberry hedge" is attacked by rust, but when growing in the proximity of a berberry tree, say at the distance of a field's breadth. Nothing is more certain to weaken the hold of science over practical men than when men of science, in order to support their own theories, set themselves systematically to deny well-known facts. We therefore greatly regret the decision at which it is understood the council of our Royal Agricultural Society has arrived, to refuse a thorough investigation of the subject which has been urged upon them, calling in the assistance of experienced men and the most able fungologists of the day. This is not the way to command the confidence of practical farmers.

We commend to the consideration of the Royal Agricultural Society the conduct of a railway company in the south of France, described in the *Bulletin de la Société botanique de France* for January of this year, to which we have already alluded (see NATURE, vol. i., p. 516). In the commune of Genlis, department of Côte-d'-Or, a berberry hedge was not long since planted on one of the railway embankments; when immediately the crops of wheat, rye, and barley in the neighbourhood became infested with rust. The complaints of the farmers caused the appointment by the company of a commission to investigate the subject, who reported, after a full inquiry, that wherever the berberry was planted the cereals were more or less attacked by rust; where they were absent the crops were free from the disease; and that the planting of a single berberry bush was sufficient to produce the rust where it had never appeared before. The railway company's own commission held that compensation was due from the company to the farmers.

Our illustration of the *Æcidium berberidis* is taken (in part) from Greville's "Scotch Cryptogamic Flora;" that of the *Puccinia graminis* from Corda's "Icones Fungorum."

ALFRED W. BENNETT

In considering the question of the influence of the berberry on the production of rust in wheat, assuming that De Bary's observations are perfectly correct, it is necessary to consider the nature of what is commonly called "rust" in cereals. Presuming that his views are strongly confirmed by the analogous connection of *Rœstelia cancellata*, the pear blight, with the gelatinous parasite of *Juniperus sabina*, it is well to attend to the following facts :—Professor Henslow in an article on the diseases of wheat, in the Journal of the Royal Agricultural Society, proved distinctly that what is commonly called rust is merely a condition of the common mildew, and this at a time when comparatively little was known about these parasites, and when many were inclined to accept the views of Unger that they were mere abnormal developments of tissue or spontaneous growths. The observations of Tulasne and others confirmed to a certain extent Professor Henslow's view, but threw further light upon the matter by showing that many so-called *Uredos* were merely a subsidiary form of so many species of *Puccinia*. Meanwhile, though *Uredo rubigo vera* was the subsidiary form of *Puccinia graminis*, it was recognised that *Uredo linearis* is nothing more than the early stage of the *Puccinia*. Though there is some resemblance between the Uredinoid form of the *Puccinia* and the rust of the berberry, there is none between the perfect condition of the parasite. Our readers will have noticed that at the meeting of the French Academy on August 1st, M. Roze contributed some further illustrations of this interesting subject.

The great difficulty has always been that mildew is most prevalent in countries where not a berberry bush is to be found ; and the same remark applies to the pear rust, which abounds where not a single plant of savine is to be seen, the parasite of the savine being comparatively of rare occurrence. I think, always assuming the fact of the connection between the two parasites, that it may be easily accounted for. It may be true that the berberry plant produces mildew ; but how is this? not probably from the spores of the present year, but from those which fell to the ground the previous season. There is no doubt that these parasites penetrate into the tissues of the young germinating plants, by means not of the original spores, but of minute secondary spores which are produced on them, a circumstance which is fully proved in the case of bunt. This, then, will account for the cereal being mildewed in the neighbourhood of the berberry. But another consideration is necessary to explain the prevalence of mildew where the berberry does not exist, or where it is confined to gardens. The subsidiary spores have no doubt, equally with the *Puccinia* itself, the property of reproducing the mildew, and there are always enough of these blown about, either from previous crops or from the neighbouring grasses, especially in the fens, where every ditch is filled with reeds affected more or less with mildew ; and thus the parasite may be propagated season after season without the Æcidioid form intervening, a circumstance which is not without analogy in other branches of the vegetable kingdom. I may be allowed, perhaps, to recall attention to an article on the development of bunt in the second volume of the Journal of the Horticultural Society of London, which seems entirely to have escaped notice on the Continent, where it is stated in a paper communicated by me on Jan. 18, 1847, with reference to the phenomena described, that " it is quite possible that in plants as well as in the lower animals there may be an alternation of generations."

M. J. BERKELEY

NOTES

A RUMOUR is current that the Government have refused both ships and assistance to the Royal and Royal Astronomical Societies, which have been for some time organising expeditions to observe the approaching total eclipse of the sun. We can hardly believe that the Government will thus venture to brave the opinion of all men of science and culture. It would be a direct acknowledgment that the Government cares as little for a recent position for England in science and the arts of peace as it did a little time ago for her position in the arts of war. Verily we are a nation of Philistines !

OUR readers will hear with great regret that Prof. Wyville Thomson is prevented by illness from taking that share in the scientific exploration of the Mediterranean basin, now about to commence, which has conduced so greatly to the success of the previous expeditions in which he has been one of the workers.

M. OTTO STRUVE, director of the Observatory at Poulkova, M. Wild, director of the Physical Observatory at St. Petersburg, and M. Mohn, director of the Meteorological Institute of Christiania, have just arrived in Paris, for the purpose of taking part in the international conference charged with establishing a universal metre. In consequence, however, of the war, the meeting of the conference is postponed until such time as it may be summoned to meet by the Government.

AMONG the chances of war which have necessitated that Paris should be placed in a state of defence against a besieging enemy, the rasing of the Bois de Boulogne has become one of the first necessary operations. The fine collection of animals belonging to the Société Impériale d'Acclimatation will then have to share the fate of those belonging to the Zoological Society of Cologne, and be dispersed or removed till better times. It is even said that the axe is already at work.

THE Franco-German War is telling heavily on science on the Continent. In the number of the *Revue des Cours Scientifiques* for August 13th, the Editor hints at the possible suspension at an early date of the publication of his journal till the war is over.

To form an idea of the results of a general armament in Germany, it will be sufficient to learn that from the Berlin Chemical Laboratory, besides a great number of students, all the assistants, seven in number, have joined the army, partly as soldiers partly as field-apothecaries. When large masses of troops passed through Berlin, the director of the laboratory placed room for twenty soldiers at the disposal of the military authorities. University lectures have been prematurely closed. The military schools, the agricultural school, and the school of architecture had to close for want of pupils. The upper forms of the grammar schools have also sent many of their pupils into the field ; one of them as many as eighteen out of forty.

THE engineering works of Messrs. Siemens and Halscke, and the ironfoundry of Borsig, are now almost exclusively occupied with the manufactory of torpedoes. It is said that great improvements have been made in these war-engines ; the point chiefly kept in view being to make them moveable from the shore by means of an electro-magnetical rotatory apparatus.

THE season for Congresses Scientific and other has now fairly set in. A Medical and an Engineering Congress are now sitting in the north ; we last week gave some of the arrangements for the forthcoming meeting of the British Association at Liverpool, and it is now announced that the Social Science Congress will meet from the 21st to the 28th of September, at Newcastle-on-Tyne, under the presidency of the Duke of Northumberland. The Social Science Congress has done what the British Association might also do to a certain extent with great advantage. It has stated the questions which press most for solution in the different branches of inquiry with which it deals. With two of these sections, namely, those of Education and Health, we are especially interested, and we willingly acknowledge the high importance of the questions which it is proposed to discuss. They are as follows :—Education. 1. Can better educational results in primary schools be obtained by the amalgamation of such schools? 2. By what means can a direct connection be established between the elementary and secondary schools and the Universities? 3. Is it desirable to teach science in elementary schools, and, if so, what branches of science? 1. Health. What is the best method of disposing of sewage and excreta? 2. What modifications are desirable in the existing sanitary laws and administration? 3. What legislative measures ought to be taken to prevent the adulteration of food, drink, and drugs?

THE British Medical Association will meet next year at Plymouth, under the presidency of Mr. Whipple, consulting surgeon to the Plymouth Infirmary.

WE have received the report of the Scottish Astronomer Royal to the Board of Visitors read at their visitation on the 29th of June. The report, in Mr. Piazzi Smyth's most curious style, refers to so many additional "facilitations" in the observatory that we may soon hope for some work to be done there, and to so many questions which have nothing to do with the observatory that we may possibly return to it.

AT the London Institution, Finsbury Circus, on the 10th inst. Mr. J. P. Gassiot, D.C.L., F.R.S., distributed the prizes awarded, and certificates granted to students who have passed examinations on courses of Educational Lectures delivered during the past session. In the examination connected with Prof. Guthrie's course on Elementary Physics, Edmund Strode gained the first prize, while T. Lyon, Miss Esther Greatbatch, and Miss Annie Piper obtained prizes of the second order. In the examination on Professor Bloxam's chemical lectures, A. J. Richardson obtained the first prize, Isidore Harris and Miss E. M. Hutton taking second prizes. In the examination on Prof. Bentley's botanical course, Miss Emma Ball took the first prize; and A. J. Wallis and Miss Ellen Benham second prizes. Mr. Gassiot stated that the Educational Lectures of the London Institution were commenced in the spring of 1869, by Prof. Huxley, and that the attendance of students from the leading metropolitan schools had fully justified the belief of the managers that increased facilities for scientific education were needed. In distributing the prizes, which consisted of standard scientific books, handsomely bound, Mr. Gassiot referred to the early days of some of the eminent authors and discoverers who had been connected with the London Institution. He stated that arrangements for developing the educational powers of the institution were in progress, and delighted his audience by the announcement that Professors Odling and Huxley would deliver courses of lectures early in the coming session.

WE have had from time to time to record evidences of the increased interest in science felt in the United States. We have just received the first number of the *American Scientific Monthly*, published at Iowa City, and edited by Prof. Gustavus Hinrichs. It contains articles of a popular rather than a deeply scientific character, on various branches of science, chemistry, geology, physics, physiology, &c.

THE Sars subscription fund has now been closed, the total amount received being 12,283 francs.

M. DAVAUNE states, in a recent number of *Cosmos*, that the proposal to raise a subscription on behalf of M. Niepce de St. Victor has met with a warm and hearty response.

REFERRING to the note in our issue of July 28, L'Abbé Moigno makes the following reply in *Les Mondes*:—"Le journal NATURE a émaillé de points d'exclamations notre petit article sur les silex du Sinaï. Il s'étonne que nous nous soyons fait fort de prouver jusqu'à l'évidence que ces silex sont plus vieux que ceux des grottes d'Aurignac et autres. M. Louis Buchner, dont la NATURE devrait bien reproduire les propres paroles, l'a dit avant nous. Il s'étonne plus encore de notre confiance dans le progrès, et rappelle de notre appel à M. Sorby:—attendons; le spectroscope jugera entre nous. En tout cas, c'est déjà quelque chose que des silex ou couteaux en pierre, vieux de 3,350 ans."

MR. ERNEST HART has been unanimously elected Editor of the *British Medical Journal*, in the place of Mr. Jonathan Hutchinson.

THE death is announced, at the age of 75, of Baron Charles von Hügel, one of the founders of the Horticultural Society at Vienna, and a collector, on a large scale, of new Australian plants. He was the author of several botanical works, and held the office of Austrian plenipotentiary at the court of Brussels.

IT is hoped that the Cornell University will be able to form the nucleus of a museum, as Professor C. Fred. Hartt, with a professor of botany and nine students, intends exploring a portion of the valley of the Amazon and the Brazilian coast southward to Bahia, and to collect objects in natural history and geology. Professor Hartt proposes to take stereoscopic views of interest along his route.

THE Royal Academy of Sciences of Belgium offers a prize of 800 francs for an essay on the Affinities of *Lycopodiaceæ*. The essays should be written in Latin, French, or Flemish, and forwarded to M. Ad. Quetelet, the secretary of the Academy, at Brussels, before June 1, 1871.

THE practical examination of workmen and students for the Whitworth Scholarships has been fixed by Sir Joseph Whitworth to take place at his works at Manchester, on the 30th August and 1st September next.

THE *Engineer* gives a plan and section of a proposed tunnel under the Bosphorus, planned by Mr. J. Haddan, one of the chief engineers to the Turkish Government. Unlike Messrs. Bateman and Révy's proposed Channel railway, the idea is to suspend the tunnel at about thirty-five feet below the surface of the water, and fix it to the bottom by means of holding chains.

MR. GEORGE FAWCUS, of North Shields, has contrived an equilateral triangular drawing-board for isometrical drawing. An ordinary T square applied on the edges of an equilateral triangle draws tangents that meet each other at angles of 120°, and other lines drawn parallel to these radiating ones form with them angles of 60° and 120°, which are the exact angles of the apparent squares of isometrical cubes. The inventor believes that the use of this new drawing-board will make the teaching of isometrical drawing both simple and easy. The practice of isometrical drawing is strongly urged in the science and art drawing classes.

A REMEDY has been found for the "borer" that ravages Indian and Ceylon coffee plantations, by applying carbolic acid before the eggs are hatched.

THE curator of the Botanical Exchange Club has just issued his Report for the year 1869. Dr. Boswell-Syme takes the opportunity of recording all the observations which have come under his notice respecting new forms or varieties of British plants, or new localities of the rarer species.

PROF. CHANDLER, chemist to the Metropolitan Board of Health, New York, gives, in the *American Scientific Monthly*, his analysis of fifteen different kinds of fashionable hair-tonics, restoratives, &c., in all of which he finds lead varying in amount from one-ninth of a grain to sixteen grains in the ounce. He states that they owe their action to this metal, and are, consequently, highly dangerous to the health of persons using them. Lotions for the skin he found to be free from lead or other injurious metals, with the exception of one containing corrosive sublimate. The enamels examined consisted of either carbonate of lime, oxide of zinc, or carbonate of lead, suspended in water. The latter kind are highly dangerous; the two former are "as harmless as any other white dirt when plastered over the skin to close the pores and prevent its healthy action." The white powders for the skin are harmless to the same extent.

THE *Western Monthly* (Chicago), in its August number, has a very readable article on Sun Spots and their lessons, in which the author discusses the consequences of the obscuration of one part in one hundred and thirty of the sun's visible surface in the present year, and thinks that he is about to open one of the sealed volumes which contains the principles of prognostic meteorology.

THE "Proceedings of the Birmingham Natural History Society and Microscopical Society" for 1869, is another of those records of natural history researches in the provinces, of which we have so many gratifying instances, the more valuable when coming from the centre of a manufacturing district, where the thoughts of men are naturally turned in such very different channels. We have papers of various lengths on mineralogy, botany, microscopy, physiology, geology, entomology, malacology, and other branches of natural history, showing, if not much originality, much careful observant work. Appended are preliminary lists of the flowering plants, mosses, Lepidoptera, and Mollusca found within a radius of ten miles from Birmingham, a by no means inconsiderable array.

THE astronomical and meteorological observations of the National Observatory of Santiago, in Chile, have now been regularly published since 1853, chiefly by Don José Tomas Vergara. They also include the Valparaiso meteorological observations.

CINCHONA culture has now so far advanced in Madras that the Government is preparing to deal with it as an annual crop.

MR. WORTHINGTON SMITH records in the *Journal of Botany* an instance of a fatal case of poisoning by eating the root of the Water-dropwort, *Œnanthe crocata*, an umbelliferous plant common in ditches and wet places. A carter at Staplehurst, in Kent, ate some of the roots whilst at work, supposing them to be the wild parsnip; in about an hour he became unconscious and convulsed, and death occurred in another half-hour, before medical aid could be obtained. The man had fed his horse with roots of the same plant, and the animal also expired about two hours after eating them. There is no doubt that the *Œnanthe* is a virulent poison, but it seems strange that the horse, as well as the man, should not have rejected a plant of so acrid and suspicious a flavour. Several wild Umbelliferæ are among the most dangerous of British plants, and it is probable that the Greek poison κώνειον was obtained from others besides the hemlock.

SHARKS appear to have recently again made their appearance in the Gulf of Trieste, and the police have issued a notice forbidding people to bathe in the port or on the coast. For each fish destroyed in the waters between Punto Grona and the castle of Duino a reward of 300 florins (about 30*l.*) is given.

THE Indian Government has selected the Khond Hills for cinchona experiments. If they succeed the cultivation will be thrown open to private enterprise, with the view of further promoting employment and cultivation among the Khonds.

THE extent of the Wurdah coal-field in India has been confirmed, and the seams in Berar have been found to be 45 feet in total thickness.

THE total eclipse of July was observed at Constantinople by the Rev. C. Gribble, H.B.M. Chaplain, formerly of the Royal Navy, a local astronomical observer. He contributes an account to the *Levant Herald* of July 20. The dogs of Constantinople continued barking until about the middle of the eclipse.

WE have had occasion to refer to wild-beast legislation and administration, an important matter in India. A curious discussion has arisen in Bombay. Tigers having come to Salsette and killed several people, the magistrates applied to increase the reward, but the Government have refused, thinking that the report of the presence of tigers there will attract English sportsmen from Bombay.

"A CATALOGUE of Maps of the British Possessions in India and other parts of Asia," published by order of Her Majesty's Secretary of State for India in Council, is a very useful publication for those interested in our Asiatic possessions.

THE first and second quarterly publications for 1870 are issued of Auwers' and Winnecke's "Vierteljahrsschrift der Astronomischen Gesellschaft."

DR. SACHS'S "Lehrbuch der Botanik nach dem gegenwärtigen Stand der Wissenschaft" has reached a second enlarged and partly rewritten edition. It is illustrated with 453 woodcuts.

DR. KARL KARMARSCH'S "Technological Dictionary, English, French, German," of which the second edition is just issued, is a most useful compilation, containing the corresponding terms in these three languages employed in Architecture, civil, military, and naval; Civil Engineering, including bridge building, road and railway making; Mechanics, machine and engine making; Ship Building and Navigation; Metallurgy, mining and smelting; Artillery; Mathematics; Physics; Chemistry; Mineralogy; and generally in the Arts and Sciences.

DR. ENGELMANN publishes the first part of his "Results of Observations in the Leipzig Observatory," comprising those made with the meridian-circle.

M. VIDAL'S statement (says the *Photographic News*), that a sensitive plate, if exposed to light in the camera, and then placed behind the yellow glass window of a dark room, becomes attacked by the yellow rays and yields a fogged image, whereas a sensitive plate previously unexposed to light is not affected in the same manner, has been confirmed by results obtained in America, and detailed in the *Philadelphia Photographer*.

PAPERS ON IRON AND STEEL

I.—A VERY COSTLY AND VEXATIOUS FALLACY

I.

"A FRIEND of mine has been converting some common cinder pig-iron into either very fine iron or steel by a very simple process, but does not know who to apply to to learn its value. He is willing to share the profit with anyone who will help him in the matter. I have some small samples of it if you would like to see it, or can tell me who would be likely to interest themselves in the matter. From what I can make out I should think it would make good steel, for it will harden and temper now."

The above, quoted from a letter I have recently received, is a typical sample of a number of others I have had at different times, and it represents the labours of quite a multitude of patient, long-suffering, and miserably deluded investigators. The published specifications of abandoned patents make painful record of wasted money, time, and ingenuity; and suggest dark tragedies of ruined hopes, all arising from the same misunderstanding of the changes which take place in the conversion of *ordinary* pig-iron or cast-iron into *merchantable* steel.

The most humiliating feature of this delusion is that it is not the offspring of popular ignorance, is not prevalent among the beer-drinking class of iron-workers, who sign their names with a ×, but crops out among intelligent self-taught men, who have studied the chemistry of iron and steel as expounded in recognised chemical books. The costly fallacy I allude to is directly traceable to the teachings of our highest scientific authorities. As NATURE is now largely circulating among the class of self-taught and energetic men who supply this ever-recurring crop of victims, and also among those who most unwittingly and unwillingly have deceived them, there can be no better medium through which to effect the demolition of this mischievous error.

By reference to almost any text-book on chemistry, it will be found that cast-iron is described as a compound or mixture of iron and carbon; that steel is another compound or mixture of iron and carbon, but with a less proportion of carbon; and that wrought iron is nearly free from carbon. Further, we are told that the ordinary method of making steel is, first to remove all the carbon from the cast or pig-iron by making it into wrought or bar-iron, and that this bar-iron is afterwards converted into steel by causing it to take up a new dose of carbon in the cementing furnace. The natural inference of a thinking reader is, that this is a clumsy complication, especially if he knows that the process of cementation is slow and costly, that on account of the irregular diffusion of the carbon in the blistered bars, other expensive processes of shearing, tilting, casting, &c., have to follow. Why not at once produce the steel from cast-iron by a process of decarburisation which shall stop at the right point, *i.e.*, when the 3 or 4 per cent. of carbon of the cast-iron is reduced to the one or one and a half per cent. required to produce steel? By doing this, not only the cost of converting wrought-iron into steel, but also the cost of puddling to produce wrought-iron will be saved; and steel, which is but a carburet of iron intermediate between cast and wrought-iron, instead of being so much dearer than either, should be made at an intermediate cost, or cheaper than wrought-iron.

If he dips further into the literature of the subject, and reads the history of the manufacture of iron, he will find further confirmation of such reasoning, as he will learn thereby that the direct production of steel is an ancient art, and that weapons of renowned quality were made from steel thus produced.

By reference to one of the most recent and elaborate English treatises on the subject, Dr. Percy's "Metallurgy," he will find on page 778 that this is described as "the ancient method, which is still extensively practised on the Continent, especially in Styria;" and further down on the same page that "if steel be regarded simply as iron carburised in degrees intermediate between malleable and cast-iron, then it is obvious that the latter during its conversion into the former in the processes of fining and puddling, must pass through the state of steel." On page 805 of the same work he will find further confirmation of his theory in the words, "it is obvious that steel must be produced by melting malleable and cast-iron together in suitable proportions."

I might multiply quotations from this and every other work I have seen in which the chemistry of iron and steel is treated, and show by each of them that the thousand-and-one of unfortunate inventors who have struggled in vain to make steel directly from English pig-iron, have been encouraged in their delusion by the teachings of high chemical authorities.

"If steel be regarded simply as iron carburised in degrees intermediate between malleable and cast-iron," these inventors are perfectly justified in seeking some substance which at the melting heat of cast-iron shall give off a definite quantity of oxygen; and they have logical grounds for believing that by bringing such a substance in contact with the molten cast-iron, and properly regulating its quantity, they may burn out just that surplus carbon which makes all the stated difference between cast-iron and steel. As a multitude of compounds when thus heated do give off oxygen, a vast field of effort is open, and accordingly every available peroxide and decomposable oxygen salt has been administered by strange devices to the melted iron, the same obvious substances used over and over again, and the same failures continually repeated by expectant inventors ignorant of what each other have done or are doing. Gas and vapours have been blown over the surface and under the surface, and through from bottom to top of melted cast-iron, and all (including Mr. Bessemer) have failed to produce merchantable steel from ordinary English cast-iron, without first making it into malleable or wrought-iron.

The reason of this is, that the removal of the surplus carbon is only a small portion of the work which has to be done in order to convert cast-iron into steel of any commercial value. Several other substances have to be removed also; *and no process has yet been discovered by which these impurities can be removed without at the same time removing the carbon in corresponding degree.* I put this in italics because I am convinced by experience of its great practical importance; because I do not find it clearly and distinctly enunciated in any general or special treatise; and further, because I have seen so plainly that the want of clearly understanding it is the rock upon which so many unfortunate inventors have split.

These inventors have not been informed with anything like the necessary degree of distinctness, that the Styrians and others who have made, or are making, steel directly from cast-iron, have started with a very different material to that which bears the same name of cast-iron in England; the difference being sufficiently great to alter totally the conditions of the problem. The cast-iron of the Styrian steel-makers is a nearly pure carburised iron; *our* cast-iron is a carburised, silicised, phosphurised, and sulphurised iron; *their* problem in steel-making is, merely the partial decarburisation of their cast-iron; *ours* is the total desilicisation, the total dephosphurisation, and the total desulphurisation in addition to this. Now, the partial removal of carbon from iron is one of the very easiest problems in practical metallurgy, while the complete removal of silicon, phosphorus, and sulphur, is among the most difficult.

To illustrate the grossness of the fallacy which represents the difference between cast-iron and steel as merely, or "essentially," due to carbon, I may state that on looking down a tabular statement of the analyses I have recently made of thirty brands of ordinary English pig-iron (excluding hæmatite pigs), I find that seven among them contain less than 2 per cent. of carbon, or an average of 1·77 per cent. Now this is below the percentage of carbon which exists in some of the finest and most expensive samples of cast-steel. Therefore, to convert these particular brands of cast-iron into the finest steel, the carbon must neither be increased nor diminished, and if, as Dr. Percy says, the differences between steel, wrought-iron, and cast-iron, "*essentially* depend upon differences in the proportion of carbon," all these brands of pig-iron should be described as steel rather than cast-iron.

Nevertheless they are utterly worthless for any of the purposes for which steel is used, and the common result of the costly experiments of the inventors who endeavour to make steel directly from English pig-iron, is to produce a material very much like them. They usually succeed perfectly in their effort partially to decarburise the pig iron. They take out, say one half of the carbon, and with it a considerable portion of the silicon, and *some* of the phosphorus, sulphur and manganese; but to make a *perfect* steel they must take out *all* of these latter, and leave nothing but pure iron and carbon. Absolute perfection is not, of course, practically attainable in steel-making, but it is approximated in exactly the same degree as the purification of the iron from everything excepting the carbon is effected.

The most notable modern attempt to produce steel directly by the simple decarburisation of English cast-iron was that of Mr. Bessemer. His first idea was to blow air through melted cast-iron, and thereby to oxidise the carbon, and then, when a sufficient degree of decarburisation was effected, to stop the blowing. He supposed that when by this means the proportion of carbon was reduced to about one and a half per cent. the result would be useful steel. He failed entirely in this; he never succeeded in producing merchantable steel from ordinary English cast-iron by this method.

The Bessemer process, as at present conducted, consists in first oxidising simultaneously all or nearly all the carbon and silicon, and then adding to the decarburised iron a new dose of carbon, by means of a known quantity of spiegeleisen of known composition; thus reverting to the old Sheffield principle of first bringing the cast-iron to the state of wrought or decarburised iron, and then adding carbon to convert it into steel.

It is commonly represented that the failure of the early attempts at direct steel-making by the Bessemer process arose simply from the difficulty of determining the right moment at which to stop the blow, and thereby to regulate the proportion of carbon; and that the whole advantage of the spiegeleisen is the means it affords of doing this. Dr. Percy says:—"In attempting to produce steel by the methods specified by Bessemer, it has hitherto been found very difficult, if not impracticable, *at least in this country*, to ascertain with certainty when decarburisation has proceeded to the right extent, and when therefore the blast should be stopped. Accordingly the plan now adopted is to decarburise perfectly, or nearly so, and then add a given proportion of carbon in the state in which it exists in molten spiegeleisen, the precise composition of which should of course be known."* Neither in Dr. Percy's nor any other account of the Bessemer process do I find that the necessity of complete decarburisation as a means of completely separating the silicon is fairly appreciated.

If merchantable steel could be made from English pig-iron by simply stopping the blow before complete decarburisation, Mr. Bessemer would surely have produced some good steel in the course of his long and costly efforts which preceded the idea of introducing the spiegeleisen, for it must be remembered that the quantity of carbon required in steel extends over a very wide range—that steel may contain from 0·40 to 2·00 per cent. of carbon, and that steel with every degree of carburisation within this wide range is in demand in the market at good prices, provided it be free from phosphorus, silicon, &c. Nothing is practically easier than to stop the blow at such a moment as shall ensure a degree of carburisation somewhere between this wide range; and there can be no doubt that, in his early experiments, Mr. Bessemer, like other inventors of direct processes, made an abundance of iron that was duly carburised within the above-stated limits, although he failed to produce useful steel.

Dr. Percy's qualification, "at least in this country," is rather curious. He has probably learned that steel has been directly made in Sweden (though he does not mention it in his work) by the Bessemer process, and he seems to attribute this to the superior ability of the Swedish operators, enabling them "to ascertain with certainty when decarburisation has proceeded to the right extent." I differ entirely from Dr. Percy in this conclusion, being convinced that Mr. George Brown, the manager of the Bessemer Department at the Atlas Works, Sheffield, who was the first to work the Bessemer process with commercial success, is better able (on account of his much greater experience and thorough knowledge of the work) than any of the Swedish manufacturers, to determine when any required degree of decarburisation has been attained. It is not the superior skill of the Swedish operators that has enabled them to make steel directly by the Bessemer process; but the fact that they, like the Styrian workers, used a very superior charcoal-iron to start with; and that the blowing out of all the carbon was not absolutely necessary for the sufficient purification of this quality of iron.

W. MATTIEU WILLIAMS

* "Metallurgy," "Iron and Steel," p. 814. The italics are my own.

ON THE NATURAL LAWS OF MUSCULAR EXERTION

THE experiments published by Mr. W. Stanley Jevons, in NATURE on the 30th June last, illustrate well two laws of muscular exertion which were established by experiments made by myself in 1862 and 1863. These laws may be thus stated:—

Law 1. The work given out by a single group of muscles, in a single contraction, is constant.

Law 2. When the same group of muscles is kept in constant action, the total work done by them until fatigue sets in, multiplied by the rate at which they are compelled to work, is constant.

Mr. Jevons' first series of experiments, in which different weights were thrown by the arm to various distances on level ground, illustrates the first law. In throwing weights in this manner, the arm, after a little practice, instinctively pitches the weight at the angle corresponding to the maximum range, and as the maximum range is proportional to the square of the velocity of projection, it may be used to replace that velocity squared, in estimating the work done by the arm.

The total work done is the same as if the weight used and the weight of the arm were concentrated at the centre of oscillation of the loaded arm, regarded as a compound pendulum.

Let us assume

w = weight held in hand;
x = weight of arm;
v = velocity of centre of oscillation.

By Law 1, the work done is constant and is represented by

$$(w + x)\, v^2 = \text{const.} \qquad (1)$$

Let

V = velocity of hand;
l = radius of oscillation;
a = length of arm.

then

$$v = V\frac{l}{a} \qquad (2)$$

It is easy to show (assuming the arm to be a uniform cylinder) that

$$\frac{l}{a} = \frac{2}{3} \cdot \frac{(3\,w + x)}{(2\,w + x)} \qquad (3)$$

By means of (2) and (3), equation (1) becomes

$$\frac{(w + x)\,(3\,w + x)^2}{(2\,w + x)^2} \times R = A; \qquad (4)$$

where R denotes the range (proportional to V^2) and A denotes a constant, if Law 1 be true.

Mr. Jevons' experiments give the following corresponding values of w and R.

w	R
56 lbs.	1·84 ft.
28 ,,	3·70 ,,
14 ,,	6·86 ,,
7 ,,	10·56 ,,
4 ,,	14·61 ,,
2 ,,	18·65 ,,
1 ,,	23·05 ,,
½ ,,	27·15 ,,

We are required to assign certain values to x and A, which will make equation (4) best coincide with the eight simultaneous values of w and R found by observation.

I find by trial that these values are

$$x = 8{\cdot}1 \text{ lbs.}$$
$$A = 262{\cdot}2.$$

If we solve equation (4) for R, we find

$$R = \frac{A\,(2\,w + x)^2}{(w + x)\,(3\,w + x)^2} \qquad (5)$$

Substituting for A and x in this equation their values above given, we can obtain by calculation the distances to which the weights should be thrown, according to Law 1.

We thus obtain the following comparison between theory and observation.

w	R (observed).	R (calculated).	Difference.
56 lbs.	1·84 ft.	1·90 ft.	−0·06 ft.
28 „	3·70 „	3·51 „	+0·19 „
14 „	6·86 „	6·06 „	+0·80 „
7 „	10·56 „	10·02 „	+0·54 „
4 „	14·61 „	13·90 „	+0·71 „
2 „	18·65 „	19·11 „	−0·46 „
1 „	23·05 „	23·85 „	−0·80 „
½ „	27·15 „	27·39 „	−0·24 „

The agreement here shown between observation and calculation founded on Law 1, is quite as complete as the agreement between observation and the empirical formula used by Mr. Jevons, which may be written, in the notation of the present paper, as follows :—

$$(2w + 7·8)\,R = 231·3. \qquad (6)$$

Mr. Jevons' third series of experiments consisted in holding various weights on the hand extended horizontally, and noting the time during which the weights could be so held. The following are the weights and times observed :—

w	t
18 lbs.	14·8 secs.
14 „	32·5 „
10 „	60·3 „
7 „	87·4 „
4 „	147·9 „
2 „	218·9 „
1 „	321·2 „

Omitting the first of these experiments I find that Law 2 satisfactorily accounts for the remaining six, and gives a constant, which is nearly identical with that obtained from my own experiments made in 1863.

When the arm is extended horizontally, if allowed to fall through an indefinitely small arc, the centre of oscillation falls like a free body under the influence of gravity, and the muscles then lift back the arm through the same arc, and this goes on continuously until the muscles are tired out.

Let us use the following notation :—

w and x are, as before, the weight held in the hand and the weight of the arm.

l = radius of oscillation ;
a = distance of centre of gravity of loaded arm from centre of shoulder joint ;
δs = small space through which the centre of oscillation falls ;
n* = number of such falls during
t = whole time required to fatigue the muscles.

The total work done by the muscles in the time t, is evidently

$$(w+x)\frac{a}{l}\,n\,\delta\,s;$$

but, $n\,\delta\,s$ varies as t, and, therefore, the total work done varies as

$$(w+x)\frac{a}{l}t.$$

The *rate* of work is evidently proportional to

$$(w+x)\frac{a}{l}$$

and since, by Law 2, the total work done before fatigue multiplied by the rate of work is constant, we obtain

$$(w+x)^2\frac{a^2}{l^2}t = \text{Const.} \qquad (7)$$

* I have ascertained the number n from acoustical observations made on the muscular *susurrus*.

And, since

$$\frac{a}{l} = \tfrac{3}{4}.\frac{(2w+x)^2}{(w+x)(3w+x)}, \qquad (8)$$

we find, by substitution,

$$\frac{(2w+x)^4}{(3w+x)^2}t = a. \qquad (9)$$

This equation (9) is the statement of Law 2, as applied to Mr. Jevons' experiments ; and we are required to find values for x and a, which will make equation (9) best correspond with the given observations.

I find, by trial, that the following values will answer best :—

$$x = 7·4 \text{ lb.}$$
$$a = 22{,}050.$$

If we solve equation (9) for t, we find

$$t = A\frac{(3w+x)^2}{(2w+x)^4}. \qquad (10)$$

From this equation, substituting the values of x and A, we obtain the following comparison of observation and theory :

w	t (observed).	t (calculated).	Difference.
14 lbs.	32·5 secs.	34·2 secs.	− 1·7 secs.
10 „	60·3 „	54·7 „	+ 5·6 „
7 „	87·4 „	84·8 „	+ 2·6 „
4 „	147·9 „	147·6 „	+ 0·3 „
2 „	218·9 „	234·4 „	− 15·5 „
1 „	321·2 „	305·5 „	+15·7 „

This comparison is very satisfactory, the differences being much less than possible errors of observations. Mr. Jevons' experiments further show that the *useful effect* has a maximum corresponding to a certain weight. This weight, which gives the maximum of useful effect, may be readily calculated from Law 2.

By equation (10), the useful effect is

$$w\,t = A\,.\frac{w\,(3w+x)^2}{(2w+x)^4}. \qquad (11)$$

This will be a maximum, when

$$(2w+x)\,(9w+x) = 8\,w\,(3w+x)\,;$$

or when

$$6w^2 - 3\,x\,w - x^2 = 0\,;$$

or when

$$w = \frac{3+\sqrt{33}}{12}x; \qquad (12)$$

or,

$$w = 0·73\,x.$$

Substituting for x its value 7·4lb., we find for the weight that gives the maximum useful effect,

$$w = 5·40\text{lb.}$$

The useful effect observed by Mr. Jevons was as follows :

w	Useful effect
18 lbs.	266
14 „	455
10 „	603
7 „	612
4 „	592
2 „	438
1 „	321

The actual maximum corresponds to 5·4lb. lying between 7lb. and 4lb.

I may observe, in conclusion, that the difference of weights x of the arm, found in the two sets of experiments is quite natural.

In the experiments in which the arm was held out horizontally, its weight, 7·4lb., is the weight of the arm below the centre of the shoulder joint.

In the experiments in which the weights are thrown by the arm, a portion of the shoulder blade is in motion, in addition to the simple arm, and the total weight becomes 8·1lb.

SAMUEL HAUGHTON

PROFESSOR ABEL'S CONTRIBUTIONS TO THE HISTORY OF EXPLOSIVE AGENTS *

THE degree of rapidity with which an explosive substance undergoes metamorphosis, as also the nature and results of that metamorphosis, are, in the greater number of instances, susceptible of several modifications by variations of the circumstances under which the conditions essential to chemical change are fulfilled. Gun-cotton furnishes an excellent illustration of the manner in which such modifications may be brought about. If a loose tuft or large mass of gun-cotton-wool be inflamed in open air by contact with, or proximity to, some source of heat, the temperature of which is about 135° C. or upwards, it flashes into flame with a rapidity which appears almost instantaneous, the change being attended by a dull explosion, and resulting in the formation of vapours and gaseous products, of which nitrogen-oxides form important constituents. If the gun-cotton be in the form of yarn, thread, woven fabric, or paper, the rapidity of its inflammation in open air is reduced in proportion to the compactness of structure or arrangement of the twisted, woven, or pulped material; and if it be converted by pressure into compact masses, solid throughout, the rate of its combustion will be still further reduced. If to a limited surface of gun-cotton, when in the form of a fine thread or of a compactly pressed mass, a source of heat is applied, the temperature of which is sufficiently high to establish the metamorphosis of the substance but not adequate to inflame the products of that change (carbonic oxide, hydrogen, &c.), the rate of burning is so greatly reduced that the gun-cotton may be said to smoulder without flame; the reason being that the products of change, which consist of gases and vapours, continue, as they escape into air, to abstract the heat developed by the burning gun-cotton so rapidly that it cannot accumulate to an extent sufficient to develop the usual combustion, with flame, of the material. For similar reasons, if gun-cotton be kindled in a rarefied atmosphere, the change developed will be slow and imperfect in proportion to the degree of rarefaction, so that, even if an incandescent wire be applied, in a highly rarefied atmosphere, to the gun-cotton, it can only be made to undergo the smouldering combustion, until the pressure is sufficiently increased by the accumulating gases to reduce very greatly the rate of abstraction, by these, of the heat necessary for the rapid combustion or explosion of the substance. If, on the contrary, the escape of the gases from burning gun-cotton be retarded, as by enclosing it in an envelope or bag of paper, or in a vessel of which the opening is loosely closed, the escape of heat is impeded until the gases developed can exert sufficient pressure to pass away freely by bursting open the envelope or aperture, and the result of the more or less brief confinement of the gases is a more rapid or violent explosion, and consequently more perfect metamorphosis of the gun-cotton. So, within obvious limits, the explosion of gun-cotton by the application of flame or any highly heated body is more perfect in proportion to the amount of resistance offered in the first instance to the escape of the gases; in other words, in proportion as the strength of the receptacle enclosing the gun-cotton, and the consequent initial pressure developed by the explosion, is increased. Hence, while gun-cotton has been found too rapid or violent in its explosive action when confined in guns, and has proved a most formidable agent of destruction if enclosed in metal shells or other strong receptacles, it has hitherto been found comparatively harmless as an explosive agent if inflamed in open air or only confined in weak receptacles. Modifications, apparently slight, of the manner in which the source of heat is applied to explosive agents, when exposed to air under circumstances in other respects uniform, suffice to modify the character of their explosions in a remarkable manner. Thus a modification of the position in which the source of heat is placed with reference to the body of a charge of gunpowder, which is only partially confined, suffices to alter altogether the character of the explosion produced.

The product of the action of nitric acid upon glycerine, which is known as nitroglycerine or glonoine, appears to be susceptible of only two varieties of decomposition. If a sufficient source of heat be applied to some portion of a mass of this liquid in open air, it will inflame and burn gradually without any explosive effect; and even when nitroglycerine is confined, the development of its explosive force by the simple application of flame or of other sources of heat, by the ordinary modes of operation, is difficult and very uncertain. But if the substance be submitted to a sudden concussion, such as is produced by a smart though not very violent blow from a hammer upon some rigid surface on which the nitroglycerine rests, the latter explodes with a sharp detonation, just as is the case with gun-cotton. Only that portion of the explosive agent detonates which is immediately between the two surfaces brought into sudden collision; the confinement of this portion between the hammer and the support, combined with the instantaneous decomposition of the portion struck, prevent any surrounding freely exposed portions from being similarly exploded by the detonation. A similar result is obtained if any explosive compound or mixture be submitted to a sufficiently sharp and violent blow, but the tendency of surrounding particles to become inflamed by the detonation is in direct proportion to the rapidity of explosive action of the substances. The practical difficulties and uncertainty which attend attempts to develop the explosive force of nitroglycerine by the agency of flame or the simple application of any highly heated body, even when the material is confined in strong receptacles (such as iron shells or firmly tamped blast-holes), appeared fatal to any useful application of the powerful explosive properties of this substance, until M. Alfred Nobel's persevering labours to utilise nitroglycerine, eventually resulted in the discovery of a method by which the explosive power of the liquid could be developed with tolerable certainty. M. Nobel first employed gunpowder as a vehicle for the application of nitroglycerine. By impregnating the grains of gunpowder with that liquid, he added considerably to the destructive force of the powder when exploded in the usual way in closed receptacles. M. Nobel's subsequent endeavours to apply nitroglycerine *per se* were based upon the belief that its explosion might be effected by raising some portion of a quantity of the liquid to the temperature necessary for its violent decomposition, whereupon an initiative explosion would be produced which would determine the explosion of any quantity of the substance.

The circumstance that nitroglycerine, or any preparation of that substance, may be violently exploded when freely exposed to air, by the explosion in contact with it of a small confined charge of gunpowder, or of a detonating substance, while other modes of explosion by the application of heat or flame, which have been described by M. Nobel, only develop explosion under special conditions, points to a decided difference between the action of the two modes of ignition, and appears to indicate that it is not simply the heat developed by the chemical change of the gunpowder or detonating powder which determines the explosion of the nitroglycerine. An experimental investigation of this subject has left no doubt on my mind that the explosion of nitroglycerine through the agency of a small detonation is due, at any rate in part, to the mechanical effect of that detonation, and that this effect may operate in exploding the nitroglycerine, quite independently of any direct action of the heat disengaged.

The readiness and certainty with which gunpowder, gun-cotton, and other explosive substances may be detonated through the agency of a blow from a hammer or a falling body, are regulated by several circumstances; they are in direct proportion to the weight of the falling body, to the height of its fall, or the force with which it is impelled downwards, to the velocity of its motion, to the mass and rigidity, or hardness, of the support or anvil upon which the body falls; to the quantity and mechanical condition of the explosive agent struck, and to the ready explosibility of the latter. Thus a sharp blow from a small hammer upon an iron surface will detonate gunpowder with very much greater certainty than the simple fall of a heavy hammer, or than a comparatively weak blow from the latter. It is very difficult, by repeated blows applied at very brief intervals, to ignite gun-cotton, if placed upon a support of wood or lead, both of which materials yield to the blow, the force set into operation by that blow being transferred through the explosive agent and absorbed in work done upon the material composing the support. If, however, the latter be of iron, which does not yield permanently to the blow of the hammer, the detonation of these substances is readily accomplished. If the quantity of explosive agent employed be so considerable as to form a thick layer between the hammer and support, the force applied appears to be to so great an extent absorbed in the motion imparted to the particles of the comprehensible mass, that its explosion is not readily accomplished; and if the material be in a loose or porous condition (as, for example, in a state of powder or of loose wool), much work has to be accomplished in moving particles of the mass through a comparatively considerable space,

* An abstract of a paper, by Prof. Abel, F.R.S., Chemist to the War Department, in the Philosophical Transactions.

and a second or even third blow is therefore required to determine its explosion.

These circumstances would appear to afford support for the belief that the detonation of an explosive material through the agency of a blow is the result of the development of heat sufficient to establish energetic chemical change, by the expenditure of force in the compression of the material, or by the friction of the particles against each other, consequent upon a motion being momentarily imparted to them. It is conceivable that, from either of these causes, sufficient heat may be accumulated with almost instantaneous rapidity, in some portion of the mass struck, to develop sudden chemical change. The circumstance that the detonation of those portions of an explosive compound (such as gun-cotton or nitroglycerine) which are immediately between the surfaces of the hammer and the support is not communicated to the surrounding portions, may be ascribed to a combination of two causes, the instantaneous nature of the explosion, and the close confinement of the portions struck at the instance of their explosion. The mechanical effect of the detonation is absorbed by the masses of metal between which it occurred, and the gases developed disperse the surrounding portions of the explosive agent, as they rush away from between the two surfaces. It is possible also to detonate gunpowder and other explosive mixtures by a blow in such a manner that only the portions immediately struck are ignited; but those substances may also be exploded, though much less violently, by a less sudden or powerful application of force, in which case they detonate much more feebly; their explosion is accompanied by a larger volume of flame, and by the ignition of those portions which surround the part struck by the hammer. The power of accomplishing the explosion or detonation of gun-cotton or nitroglycerine in open air through the agency of a detonation produced in its vicinity, would therefore appear to be correctly ascribable to the heat suddenly developed in some portion of the mass by the mechanical effect, or blow, exerted by that detonation, and would seem to be regulated by the violence and suddenness (either singly or combined) of the detonation, by the extent to which the explosive material is in a condition to oppose resistance to the force, and by the degree of sensitiveness of the substance to explosion by percussion. There are, however, several well-known facts, and some results of experiments instituted with special reference to this subject, which do not appear to be in harmony with the assumption that the detonation of nitroglycerine and gun-cotton in the manner described is simply due to the *suddenness* of the development and application of physical force.

With the view of ascertaining whether the relative power of different explosive agents to accomplish the detonation of gun-cotton appears to be in direct proportion to the relative mechanical effects of their explosion (*i.e.* to the work performed by them upon a body placed in contact with them), a series of experiments was instituted with the object of comparing this particular action of the several explosive materials. It would appear from these experiments that, when unconfined, the violence of explosion of chloride of nitrogen is less than that of the iodide, and that, if confined under water, it very considerably exceeds that of the exposed iodide, but falls very short of that exerted by unconfined silver-fulminate. It also appears that the mercuric fulminate, which is much less rapidly explosive than either of the other substances, exerts less mechanical force than any of them, if freely open to air, and if inflamed at some portion of the exposed surfaces; if ignited at the lower inner portion of the mass, where the part first inflamed is enclosed by the mass of the material itself, it exerts a destructive force little inferior to that of the chloride of nitrogen enclosed by water; but if confined in a strong envelope (*e.g.* of sheet tin), the mercuric fulminate is greater in violence of action than the unconfined silver-fulminate. These results to a great extent confirm the correctness of the view that the readiness with which the detonation of gun-cotton is accomplished is in proportion to the mechanical force exerted by the initiative detonation to which it is subjected. The force exerted by small quantities of strongly confined silver and mercuric fulminate greatly exceeds that developed by the explosion of comparatively large proportions of the iodide and chloride of nitrogen. This may be accepted as accounting, to some extent, for the fact that the detonation of gun-cotton could not be accomplished by an amount of iodide of nitrogen twenty times greater than that of fulminates required for the purpose, while ten times the quantity of the confined chloride were required to produce the result. That the quantity of mercuric fulminate required to produce detonation is reduced in proportion as means are applied to increase the violence of the force exerted by it at one time, is quite in accordance with the above view.

I venture to offer the following as being the most satisfactory explanation which occurs to me of the remarkable differences exhibited in the behaviour of different explosive agents. The vibrations produced by a particular explosion, if synchronous with those which would result from the explosion of a neighbouring substance which is in a state of high chemical tension, will, by their tendency to develop those vibrations, either determine the explosion of that substance, or at any rate greatly aid the disturbing effect of mechanical force suddenly applied, while, in the case of another explosion which produces vibrations of different character, the mechanical force applied by its agency has to operate with little or no aid; greater force or a more powerful detonation must, therefore, be applied in the latter instance, if the explosion of the same substance is to be accomplished by it.

In conclusion, it may not be out of place to refer briefly to a few illustrations of the important bearings which the new mode of developing the explosive force of gun-cotton has upon the practical uses of the material as a destructive agent. The confinement of a charge of gun-powder or gun-cotton in a blast-hole, by firmly closing up the latter with earth, powdered rock, or other compressible material (by the process known as tamping or stemming) to a depth greater than the line of least resistance opposed to the action of the charge, is essential to the success of a blasting operation; but the great rapidity of explosion, by detonation, of a charge of gun-cotton greatly reduces the value of this operation; the destructive effect of the material, when exploded in a hole which is left open, is not inferior in extent to that obtained by similarly exploding a charge confined in the usual manner. Thus the most dangerous operation in connection with blasting may be entirely dispensed with. In submarine operations, it is no longer necessary to enclose the charge of explosive agent in the strong and therefore cumbersome metal receptacles hitherto required to ensure the full development of its explosive force; the destructive action of a charge of gun-cotton, enclosed in a waterproof bag or thin glass vessel and exploded by detonation, being decidedly greater than that furnished by a corresponding charge confined in a strong iron vessel and exploded by flame. Small charges of gun-cotton simply resting upon the upper surfaces, or loosely inserted into natural cavities, of very large masses of the hardest description of rock or of iron, have broken these up as effectually as if corresponding charges had been firmly imbedded in the centre of the mass and exploded in the usual manner. Lastly, the certainty, facility, and expedition with which certain important military destructive operations may be accomplished by means of gun-cotton exploded by detonation, are not among the least important advantages which are now secured to this interesting and remarkable explosive agent.

SCIENTIFIC SERIALS

POGGENDORFF'S *Annalen der Chemie und Pharmacie*, vol. cxl. part 1.—This number contains (1) the first part of an elaborate paper by E. Ketteler, "On the Influences of Ponderable Molecules on the Dispersion of Light, and on the Signification of the Constants in the Mathematical Formulæ for Dispersion" (pp. 1 to 53). This is a critical examination, based chiefly on Mascart's experimental measurements, of the formulæ by which Cauchy and others have endeavoured to connect the indices of refraction of the various kinds of light with their wave-lengths. The nature and scope of the investigation may be gathered from the four following criteria which the author gives as the tests of a satisfactory formula:—"1. A rational formula must enable us to calculate accurately from their wave-lengths the succession of the several colours and their distribution in space, for the whole measured extent of radiation, for some definite density of the dispersive medium. 2. The constants of the formula must be capable of a distinct physical interpretation, analogous to the interpretation assigned by Cristoffel to the constants in his formula. 3. When the density of the dispersive medium is altered, these constants must participate in the change of molecular constitution in some simple manner, corresponding to what has been ascertained in respect to them in the case of gaseous media. 4. Consequently, as the medium approaches the limit of rarefaction, all the indices must approach unity as their limiting value." The author finds that none of the formulæ hitherto proposed reproduce the experimental results within the limits of error of the measurements, but that this can be done by a formula which he proposes. (2.) "On the Sounds produced by Heated Tubes, and on the Vibrations of Air in Pipes of various Forms," by C. Sondhaus (pp. 53 to 76). Many experimenters must have observed the frequent production of a musical tone when a bulb has been blown at the end of a rather short and narrow glass tube, the sound beginning just as the tube with the still hot bulb is removed from the lips. This phenomenon formed the subject of an investigation by the author twenty years ago, and he now returns to it in a paper which is to be concluded in the next number of the *Annalen*. The principal result which he now publishes is that when the dimensions of bulb and tubes are properly proportioned, similar tones can be obtained with heated glass bulbs from which two open tubes proceed in opposite directions. He also gives an empirical formula which expresses approximately the pitch of the tones obtained in terms of the dimensions of the bulbs and tubes; but as this formula does not seem to be based on any physical explanation of the way in which the sounds are produced, and as it takes no account of temperature, the agreement between its results and those of observation must be considered as at least to some extent accidental. Perhaps the remainder of the paper may give further explanations on these points. (3.) "On Chromates," by C. Freese (pp. 76 to 88), to be concluded in the next part. (4.) "Thermo-chemical Investigations" (continued), by Julius Thomsen (pp. 88 to 114). This section of Professor Thomsen's researches relates to the acids of nitrogen, phosphorus, and arsenic. The thermo-chemical behaviour of these acids, when neutralised with caustic soda, appears to agree in the main with the commonly-received views of their basicity founded upon their chemical properties. (5.) "Further Researches into the Development of Electromotive Force between Liquids," by Jacob Worm-Müller (pp. 114 to 144). Among other results the author arrives at the following remarkable conclusion: "Solutions of acids and alkalis in equivalent proportions (that is such that equal volumes of the solutions neutralise each other) and of the salts formed by mixing equal volumes of these solutions, do not give rise to electric currents when connected so as to form a circuit." This paper also is to be concluded in the next number of the *Annalen*. (6.) "Researches in Electrical Dust-figures," by Wilhelm von Bezold (pp. 145 to 159). (7.) "On the Law of Formation of Kundt's Dust-figure," by Theodore Karrass (pp. 160 to 168). (8.) "On an Electrophorus-machine for Charging Batteries," by Peter Riess (pp. 168 to 172). The author describes a modification of Holtz's electrical machine, which renders it applicable for charging Leyden batteries to a high tension. (9.) "On the Measurement of the Absorption of Light by transparent media by means of the Spectroscope," by C. Vierordt (pp. 172 to 175). The author's method of measurement consists essentially in diminishing the intensity of each part of a normal spectrum, by means of smoked glasses of known absorptive power and the partial closing of the slit of the spectroscope, until it is identical with that of the light transmitted by the medium to be examined. (10.) "An Observation on the Induction-spark," by Dr. A. Weinhold (p. 176).

In the *Journal of Botany* for August, the original articles relate almost entirely to extra-English botany, with the exception of the conclusion of Mr. Worthington Smith's *Clavis Agaricinorum*, which forms an important contribution to the literature of cryptogamic botany.

In the *Proceedings of the Asiatic Society of Bengal* for June are three articles on the Andamanese, the most important of which is by Surgeon Francis Day. He estimates the number now living on the island as probably not much over 1,000, divided into several tribes, which have distinct dialects, so that members of the Little Andamans are scarcely able to understand those of the South Andamans. Their language is very deficient in words; many English and Hindustani words are now beginning to be incorporated in it; numerals are entirely absent. They are anything but prolific, and appear to be gradually dying out from excess of deaths over births. Mr. Day only saw one woman who had as many as three living children; during one year thirty-eight deaths were reported, and only fourteen births among the families living near the European settlements; few appear to live to a greater age than forty, and they are subject to a variety of diseases. We hope to return to this article again. Dr. G. von Martens contributes "Notes on some Javanese Algæ." The remaining articles in the number are philological.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 8.—Papers were read on the relation between the specific heats and the coëfficients of dilatation of any body, by M. Phillips, and on the decimal division of the quadrant, by M. A. d'Abbadie, in which he communicated two letters on the subject from M. Nadau and Prof. Airy; and MM. Jamin and Richard contributed some observations on the determination of the relation between the two specific heats of gases.—M. Jamin replied to the two notes by M. Sainte-Claire Deville on July 18th, and entered again at length into the subject of the variations of temperature produced by the mixing of two liquids.—M. Laborde contributed a note on some new experiments on Holtz's electrical machine.—M. Elie de Beaumont presented, on behalf of M. Delesse, a lithological map of the embouchure of the Seine.—A note by MM. Rabuteau and Peyré was presented by M. Ch. Robin, on the poisonous effects of the m'boundou or icaja, a poison used at the Gaboon. The poison used was extracted chiefly from the bark, a small quantity also from the root. The experiments showed that the poison is extremely rapid; but that its fatal effects can be prevented by artificial respiration; the symptoms are in some respects similar to those produced by strychnine.—A letter was read from M. Lichtenstein to M. Dumas, on a means of preventing the irruption of the *Phylloxera vastatrix* in vines not yet attacked. The proposed plan is simply by destroying carefully, from May to August, all the branches on which the winged form of the insect has made its appearance.—A short note was also presented by M. L. Laliman, on a variety of vine (of the American species *V. æstivalis*) not subject to the attacks of the *Phylloxera*.

SCIENCE AND MILITARY SURGERY

IT is matter of no small interest at the present time to know something of the scientific position of our Army Medical Service. The question has two aspects—first, the purely professional and technical; and second, the general and scientific. In former times sick and wounded soldiers in all services had inadequate care bestowed on them, but for many years past the advance of humane principles, and improvements in education and in all manner of appliances, have been gradually making way in different European armies; and at this time we are presented with the astonishing spectacle of distinct corps of men and women, many of them of noble and gentle birth, following the example first set by Florence Nightingale, leaving their families and homes to accompany armed hosts to the battle field—their lives considered sacred by both sides—with the single object of conveying away poor wounded men as speedily as possible to shelter and to surgical and nursing care.

It would not be difficult to trace this great movement to the disasters of the British army during the Crimean war; and to the same event we have been indebted for the striking scientific advance in our own army medical service. We have been led into making these remarks by a perusal of the Army Medical Department Report for 1868. This is the tenth volume of an interesting series of official documents, the commencement of which dates from the reforms introduced by the late Lord Herbert.

The present volume maintains the reputation already gained by its predecessors, and even for non-professional readers it affords information of much general interest. A brief sketch of its contents will be sufficient for the object we have in view.

In turning over its pages we find in the first place the medical statistics of the whole British army. Wherever Her Majesty's troops are stationed, there the statistical officer is at work collecting and registering facts, which show not only the state of health at each station, but the diseases incidental to countries and climates the most diverse.

The death rates, which for foreign stations include deaths among invalids, show a large reduction over those which ruled in former years, but in many cases they are considerably too high, and indicate the necessity for increased sanitary precautions. The greatest reductions have been effected in India, where for the first half of the present century the rates averaged no less than 69 per 1000. In 1868 the death-rate was 21·7 per 1000.

The reports from stations are accompanied by sanitary notes, in which the reasons for these death rates are more or less discussed, and there are valuable reduction tables showing the influence of age, locality, &c., on the rates.

The net results of the Abyssinian expedition are given as follows:—The aggregate strength of British troops sent to Abyssinia at various dates was 4,208. There were 42 deaths in Abyssinia, and 12 among invalids in England, making 54 in all; equal to 12·8 per 1000. There were 12 admissions but no deaths from wounds. The total loss arose from disease and accident, the latter cause occasioning 14 deaths.

Among the scientific papers is one by Dr. Wright, giving an account of experiments on the ventilation of a barrack-room, and affording an insight into the nature of solid particles floating in impure air, which particles formed the subject of Prof. Tyndall's lecture on "Dust and Disease," at the Royal Institution, last spring.

The presence of dust particles in the air of the Royal Institution was shown by their reflecting a strong light thrown on them. In Dr. Wright's experiments made at Netley Hospital, 26 cubic feet of air were drawn through an aspirator, and the suspended matters in this air were condensed, and gave the following results under a ⅛th inch object glass:—

Cotton fibres.
Starch granules.
Crystalline substances, sand, or dust.
Vegetable tissues of various sorts.
Pollen.
Amorphous Molecules (? Detritus of epithelium).
Indefinite filaments.
Minute moving particles (? Zoospores).

It is important to point out that these substances were detected in the air of a sleeping-room occupied by 11 men, where each man had 828 cubic feet of air space, the air of which was renewed upwards of four times every hour. The carbonic acid ratio in the outer air was ·393 per 1000 volumes, and in the room air, ·643 per 1000 volumes. The practical result being that for some reason the actual ventilation of the room was very defective, although the quantity of air ought to have been more than sufficient.

Dr. Parkes has supplied an interesting paper on Dr. Hassall's Flour of Meat, giving an experimental account of its effect as a diet on two healthy persons. The object was to ascertain whether it could be used by soldiers, and to what extent. The results arrived at are what might have been expected, viz., that nitrogenous foods of this class are, by themselves, insufficient for purposes of health and nutrition; while, as Dr. Parkes tells us, "the effect on each gentleman of the addition of other articles of diet (vegetables, fat, and a little more starchy food) was described by both as perfectly marvellous." This result gives the clue to the proper manner of using prepared foods of this class.

Dr. Parkes likewise furnishes a report on the progress of hygiène for the year 1869, in which a useful digest is given of the leading contributions made to this important subject in various countries. One important scientific result of painstaking inquiries into the relation of cattle diseases to specific fungi, carried out in America, is stated as follows:—"It will thus be seen that the authors trace all the forms of fungi seen in the blood and fluids in the pleuro-pneumonia, or splenic disease of cattle, to common forms, and that they entirely differ from Hallier on this point."

Hallier has fared no better with his theory of specific cholera fungi at the hands of Drs. Lewis and Cunningham, the two observers appointed by the Indian Government to examine into the question in India. These gentlemen furnish a paper on this subject, in which they state that up to the time of report the fungi supposed to be peculiar to cholera belong to common forms.

There is a curious paper by Dr. Smith on the notorious Delhi boil, in which he goes a long way in connecting this disease with impure water used for ablution purposes by the troops. He shows that dogs who drink this water get boils on their noses, while human beings are affected at the points where the skin is rubbed in the process of ablution. Microscopic preparations of the boil appear to show the presence of ova of distomata similar to those detected long ago in London waters by Dr. Hassal.

Professor Longmore furnishes some valuable remarks on the Prussian arrangements now in actual operation for transport of wounded in time of war. These remarks have a special interest at the present time, and they are illustrated by Professor Longmore's own personal experience. Ordinary railway-carriages and goods-waggons have been selected by the Prussians for the conveyance of wounded by rail. In ordinary fourth-class carriages hooks are screwed into the opposite sides of the carriage, and the field-stretchers with wounded are carried inside and suspended by elastic rings on the hooks. The operation is facilitated by the lower class carriages having a door at each end. When goods-waggons are used, the stretchers are either suspended or, which is far better, they are placed on poles laid on semi-elliptical steel springs inserted in the floor of the waggon. Professor Longmore prefers the arrangements in the fourth-class carriages, as being easier in practice.

There is in the Prussian army a complete organisation of medical officers, bearers, stretchers, field ambulances, &c., for collecting the wounded, dressing them on the spot, and conveying them either to the railway or to hospital, where, as we are glad to learn, they are now meeting with every care and kindness at the hands of humane men and women, whose motto may well be that adopted by one of the societies—"Point d'ennemis pour nous." * After describing the exercises he witnessed, Professor Longmore very properly suggests whether we in this country might not do something in the way of organising a suitable ambulance corps? This was one of Lord Herbert's proposed reforms, but we are afraid little has been done in giving effect to it.

Another subject discussed is the method adopted for identifying the bodies of the killed by means of tickets attached to the clothes or worn round the neck.

There are several other papers, including monthly meteorological abstracts for stations scattered over the whole British Empire, which we should have gladly noticed had our space permitted. But we have said enough to show that, in scientific advantages, the Army Medical Department, with its efficient school at Netley, stands second to none in Europe. It is for those who have the direction of the army to see that there is an organisation provided to give practical effect to it in the field where its services are most required.

* Contributions in aid of this great work may be sent to the National Society for the Aid of Sick and Wounded, 2, St. Martin's Place, Trafalgar Square, S.W.

THE ANNUAL REPORT OF THE ROYAL COLLEGE OF SURGEONS

FOR some years past it has been a custom at the College of Surgeons for the Conservator to collect the various specimens that have been mounted during the preceding twelve months into one room; enabling not only the Museum Committee, but the members of the medical profession, or visitors introduced by them, to see at a glance the additions that have been made during that period. We consider the plan to be an excellent one. It is a powerful incentive to the Conservator to work so that each year's results may surpass the previous one; whilst it calls forth gifts from those who have the opportunity of obtaining rare or valuable specimens, when they see what loving care and diligence are spent on their preparation and exhibition, and to how large a number they afford instruction. We had recently an opportunity of minutely inspecting these additions, and must express our warm admiration at their number and beauty. The Museum, as every naturalist knows, was commenced by the genius of Hunter, who, recognising the value that would attend the comparison of the same organ in the different groups of animals in enabling us to acquire precise knowledge of its function, and to penetrate the mysteries of disease, collected from all quarters typical specimens which he carefully dissected and described; but worker as he was the preparations he left have constituted but landmarks for the direction of succeeding observers. Although neither his time, strength, nor opportunity permitted that he should bring home more than a few examples displaying the wondrous fertility of the new region he had discovered, his success stimulated others to do their utmost. Preparation after preparation of every organised being that could be obtained by purchase or gift was rapidly added, and many times it has been found necessary to enlarge the receptacle for the sake of the new and important preparations that had been obtained, till at length it has attained its present lordly dimensions, and stands without a rival in the world. Nothing, perhaps, could give such an idea of the vast increase it has undergone —which would surely have well pleased its founder, could he have seen how his small though valuable beginnings had increased and multiplied—as the fact that a roomful of preparations that would handsomely furnish forth an entire country museum, is year by year absorbed into it, and scarcely appreciably augments its size.

The additions are divided into six classes—1, The Pathological Collection; 2, The Osteological; 3, The Physiological; 4, The Teratological; 5, The Dermatological; and 6, Anatomical preparations. The first of these has received many additions, and in particular one very important one, in which the carotid and subclavian arteries were tied by Mr. C. Heath for aneurism, and in which life was preserved for four years, and would probably have been considerably prolonged but for the extremely unsteady habits of the patient. The duration of life after the operation has permitted the collateral circulation to be fully established, and all the parts have been beautifully dissected out by Mr. Mosely.

In regard to the osteological collection, a large collection of ancient and modern Italian and Greek skulls has been purchased from the well-known Italian ethnologist, Dr. G. Nicolucci, of Isola di Sora. The number of these skulls was 166, and the entire number in the museum now amounts to 795, the great proportion of them being well authenticated and characteristic examples.

It is one thing, however, to have fine specimens, and another to display them to the best advantage; and often the chief value of a specimen, or even of a collection, is spoiled by the slovenly manner in which the mounting is effected, or the imperfect way in which they can be examined. The difficulties which have hitherto lain in the path of osteological investigation of the skeletons of different animals, have been admirably overcome by the workmen under Mr. Flower's direction. The skeletons are mounted upon very light frames of iron, and the limbs are so articulated with the body as to be removeable on the extraction of a single rivet, and their several segments can be detached with equal facility. The head can be removed, and even its interior be examined, whilst the several vertebræ can be separately taken off without disturbing the position and arrangement of the skeleton generally. The advantages of this mode of mounting for the purposes of comparison and investigation to the real worker are simply incalculable. The mode in which the preparing has been done reflects the highest credit on Mr. Mosely and those who assisted him. We must call attention in particular to a wonderful skeleton of a pike, weighing 32lb., in which every bone has been cleaned and re-attached with wonderful dexterity. The fish was presented by Mr. Petre, of Westwick, Norwich, at the instance of Mr. Frank Buckland. The council of the Zoological Society have given a very fine adult specimen of the recently discovered long-tailed Chinese deer (*Elaphurus davidianus*), with one of the very rare and remarkable South African "Aard wolf," or *Proteles*.

Mr. Flower is gradually performing a great service to all comparative anatomists by carrying out the original idea of Hunter, and placing side by side the same organ as it presents itself in a great variety of animals. By such a method many points are seized in a moment, which it is impossible for the most careful describer to render into words, or for the most diligent reader to grasp, whilst likenesses and correspondences hitherto unrecognised everywhere make themselves apparent. This year we observe that a large number of specimens of the intestinal organs and of the larynx have been mounted, the plan pursued with the latter organ being similar in all; on one side the bones, cartilages, and ligaments being displayed, whilst on the other the muscles are exquisitely dissected.

The Teratological Division, or that treating of malformations and monstrosities, has scarcely received the scientific attention it deserves, whilst the specimens that have accumulated in the College are very numerous, and we are glad to observe that the work of their arrangement has been entrusted to so laborious and intelligent a worker as Mr. B. T. Lowne, whose work on the Blowfly is, we have no doubt, in the hands of many of our readers.

In regard to the Dermatological collection it may be remarked that the past year has been signalised by the institution of what may be termed an entirely new department of the collection; for such illustrations of diseases of the skin as the Museum formerly contained were very limited in number, and were incorporated in the general Pathological series. Moreover, the great majority of the morbid appearances presented by the skin cannot be shown in an anatomical museum by actual specimens, but recourse must be had to models and drawings to perpetuate and illustrate their characters, and no collection of such objects had hitherto been formed in the College.

When the Professorship of Dermatology was founded and endowed last year by Mr. Erasmus Wilson, it appeared necessary that the means of illustrating the lectures should also be provided; and for this purpose, as well as for the general advancement of the study of the subject, Mr. Wilson has presented to the College an extensive collection of drawings, casts, and models of cutaneous diseases, the greater proportion of the latter having been recently executed with great artistic excellence and fidelity by M. Baretta from patients in the Hospital St. Louis at Paris.

In order to provide space for the exhibition of this collection, and for any further additions that may be made to it, the council determined upon the erection of a set of rail-cases around the upper gallery of the western museum, on the same plan as those put up in 1863 in the lower gallery. Their cost will be defrayed out of the proceeds of the Endowment of the Chair of Dermatology, so that the cases as well as the collection must be looked upon as the gift of Mr. Wilson to the College.

Since the completion of the cases, Mr. Wilson has been engaged in arranging the preparations in systematic order, and in preparing a descriptive catalogue of the whole collection, the manuscript of which is now ready for the press.

PSYCHOLOGY IN ENGLAND

La Psychologie Anglaise Contemporaine (*Ecole Expérimentale*). Par Th. Ribot. (Paris: Ladrange, 1870.)

THIS book expounds to French readers the psychological doctrines of Mr. Jas. Mill, Mr. J. S. Mill, Mr. Herbert Spencer, Professor Bain, Mr. G. H. Lewes, and (more briefly) of Mr. S. Bailey, Mr. Morell, and Mr. Murphy. It ends with a short summary of general results won in the course of the great English psychological movement marked by these names, and is prefaced by an introduction giving the author's view of the development of the sciences, and particularly the science of psychology. For the English thinkers, also, of another type (Hamilton, Whewell, Mansel, Ferrier), he seems to promise to do next what he does here for those whom he classes together as making, after the proper tradition of English thought, an experimental school.

The appearance in France of such a work, at the present moment, has a real significance. Taken along with M. Taine's new and weighty contribution to psychological science (*De l'Intelligence*), and with another work or two, it means that the tide of thought is there turning, if it has not already turned. Between the contempt of M. Comte and the airy attentions of M. Cousin, it has fared indifferently with psychology in France for more than a generation. At a time, when in England, a number of active inquirers, continuing the work of last century, have been pushing forward psychological research in a spirit of strict science; when in Germany a number more, reclaimed from high priori roads of speculation to habits of careful introspective search, or starting from a physiological base, have been vying with their English compeers in efforts to resolve the subtle complicacy of psychical states, and thence to explain the most obscure and varied o all growths; the philosophical mind of France has been mostly turned to the history and criticism of opinion, content to retail the cut-and-dried psychology of an earlier day. From this state of things the original scientific inquiry of M. Taine is a refreshing departure, and M. Ribot's work, though in the main expository merely, has its face also set away. The younger French minds are again coming under the influence of English thought, as more than a century ago their forefathers came; and yet far otherwise than then. For, whereas then the triumph of Lockian ideas in France was, in truth, the overthrow of one national system of thought by another, now that mental philosophy in England bears the cosmopolitan character of science, it is but a case of one nation being guided by another into the path of progressive inquiry. Lighting the way in this work, M. Ribot expounds and summarises with all the arts of a Frenchman, and, for the most part, with good insight. Nor, though evidently in accord with the direction of thought which he makes known, is he a slavish expositor: serious gaps in the work both of individuals and of the school he does not fail incidentally to note. His very art, however, may be thought to lead him somewhat astray, when he seeks at the close to strike a general balance of scientific results, presuming upon the idea of a community of thought among so many inquirers. It is no reflection upon the English thinkers, and hardly even upon the scientific value of their labours, that in a matter so great and difficult, their work thus far is more distinguished for the many fruitful lines of inquiry that it has fairly opened, than for the number of questions that it has finally and unanimously closed.

The author's introductory chapter deserves more particular notice, having a lesson not for Frenchmen only. In England, where the cast of philosophical thought has all along been psychological, and well, as even Germans have come to see, where, also, psychology has first and most conformed to the conditions of science, there is yet a certain tendency, and not only in the minds of common people, to think and speak slightingly of mental inquiries. Philosophy (meaning mental philosophy, not, of course, *natural* philosophy in the land of Newton) is opposed to science, chiefly in the sense of being quite unscientific, and "metaphysics," vaguely supposed to be the same thing or the same nothing, is even a time-honoured term of abuse. This is a state of opinion on which M. Ribot's remarks bear so directly, that there may be an advantage in shortly giving the point of them; and perhaps they may suggest an observation or two not unseasonable at the present moment.

Philosophy, according to M. Ribot, was originally the name for science universal; at present, it is a name indefinitely and irregularly applied to an aggregate of several sciences, having relation chiefly to mind; in the future, it will again have the character of universality, but not be science. In other words, it was once the sum of human knowledge, such as that was; it is now, in part at least, a special kind of knowledge, real and scientific, but vaguely defined; it will become (under the name of metaphysics strictly understood) an extra-scientific, but necessary, complement of knowledge. The sciences, such of them as have not grown out of mere arts, have, in fact, detached themselves from philosophy as a great trunk; mathematics as early as the third century B.C., physics as late as the last three centuries, and not, perhaps, completely until the last. Detached, these have a being quite apart from what was called philosophy; they advance, and grow ever more special, untroubled by philosophic questionings about their foundation; indeed they advance because, and from the moment when, they have left all such aside. And this is now not more true of these than of other sciences concerned less with external nature than with man, and has become true even of sciences like psychology, still confusedly spoken of as philosophy. For already in England, and in Germany also, there is an investigation of mind conforming to all the conditions of scientific progress. It deals with actual phenomena, and attempts to explain them by discovering laws; troubling itself no more about an ultimate essence of mind, than mathematics or physics about the ultimate nature of space or motion, and only labouring by every resource of scientific method—observation of individuals, external as well as internal, and of masses through history and statistics, comparative study of the lower animals, investigation of all abnormal mental conditions, and artificial experiments as far as possible—to master the exceptional subtlety and complexity of the phenomena. For the rest, in philosophy proper, or metaphysic, there must ever remain to nobler minds a boundless sphere of consideration and mental endeavour. The underlying questions, which the sciences must ignore in order to advance, are nevertheless there, and will be answered somehow by all but narrow intellects. Speculation on the first principles and last reasons of things, so far from being superseded, is rather more deeply stirred as the sciences become greater, which is to say, more special. Only, verified science such metaphysical speculation can never be. Like poetry (and no more to be got rid of than poetry) it must always have a certain personal and subjective character. In truth, the metaphysician differs from the poet just in this, that in reconstituting the synthesis of the world, he works with abstract ideas instead of concrete pictures. So far, M. Ribot.

There is much that is noteworthy in the view thus roughly sketched. Some things, regarding the origin of the special sciences, could not easily be said better than by M. Ribot; and, in particular, his whole excursus on the question of the conditions, sources, and method of scientific psychology—a question that has perhaps been less considered by English than by German psychologists—may be commended as highly suggestive. In point of actual achievement in psychological science, distinguished from metaphysical speculation, this country is frankly placed first. It seems time, then, that we should cease to be blinded by any mere associations of language to one of our best titles to national fame. Nay, it even becomes our duty, if philosophy is no more than M. Ribot (to say nothing of others) declares, to lift the shadow of the name from off an arduous line of inquiry, sharply enough defined, clearly enough admitting, as it requires, scientific treatment, and already carried to no mean length in spite of popular misapprehension and the graver indisposition of physical inquirers to recognise in it a true branch of science. There is a science of mind, call it by whatever name, that has come into being like other sciences; and it is a natural science too, unless we are prepared to assert that man, on the most characteristic side of him, is an unnatural object.* Still there is likely to be some reason why, to this

* In the newly-constituted Faculty of Science in University College, Psychology, under the name of Philosophy of Mind, is included along with Logic. Already for some years the two subjects have been recognised in the science-programme of the London University; the Bachelor of Science must pass in both, and the Doctorate of Science may be taken for special proficiency in them, along with certain subsidiary subjects, such as Political Economy. A knowledge of them is required also for the degree of M.D.

science of mind in particular, the name of philosophy should have clung, and if the reason be good, philosophy may not be on the road to become the mere poetry of abstracts that M. Ribot foresees. Let us look a little way into this matter.

Psychology is a natural science if it deals with a definite class of phenomena constantly occurring in nature, deals with them on approved principles of scientific method, and marches steadily from old to fresh results: and that it does conform even to the last of these conditions, M. Ribot often in the course of his exposition has occasion, as he always is properly anxious, to show. What, then, is peculiar in the natural science of psychology? The phenomena dealt with are, beyond all others, complex, subtle, and obscure, requiring a finer tact and a larger scientific vision to single them out with any effect; but this, if it explains why psychology has lagged behind the other sciences, gives it no claim to stand apart. The phenomena, however, are quite peculiar, in being, as it were, two-faced, in having not only a side by which, like all other phenomena of nature, they (or, at least, many of them) fall under external observation, but also a side by which, unlike any other natural phenomena, they fall under so-called internal observation. This is, indeed, a peculiarity; and, further, let this go with it, that, as amongst such double-faced phenomena are all facts of human cognition, the subject of psychology extends, in a sense, to all things known or knowable; viewed, namely, as they are or may be known. Nothing to the same degree, nothing of the same kind, can be said of any other science; for though the general sciences, going backwards from biology, have an ever wider and wider sweep, extend, that is, to more and more objects viewed in the special aspects that each considers, psychology in this respect surpasses the most general of them all more than any of them, and in a way that none of them surpasses another. The science of mind does, therefore, stand on a certain level of its own. It has a place among the general sciences, and a place far down, namely after biology, from dealing with phenomena as much more complex than vital phenomena, as these are more complex than chemical phenomena. But it also has a place before all the sciences, from dealing with the growth of consciousness, and specially the laws and limits of those mental processes whereby all knowledge, scientific or other, must come. So that, if as a science it ought to be studied in its place among the sciences, in the light of their results as far as these bear on its subject, and in the spirit of rigid inquiry which they are best fitted to engender, its subject is still such that its results, when thus obtained, are not as theirs. Its results have not only, like theirs, a value in themselves and a forward reference, but they have a backward reference also. From the psychological stage, once reached, all the science that went before is seen over again in a new light. The true sense of the very language of the sciences—of such a word, to take but one instance, as "phenomenon"—is then first understood; and what before was mere practical assumption is turned into intellectual conception. Or, may we not say that there is gained a certain *philosophic* insight? A multitude of questions, M. Ribot truly said, were left unsolved at the root of the sciences, at the root of psychology itself among the rest. But some of them can be solved psychologically, and such of them as cannot are perhaps not all real questions. Where it is possible, the deeper psychological reading of an objective physical fact may not without reason be called *metaphysical*. It would seem, then, that there may be a metaphysic that does not break with science, and that one kind of science still, in some sense, deserves to be called philosophy. Psychology, in short, is Science in its method and Philosophy in its scope.

G. CROOM ROBERTSON

OUR BOOK SHELF

Dictionary of Scientific Terms. By P. Austin Nuttall, LL.D., editor of "The Classical and Archæological Dictionary," "Standard Pronouncing Dictionary," and numerous Educational Works. (London: Strahan and Co., 1869.)

WE are thankful to be able to say that we know nothing more of Dr. Nuttall than we learn from his title-page. We never even heard of him till we read his book, and we most sincerely hope that, as an author of scientific works, we shall know him no more. What the "numerous educational works" that he has published are we cannot tell, but if they are at all like his "Dictionary of Scientific Terms," the sooner they are consigned to the trunk maker and the butter-man, the better will it be for the welfare of the unhappy youths for whose benefit they were composed. These may seem hard words to apply to a writer who hopes to "receive every indulgence from a generous public" (p. xi.); but when that writer outrages all our better feelings by stringing together a series of idiotic absurdities, and calling the result a "Dictionary of Scientific Terms," how are we honestly to deal with him, except by exposing a few of his blunders? We will begin by testing his chemical knowledge. It will hardly be believed that he regards black-lead, brass, magnet, ochre, pewter, and steel as constituting "a few of the principal metals" (p. xviii.); that nitrogen is "unrespirable" (p. 230), although he has previously told us at p. 12 that it forms about 80 parts of atmospheric air); that oxygen "generates acids" (p. 239); that alum is "an earthy chalk, a sulphate of alumina *or* of potash" (p. 18); and that "culinary, rock, or sea salt, is chloride of soda" (p. 277). His natural history is as peculiar as his chemistry. We will merely put his zoology to the test, assuring our readers that in so far as accuracy is concerned, his zoology, botany, and mineralogy are much on a par. "Zoology," he tells us, "embraces an account of all animal creation, the principal classes being the *Mammalia*, *Aves*, *Reptilia*, *Pisces*, *Invertebrata*, and *Insects*." The first class is subdivided into nine orders, of which one is "*Edentata*, or animals wanting some of the teeth of other animals" (p. xiii.) Being anxious to learn more of these covetous, commandment-breaking creatures, we turned to *Edentates*, and found that they are "an extensive order of the class Mammalia, comprehending those unguicolated quadrupeds which have no front teeth, and divided into three tribes, the Tardigrada, the ordinary Edentata, and the Monotremata." We leave our zoological readers to decide how far this description is an accurate definition of the order, according to recent views, such as our author might have learned by consulting the works of Owen, or of Huxley.

"Invertebrate animals are divided into *Mollusca*, *Articulata* and *Radiata*" (p. xiv.) We had hoped that by this time the "Radiata," having done their work, had modestly withdrawn themselves from their old position, and had been replaced by other classes; but Cœlenterata, Hydro-medusæ, &c., are terms unknown to Dr. Nuttall. "The Mollusca is (*sic*) so called from the body being soft and molluscous. It is divided into four classes, the *Mollusca*, *Conchifera*, *Tunicata*, and *Cirripeda*" (p. xiv.) How this marvellous division is accomplished we are unfortunately not told. In the next page we find that the molluscs or soft animals are composed of radiata, starfishes, &c., polyps, corals, &c., naked molluscs and testacea or shell-fish. Need we carry our investigation further?

The terms which the author supposes are used by surgeons and physicians are of the most astounding nature, and many of them, although possibly used a century or two ago, are perfectly new to us. We only confine ourselves to the letter A. Do any of our readers suffer from acatharsia, acratia, acrisy, acropathy, acropy, acroteriasm, acrothymion, adenopharyngitis, aerophobia, agalaxy, agennesia, agrypnocoma, anagogy, anopsy, antispasis, antritis, apagma, apolepsy, apolysis, apotrepis, or arthropuosis? Let them have recourse to such remedial agents as acidulum, acopica, adipson, alborga (a kind of sandal wood made of mat weed), aldehydic acid (which "is a solution of oxide of silver in aldehyde"), alloxan (which our readers will be surprised to learn is "the action of nitric with uric acid"), amylum (which we are told is "a preparation of starch"), anacathartics (which are "any medicines that operate upwards; a cough attended with expectoration;" it is of course the "medicine that operates upwards" and not the cough, that we recommend as a remedial agent), antephiatic medicine, or arrowroot (consisting of starch, albumen, volatile oil, chloride of calcium, and water), which we presume may be obtained at an antidotarium. Should surgical aid be required, an arthrembolum may prove of service. We can only account for this appalling list of medical terms and for the information regarding alloxan, arrowroot, &c., on the supposition that Dr. Nuttall's medical attendant is an incorrigible wag, and that he took a most dishonourable advantage of his position.

Our readers will, we think, by this time be satisfied that our introductory remarks upon this discreditable production were not at all too severe. It is a disgrace to English science that such books should find a respectable publisher.

Das Gesetz der vermiedenen Selbstbefruchtung bei den höheren Pflanzen. Von Dr. O. W. Thome. (Williams and Norgate.)

WE opened this little pamphlet in the hope of finding in it a new contribution to the literature of the self-fertilisation and cross-fertilisation of plants, but were disappointed to discover that it consisted of little besides a *résumé* of the labours of others in this field. The instances in which the self-fertilisation of hermaphrodite flowers is prevented by the fact that the stigma and the stamens ripen at different times, are mostly taken from Prof. Hildebrand's "Die Geschlechter-Vertheilung bei den Pflanzen," and from that botanist's contributions to the "Botanische Zeitung." On the laws of dimorphism and trimorphism we have little but the examples so elaborately worked out by Mr. Darwin in the genera *Linum*, *Primula*, and *Lythrum*. It is singular that from the time that Sprengel first called attention to the provisions which favour cross-fertilisation in plants, now more than seventy years since, so little had been done in this field until the researches of the two eminent botanists above named, and even now they have so few fellow-labourers. There is no department of physiological botany more beneath the eye of every dweller in the country, or of any one who possesses a garden, none which presents so many points of interest even to the casual observer, and so many illustrations for the advocate of the doctrine of "design," and none in which a careful series of observations would be more fertile in results of importance. If country botanists would bestow a portion of the energy which has been wasted in mere collecting, and the eradication of rare plants from their native haunts, on systematic physiological observations, the gain to genuine science would be immense.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Gulf-Stream

As a note appended to Prof. Wyville Thomson's lecture "On Deep-Sea Climates," published in your number for July 28, may lead your readers to suppose the divergence of opinion between my colleague and myself upon the subject of the Gulf-Stream to be greater than it is, I shall be obliged by your placing before them a few observations which may put the question really at issue between us in a more definite form.

The term "Gulf-Stream" is continually used in two different senses. By myself it has been employed to designate the current issuing from the Gulf of Mexico through the "Narrows" between Florida and the Bahamas; and this I apprehend to be its true signification. My colleague's definition of it I give in his own words:—"The water of the North Atlantic thus consists first of a great sheet of warm water, the general northerly reflux of the equatorial current, the most marked portion of it passing through the strait of Florida, and the whole generally called the Gulf Stream." He thus distinctly recognises, with myself, the participation of a *Subsidiary Current* with the *Gulf-Stream proper* in the production of the two great temperature-phenomena of the North Atlantic, determined by the *Porcupine* soundings —(1) the elevation of the temperature, not of its surface-layer only, but of a stratum 800 or 900 fathoms deep, by a north-east movement of tropical water; and (2) the depression of the temperature of its deepest portions by a reflux of glacial water from the Arctic and Antarctic basins.

Now I have on no occasion, so far as I can recollect, spoken so disrespectfully of the Gulf-Stream proper as to "deny that it exercises any influence upon the temperature of the basin of the North Atlantic," nor am I aware of having expressed a "doubt whether it reaches the coast of Europe at all." That the Gulf-Stream proper, by raising the temperature of the portion of the Atlantic basin over which it can be distinctly traced, has a most important *indirect* influence upon the temperature of its north-eastern extension, I cannot doubt for a moment; and that its *direct* influence is traceable to the western coast of Europe, as far north as the Bay of Biscay, I accept on the authority of the recently-published Admiralty charts of its course and distribution. But I *have* expressed a doubt as to the extension of the Gulf-Stream proper to the channel between the North of Scotland and the Faroe Islands; and I have ventured to think it an open question whether the super-heating of the surface-water observed on a hot Midsummer day beyond the northern border of the Bay of Biscay was not as probably due to the direct influence of the sun as to the extension of the Gulf-Stream to that locality.

The main questions between my friend and myself are therefore as follows: What are the relative shares of the Gulf-Stream proper, and of the Subsidiary Current, in producing the elevation of temperature in the upper stratum of the North Atlantic to a depth of about 800 fathoms—and what is the motive power of that Subsidiary Current? These questions can only be answered, as it seems to me, by an appeal to certain general probabilities—definite data for their determination being still deficient, for, in the first place, all the calculations which have been made as to the quantity of water which issues from the Narrows, and the amount of heat which it conveys, are based (if I recollect aright, having here no access to books on the subject) upon the assumption that both its temperature and its rate of movement are the same throughout its depth as they are at its surface. Now, until reliable proof shall have been furnished as to both these particulars by our friends of the United States Coast Survey, I must claim a suspension of judgment, many probabilities leading to the suspicion that the bottom-flow may be considerably less rapid than the surface-current, and its temperature considerably lower. Secondly, even admitting in its full force the reputed "glory" of the Gulf-Stream at its exit from the Narrows, I fail to see the evidence that either its heat or its movement is directly concerned in the flow of the warm upper stratum of the north-east extension of the Atlantic towards the Hebrides, the Faroes, and Spitzbergen. For as the stream of superheated water, on its emergence into the open ocean, spreads itself out like a fan, it must necessarily become shallower as it extends instead of deeper, and this (if I remember aright) is what all observation indicates. That a large proportion of it is deflected back towards the Equator is universally admitted, and that the remainder can be gathered together after its initial velocity has been expended, and forced downwards so as to displace colder water to the depth of 800 fathoms whilst still moving north-east, seems to me in the highest degree improbable.

To what then is the north-east movement of the warm upper stratum of the North Atlantic attributable? I have attempted to show that it is part of a *general interchange* between Polar and Equatorial waters, which is quite independent of any such local accidents as those that produce the Gulf-Stream proper, and which gives movement to a much larger and deeper body of water than the latter can affect. The evidence of such an interchange is twofold—that of physical theory and that of actual observation. Such a movement *must* take place, as was long since pointed out by Prof. Buff, whenever an extended body of water is heated at one part and cooled at another; it is made use of in the warming of buildings by the hot-water apparatus, and it was admirably displayed at the Royal Institution a few months since in the following experiment kindly prepared for me by Dr. Odling:—A long but very narrow trough, with plate-glass sides, having been filled with water, a tube into which a steam-jet was conveyed was introduced vertically at one end, whilst a lump of ice was wedged between the sides of the trough at its opposite extremity. Some red colouring matter mixed with gum, of such viscidity as to be carried along by any movement of the liquid mass without mingling with it, was introduced into the water at the end of the trough warmed by the steam-jet, and a like mixture of a blue colour was introduced at the end cooled by the ice. The latter very speedily sank to the bottom along the side of the ice-wedge, and then crept slowly along the floor of the trough, towards its warm end, where it rose along the side of the heated tube until it reached the surface, and then slowly flowed back towards the cold extremity. On the other hand the red liquid passed slowly along the surface in the first instance from the warm to the cold extremity, then sank (as the blue had previously done), crept along the surface of the blue layer covering the bottom of the trough, and then rose (as the blue had previously done) along the side of the heated tube to the surface. Thus a circulation was shown to be maintained in the trough by the application of heat at one of its extremities and of cold at the other, the *heated* water flowing along the *surface* from the warm to the cold end, and the *cooled* water flowing along the *bottom* from the cold to the warm end: just as it is here maintained that Equatorial water streams on the surface towards the Poles, and that Polar water returns along the bottom towards the Equator, if the movement be not interfered with by interposed obstacles, or prevented by antagonistic currents arising from local peculiarities. So far is this from being the case with the general surface-movement in the Atlantic basin, that it will concur with and supplement the motion of the Gulf-Stream proper, which may thus be regarded as a portion of the general Equatorial-polar current, deflected in the first instance by the action of the trade-winds, but subsequently rejoining the great body of water having a north-east motion of its own and imparting to its surface-layer a higher temperature than it would otherwise convey.

Now that this hypothesis is at any rate deserving of consideration, and is not to be dismissed by the *ipse dixit* even of so high an authority as Dr. Petermann, though backed by my excellent colleague, I venture to maintain on the strength of the parallel case afforded by the temperature-phenomena of the Southern Indian Ocean. For, as Capt. Maury has shown, a definite current exists in the midst of it, carrying tropical waters far into the southern temperate zone, and not attributable to any such local peculiarities as those which produce the Gulf-Stream of the Atlantic. Conversely, the Hydra soundings in the Arabian Gulf have given evidence of a northerly reflux of glacial water from the Antarctic basin along the deep-sea bed of the Indian Ocean to replace the more superficial stratum which has moved southwards. This glacial water will in its turn be raised from the depths by the heating action of the tropical sun, and then return as the southerly surface-stream to the Antarctic basin, and would there sink by surface-cooling and again flow northwards along the sea-bed.

The facts of observation, then, being in the case last cited entirely accordant with physical theory, I submit that the same theory may be fairly applied to the explanation of those temperature-phenomena of the North Atlantic, which (as it seems to me) cannot be more than very partially, if at all, accounted for by the agency of the Gulf Stream proper. And I am content to leave it to the judgment of those who are competent to deal with the question whether the north-east movement of the vast breadth of water lying between the coast of Greenland and that of Northern Europe, usually extending to a depth of 5,000 feet, is more likely to depend upon an impetus derived from a portion of the comparatively narrow and shallow current which issues from the Narrows thousands of miles off, or to form part of a general circulation of oceanic water, the cause of which is quite independent of local accidents.

The readers of NATURE will, I am sure, join with me in deeply regretting that Prof. Wyville Thomson is prevented by illness from taking that share in the scientific exploration of the Mediterranean basin, now about to commence, which has conduced so greatly to the success of the two previous expeditions in which we have had the pleasure and advantage of being fellow-workers.

Gibraltar, Aug. 11 WILLIAM B. CARPENTER

Dr. Hooker's "Student's Flora"

ALL the reviews which I have read of the "Student's Flora of the British Islands" are, as they undoubtedly should be, appreciative, but your reviewer has done well in pointing out a few seeming discrepancies, which it would, perhaps, be well if attended to in a second edition; and, if you will permit space, I will endeavour briefly to add to your list of desiderata. In the first place I take it that a good glossary is an essential, if not an absolute necessary, adjunct to a students' manual; yet we look in vain for anything of the kind in Dr. Hooker's new "Flora." Dr. Hooker could scarcely have thought beginners in botany able to interpret many words used by him in his generic and specific descriptions. I am also sorry to see that little word "*sub*" used so extensively; for my own part I do not understand its meaning as applied in zoology and botany. I can quite understand its applied use in sub-contractor, sub-lieutenant, subterranean, &c., but who dares tell us that one tribe, or one family, or genus, or species is subordinate to another? I comprehend a "species" as a form of animal or vegetable life which differs slightly but materially and permanently from its nearest ally; such a form is, in my humble opinion, worthy to hold its own as a good species, not subservient or subordinate to any other form that can be so described, no matter how apparently closely related. Forms of this kind may have (I say it advisedly: we have no proof to the contrary) approached each other through natural selection, without being off-sets in a direct line from a common parent.

Again, why use the term "sub" at all, when a much simpler and less confusing arrangement may be employed in its stead. All naturalists are pretty well agreed that natural arrangements shall consist of orders, tribes, families, genera, species, and lastly, varieties. Beginning with "tribes" of any given order, we have—Tribe 1, consisting of certain families all agreeing in certain recognisable features or parts. Families which cannot be grouped under Tribe 1 would fall under Tribe 2, and so on numerically *ad libitum*, without one being subordinate to the other, which they really are not in nature. The same may be said of genera grouped into families, species into genera, &c.

Dr. Hooker has done well in making varieties (or, as he terms them, "sub-species") of some plants which certainly have no other specific claim. As an instance, I may cite the three almost equally common forms of *Aspidium*, all of which are included under *A. aculeatum*, Sw. This is decidedly a step in the right direction; but should not the forms have retained the name of *angulare* in preference to *aculeatum?* The latter, I believe, claims priority, but the form described under *angulare* is decidedly the most highly developed, having stalked pinnules.

Woodhay, Aug. 12 HENRY REEKS

On Supersaturated Solutions

MY friend Mr. Rodwell was so good as to forward to me a copy of NATURE for the 4th inst., containing an account of some interesting experiments by Mr. Grenfell on the action of fatty bodies on supersaturated saline solutions.

During the last two years I have made a large number of experiments in order to ascertain the function of oils and fatty substances in determining the crystallisation of such solutions. The results of my inquiry are included in a paper, the abstract of which was read before the Royal Society on the evening of the 16th of June last, to which I beg leave to refer.

I may, however, be permitted to make a few remarks arising out of Mr. Grenfell's paper.

According to my view, a *nucleus* is a body that has a stronger attraction for the gas, or the vapour, or the salt, of a supersaturated solution than for the liquid that holds it in solution.

Nuclei, with certain limitations, cease to be such when made *chemically clean*.

A body is chemically clean, the surface of which is entirely free from any substance foreign to its composition.

Thus oils and fatty bodies are chemically clean, if chemically pure, and containing no substance, mixed or dissolved, that is foreign to their composition.

The limitations above referred to are two: (1) the oils, &c., when chemically clean, do not act as nuclei while in the mass, such as a lens or globule; but these oils, &c., whether clean or not, in the form of thin films, act powerfully as nuclei; (2) a liquid, at or near the boiling point, is a supersaturated solution of its own vapour, and a porous body, such as charcoal, pumice, &c., whether clean or not, is a powerful nucleus in separating vapour.

I have on several occasions taken the liberty of opposing M. Gernez's views as to the action of nuclei. He supposes (1) that supersaturated gaseous solutions (soda water, seltzer, &c.) give off their gas to nuclei by virtue of the air that these latter introduce into the solution: in other words, gas must escape into air, and the function of the nucleus is to carry down air; hence rough bodies act better as nuclei than smooth ones. I have shown (Phil. Mag., August 1867) in a series of twelve experiments, that air is not a nucleus, and that rough bodies are inactive, if *catharised* or made *chemically clean*. A rat's-tail file, for example, is a good nucleus, because it holds between its teeth not air, but that filmy kind of matter that is powerfully *nuclear*, and it is not easy to clean a body of this kind; but when clean, it is quite inactive. So, a flint stone that has been exposed to the air, or handled, acts as a powerful nucleus, but when broken, the newly-fractured surfaces are inactive, because chemically clean. And such surfaces are inactive, because the gaseous solution adheres to them as a whole; whereas, if a clean body be handled or exposed to the air, it becomes covered, more or less, with filmy matter, to which the gas adheres more strongly than the liquid does, and hence there is a separation.

There is, I think, abundant proof that air is not a nucleus, its function, if it have any, in this class of phenomena, being that of a *carrier of nuclei*. Proof also is wanting, I imagine, that when a nucleus determines the crystallisation of a supersaturated saline solution, a salt of its own kind is present. When M. Gernez so laboriously prepared his nuclei, so as to free them from salt, he did not perhaps reflect that he was making them chemically clean. Of course I fully admit that, in general, a salt of the same kind as the solution, acts as a powerful nucleus; but in order for it so to act it must adhere more strongly to the saline than to the liquid portion of the solution. It may even happen that a crystal of the same kind, and of the fully hydrated salt, has no nuclear action, because it is in a perfectly catharised condition. And here I must refer to the objection raised by Dr. De Coppet, that in one of my forms of showing this experiment, the hydrated crystals, say of magnesic sulphate, being introduced into the neck of the flask while the solution was boiling, and so left in the covered flask while the solution cooled, such crystals become so changed by the heat as no longer to represent the normal salt, so that when lowered into the solution they formed a different salt, and hence were no test of the point in question, as to whether a salt of the same kind may be rendered inactive as a nucleus. I admit the criticism to be just, but in my original account of the experiment (Phil. Trans., 1868, p. 665) I did not rely upon one form only. Highly supersaturated solutions in clean tubes, plugged with cotton wool, were put, when cold, under the receiver of the air-pump, and left for some time *in vacuo*, over sulphuric acid, the effect of which was to produce crystalline crusts of the normal salt on the surface, and these by shaking fell through the solutions without acting as nuclei; whereas on removing the cotton wool in the presence of air, the solutions crystallised immediately into a solid mass. So also by keeping supersaturated solutions during some months, water escapes through the cotton wool, and a crystalline crust of the normal salt creeps up the air-filled portion of the tube, and this has no nuclear character, because the adhesion between it and the solution is perfect.

So necessary is the action of a nucleus in determining crystallisation in these solutions, that, if care be taken to exclude nuclei, highly supersaturated saline solutions may, by reduction of temperature to 0° F., or from that to − 10° F., be made solid, and by placing the tubes in snow and water at 32° F., the solids rapidly melt into clear bright solutions, without any separation of salt. These effects may be shown any number of times; but whether the solution be solid or liquid, if the cotton wool be removed, crystallisation always sets in, in the case of the solid during the melting, while in that of the liquid the effect is immediate.

With respect to the editorial note that the solutions of hydrated salts contain the anhydrous salt, I have shown in the paper last quoted, and with still greater elaboration in the *Chemical News* for Dec. 10th, 1869, that such is the case with respect to sodic sulphate. I insist on this point, as it is one of first-rate importance in considering the theory of supersaturated saline solutions. I endeavour to prove that it is the anhydrous salt in solution, by showing that at various points of the scale a sudden lowering of temperature produces a shower of the well-known octahedral crystals of the anhydrous salt. I also explain in my original memoir, that it is necessary for these crystals to be deposited before the modified 7-atom salt can be formed, and that even when there is a copious deposit of this salt the liquor above it is not, as Löwel supposed, the mother liquor of the 7-atom salt, but it is still a solution of the anhydrous salt. And more than this, when the sudden change in the curve of solubility takes place at 33° or 34° C., and there is, according to Gay Lussac's supposition, a change in molecular condition, it is still the anhydrous salt that is in solution.

There are several other points that might be enlarged on, but that I fear to trespass further on your valuable space.

Highgate, N. CHARLES TOMLINSON

Astrology

THE belief in astrology which still prevails among the English lower classes to a much larger extent than is supposed, will derive a fresh impulse from the happy guesses which have been made by the editor of "Moore's Almanac" in his issue for the current year. The hieroglyphic with which it is illustrated is less vague than usual, and represents two eagles fighting in the air, and on the plains beneath them hosts of armed men (in decidedly foreign uniforms) engaged in a bloody struggle. Lest the point should be missed, the prophet begins the forecast of the year with the distinct assertion that there will be war between France and Prussia, and that the month of July will be especially disastrous to the Emperor Napoleon. Thus far events have coincided with the voice of the oracle, and seem to confirm the poet's view that

"The warrior's fate is blazoned in the skies."

But we have yet to see whether "in October the King of Prussia (if living) will meet with defeat, and the ex-King of Hanover recover some of his prestige, if not his throne also." M. Comte would have us deal tenderly with astrology, because it was, in his opinion, the first systematic effort to frame a philosophy of history out of the apparently capricious phenomena of human actions. In theory we may do so, but astronomical science is hardly likely, for the sake of sentiment, to treasure up the discarded swaddling clothes which for so many centuries impeded its onward progress.

Norton Canon, Weobley C. J. ROBINSON

On Volcanoes

HAVING only last night returned from Norway, I was not aware before to-day that No. 40 of NATURE (August 4) contained "an outline" of a lecture on volcanoes delivered by me in St. George's Hall, Langham Place, on the 19th June (not 9th as therein stated) last.

Although I cannot but feel highly flattered at the length of this notice, I must regret that the author of this "outline," who, strangely enough, signs himself by my name, has, as will be seen upon reference to the text of my lecture as reported in the *Geological Magazine* for July, omitted every word which could convey to the reader the remotest idea of the object of the lecture itself, or the conclusions arrived at from the evidence brought forward. Just as a man without life is but a corpse, neither can a mere string of facts be called even the "outline of a lecture," when we have only the body without the spirit.

The object of my lecture was to institute a comparison between the relative magnitudes of the operations of internal and external forces in determining the main external features of our globe, and the conclusion arrived at was, to "grant the first rank to the internal, volcanic, or cataclysmic agencies, since, had it not been for their operations, our globe would still have remained a comparatively smooth sphere, surrounded by its external envelope of water, with no visible land for the rivers to traverse or the rain and ice to disintegrate and wear away," &c.

In order that your numerous scientific public may not be led to judge of the lecture by this outline, I trust to your good will in asking you to insert these remarks in your next number.

A Vivid Mirage

THE illusion known as the mirage is, I believe, not unfrequently observed in the British Isles; but the vividness with which it was displayed on the present occasion will, I trust, be a sufficient apology for troubling you with this letter.

The land bordering the River Nene is protected by banks of from twelve to fifteen feet in height, enclosing a space called the "Wash," which receives the flood waters. It was from one of these banks that the appearance in question was observed, nothing unusual being seen from the level of the fen. I may mention that the Wash at this season is as dry as any other portion of the land.

The day (August 12) was hot, the sky cloudless, and a strong N.E. wind was blowing. About eleven o'clock the phenomenon was first noticed. To the eastward a dark line of trees, some eight miles distant, stood out in bold relief against the clear sky, and in front of this a shining line of silvery brightness was seen, which gradually widened until about twelve o'clock it presented the appearance of a broad expanse of water, ruffled into waves on its near side, but perfectly calm and clear toward the horizon where the line of trees was beautifully reflected on its surface. As I had been approaching the scene all this time, the expanding of the lake appeared perfectly natural, and I could scarcely help thinking the river must have overflowed during the night and drowned the "Wash." This, of course, I knew to be quite out of the question, but the semblance was so perfect that it required an effort to believe that it was but an illusion. Its shores were clearly defined, little bays dimpled it, tiny headlands jutted out from it, and the waves were seen rising and falling with life-like exactitude. The whole appeared quite stationary, and as I approached the spot it gradually faded away, until nothing but a thin blue haze beneath the trees remained, and this at length dissolved.

On looking behind me (*i.e.* westward) another mirage seemed forming, which increased in apparent extent as I went farther from it. In this case the illusion was, if possible, more perfect than in the last, and the comparatively high land of Whittlesea rose like an island from the shining sea. Vehicles passing along the road seemed floating on its surface, their dark drawn-out reflections showing vividly against the sun-lit water, which, in this instance, was quite calm. How long this illusion lasted I know not, but when, about two o'clock, I quitted the bank it was still very distinct.

The dead level of the fen, and the bright sunlight falling upon the parched land, from which the heated air rose tremulous as from a hot plate, render this district peculiarly favourable to the production of such effects. For the accuracy with which the appearance of water was simulated it was quite equal to any mirage I have witnessed on the African deserts.

Geological Survey, Whittlesea, Cambridge, Aug. 12

Mirages made Easy

THE very interesting account of a mirage in this week's NATURE induces me to send a few observations. The mirage phenomenon is by no means so uncommon in England as many think. Three or four summers ago, on a strip of sand three miles long at Morecambe Bay, I was able to see one almost every hot day, by simply stooping until my eyes were about a yard above the ground. The further part of the sand then appeared as a lake of water, with objects reflected, &c. The nearer edge of this lake receded as the eyes were raised, the whole soon becoming invisible. I saw the same effects last summer off the Holderness Coast, but again only by stooping. At Cambridge I have lately seen a very good lateral mirage, by looking closely along the surface of a wall fifty yards in length, which had been exposed for some hours to a western sun. Objects near the further end of the wall were distinctly reflected.

Science and the Government

THE announcement in your last number of a rumour that the Government is about to withdraw its promise of aid to the Total Eclipse Expedition, seems to bring to a climax the relations of the Government towards science. We can hardly forget that one of the prominent members of the present ministry, and the one considered to have the special control over the spending of the public funds, is member for the University of London. Mr. Lowe was sent to Parliament, irrespective of party considerations, as the representative of a body which thinks it has some claim to a leading place among the scientific institutions of our country. Is it not worth while to consider whether the views of the graduates of London University are represented in the present attitude of the ministry, and whether some representation might not be made to the Government, through the Chancellor of the Exchequer, of the manner in which the present relations between the Government and science are regarded by his constituents?

3, Park Village East, Aug. 20 ALFRED W. BENNETT

*AROMATIC GLYCOL**

ALL chemists recollect the profound impression caused by the discovery of glycol in 1855 by M. Wurtz. Up to that time the bodies which were recognised as belonging to the group "alcohol" only included what we now call monatomic alcohols (common alcohol and its analogues), and M. Berthelot hesitated before venturing upon declaring glycerine a triatomic alcohol—an opinion to which Gerhardt never entirely adhered.

M. Wurtz showed that besides ordinary or monatomic alcohols, there are others which, when submitted to certain reagents where ordinary alcohols furnish only one, produce two derivatives. To these substances he gave the name of diatomic alcohols or *glycols*, and recognised that to each monatomic alcohol belonged a corresponding glycol, which only differed from it by the addition of an atom of oxygen. This new view became rapidly extended. It was admitted that belonging to each glycol there was, or might be, a triatomic alcohol or glycerine; that to each glycerine there might be a corresponding tetratomic alcohol, and so on; these alcohols only differing from one another by the number of atoms of oxygen which they contained, the number being always denoted by the atomicity of the alcohol.

Shortly before M. Wurtz's discovery of glycol, Signor Canizzaro, now Professor at the University of Palermo, but then Professor at Genoa, had announced the discovery of a new alcohol, which he called benzylic alcohol, having to benzoic acid the same relation as vinous alcohol has to acetic acid. He had obtained this substance by the action of potash in alcoholic solution, on the essence of bitter almonds.

Some time later the same chemist discovered that this alcohol might be equally obtained by means of toluol (*toluène*). The method he employed was to subject chlorinated toluol to the action of acetate of potash; and finally to decompose the acetate of benzyl thus obtained by means of potash.

This benzylic alcohol was the starting point of a new series of alcohols known as aromatic monatomic alcohols, and in fact soon afterwards cumylic alcohol was obtained, and Signor Canizzaro himself shortly afterwards published his discovery of tolylic alcohol.

It should, however, be observed that the process by means of which Signor Canizzaro had obtained his benzylic alcohol from toluol, succeeded ill with the homo-

* "Sur un Glycol Aromatique." Par M. Edouard Grimaux.

logues of this hydro-carbon, and gave, even with toluol, but small quantities of the alcohol.

Herr Beilstein, however, took up the matter at the point where others had abandoned it. He showed that when chlorine is made to act upon heated aromatic hydrocarbons, there is obtained a chloro-derivative, easily acted upon by acetate of silver or of potassium, and consequently admirably fitted to furnish the corresponding alcohol; whilst on the other hand when used cold, a very stable chloro-substitution compound is formed of the same composition, but furnishing no alcohol.

From this moment no difficulty remained in completing the series of the aromatic monatomic alcohols; but up to this time no diatomic alcohol, or aromatic glycol was known. It was, however, evident that the preparation of such compounds was possible, inasmuch as the knowledge already existed of such acids as formobenzoilic acid, and terephtalic acid, which bore the same relation to these unknown bodies as glycolic and oxalic acids to ordinary glycol.

M. Edouard Grimaux, after much long and careful investigation, has at length filled up the blank by the discovery of tolylenic or xylenic glycol, that is to say a glycol which presents in its composition xylol to which two atoms of oxygen are added without substitution.

To obtain tolyl-glycol M. Grimaux takes the xylol of commerce which he raises to the boiling point in a retort, surmounted by an inverted refrigerator, from which the condensed vapours flow back into the retort, the tubulure of which is closed by a cork, into which a funnel with a tap is inserted. He then introduces drop by drop into the boiling hydro-carbon half its weight of bromine. The bromine is at once absorbed with the production of hydrobromic acid, and on cooling a black crystalline mass is obtained which is first washed with ether, and its purification completed by crystallisation from chloroform. This substance is a bibromo-xylol easily acted on by re-agents.

Treated at a temperature of 150°, or in a closed vessel with an alcoholic solution of acetate of sodium, the bromo-product gives rise by double decomposition to bromide of sodium and to diacetate of tolylene, which takes the form of beautiful colourless crystals.

Subjected in its turn to the action of thirty times its weight of water at a temperature of 170° or 180° in a closed vessel, this acetate of tolylene is separated into acetic acid and tolylenic glycol, which, on the opening of the tube and by the evaporation of the liquid, is deposited in needle-shaped crystals.

The formation of tolyl-glycol may be represented by the following equations:—

$$1.\quad C_6H_4<\begin{matrix}CH_3\\CH_3\end{matrix} + 2\left\{\begin{matrix}Br\\Br\end{matrix}\right\} = 2\left(\begin{matrix}H\\Br\end{matrix}\right\} + C_6H_4<\begin{matrix}CH_2Br\\CH_2Br\end{matrix}$$

Xylol. — Bromine. — Hydrobromic acid. — Bromine of tolylene.

$$2.\quad C_6H_4<\begin{matrix}CH_2\,Br\\CH_2\,Br\end{matrix} + 2(C_2\,H_3\,O_2.\,Na) = 2\,Na\,Br + C_6H_4<\begin{matrix}CH_2.C_2H_3O_2\\CH_2.C_2H_3O_2\end{matrix}$$

Bromine of tolylene. — Acetate of sodium. — Bromide of sodium. — Acetate of tolylene.

$$3.\quad C_6H_4<\begin{matrix}CH_2.\,C_2H_3O_2\\CH_2.\,C_2H_3O_2\end{matrix} + 2\left(\begin{matrix}H\\H\end{matrix}\right\}O\Big) = 2(C_2H_3O_2H) + C_6H_4<\begin{matrix}CH_2\,OH\\CH_2\,OH\end{matrix}$$

Acetate of toluol. — Water. — Acetic acid. — Tolyl glycol.

The path is now open, and nothing will be easier than, by following the method proposed by M. Grimaux, to prepare all the aromatic glycols, of which the hydrocarburets are already known to us.

ALFRED NAQUET

SPECTROSCOPIC NOTES *

SPECTRUM OF A SOLAR SPOT, APRIL 9, 1870, P.M.

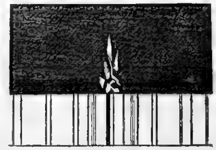
EXAMINED the spectrum of a large group of spots a little north and east of the sun's centre.

The nucleus of the most southerly member of the group reversed the C line finely, turning it into a conspicuous bright line for about 20″ of its length, without any distortion, however, such as is common upon this (dark) line in the neighbourhood of spots.

F was also reversed, but rather faintly.

D_3 could not be made out at all in the nucleus spectrum; neither were 2796 (the numbers refer to Kirchhoff's map) nor *h* reversed. I thought, however, that they were somewhat *thinned*.

The reversal of C and F continued through the whole afternoon.



On the other hand, many of the dark lines were widened and deepened in this nucleus spectrum in the manner which the description and figures of Mr. Lockyer have made familiar. Many also were unaffected. Among these were notably *a*, B, E, 1474, the four lines of *b*, 1691 and G.

The two sodium lines D_1 and D_2, and 850 (Fe) were distinctly, but not greatly, widened.

The effect was most marked upon the following: 864 (Ca), 877 (Fe?), 885 (Ca), 895 (Ca and Li), 1580 (Ti), 1599 (Ti), 1627 (Ca), and 1629 (Ti). I have marked 877 doubtful, because there lies very near it a line whose origin is unknown, and I am not sure to which of the two the thickening was due. The Titanium lines are identified as such by reference to Ångström's Atlas. I was greatly surprised at the prominence they assume in the spot-spectrum, as they are inconspicuous in the normal spectrum; and a similar remark applies to the calcium lines.

I do not intend to convey the idea that the lines mentioned were the only ones that were much deepened; there were many others, mostly faint, affected to nearly the same degree, but I had not time to identify them.

There was at the same time an exceedingly brilliant protuberance on the south-west limb of the sun (position angle 230°), near but not over, a large spot which was just passing off. At the base of this prominence, which was shaped like a double ostrich plume, the C line was intensely brilliant, so that the slit could be opened to its whole width in studying the form above described, but it was not, so far as I could see, in the least distorted. On the other hand, the F line, also very brilliant, was shattered all to pieces, so that at its base it was three or four times as wide as ordinary, and several portions of it were entirely detached from the rest. The figure, without pretending to exact accuracy, and for the sake of distinctness a little exaggerated, gives a fair idea of the nature and extent of the "shattering" alluded to.

Since the C line was not similarly affected it is hardly possible to attribute this breaking up of F to cyclonic motions in the gas from which the light emanates, and it becomes very difficult to imagine a cause that can thus disturb a single line of the spectrum by itself. Possibly this appearance may be the result of local absorptions acting upon a line greatly widened by increase of pressure or temperature.

It continued unchanged for more than half an hour, and until the sun passed out of sight behind a building. The observations were made with the 5 prism spectroscope.

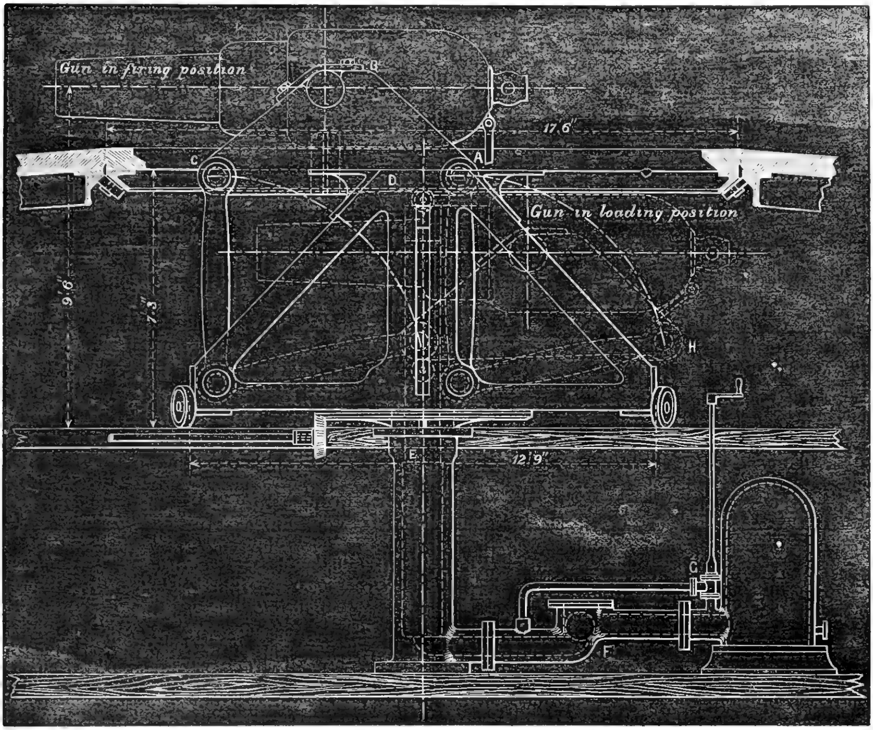
THE SCIENCE OF WAR

I.

CAPTAIN MONCRIEFF'S HYDRO-PNEUMATIC GUN-CARRIAGE FOR SEA SERVICE

SOME apology is needed for venturing to trouble the quiet of NATURE with an account of military engines. The desolation that war is now spreading over some of Nature's fairest scenes, and the waste caused thereby of her bounteous annual gifts, may account for these jottings, which have, perhaps, strangely found their way into her note-book; such topics have been suddenly and violently forced of late upon her attention.

But a further and more substantial reason for finding a place for a subject of this kind within NATURE'S domain is that the action of Nature's forces is in some ways best displayed in warlike engines. In them we use, examine, and experiment with force in sudden and violent action. To produce and also to control and direct the instantaneously created power of explosives has taxed the ingenuity, and also enlarged the knowledge of both the chemist and the mechanician. But for the necessities of war we should know little of Nature's forces in this aspect. The arts of peace only in a very limited form make use of explosive agents. The wonderful progress made of late years in military engines—a progress whose rapidity surpasses the advances of any mechanical inventions for other purposes—has called an amount of attention to those forces and agents which the modern artillerist employs, that has not failed to bring out many special facts in relation to them. Nature's territories are everywhere so rich that he who diligently ploughs any corner, however remote, seldom fails to be rewarded, not only by the crop which he seeks to cultivate, but also by some unsuspected fragments of truth which his plough-share has, as it were, accidentally turned up. For instance, some of the most remarkable examples of conservation of energy are to be found in the action and effects of the mighty projectiles of modern times.



The inventions of the gentleman whose name stands at the head of this paper, afford several important illustrations of the foregoing remarks. It is not more than two years since his Protected Barbette Gun-Carriage for land defence was tried with an instantaneous success that filled the public with astonishment—an exceedingly rare occurrence in inventions so entirely novel in their principles. Having previously existed only in the inventor's mind and in small models, when applied to a 7-ton gun (a monster unknown so recently as the Crimean war), it was found to work with perfect exactness and to realise all that had been promised for it. It may be well to recall briefly to the reader's mind what this carriage effected, and the means by which it acted, as the new carriage is designed to effect a somewhat similar object, though by a wholly different agency.

The purpose which the Protected Barbette Carriage accomplishes is the utilisation of the recoil. This force, which in modern heavy ordnance is a very considerable one, was previously known only as a destructive force. It strained racers and pivots almost beyond the endurance of iron, and shook the granite foundations on which they rested; and artillerists sought to coax it to waste itself as harmlessly as they could in friction. The Protected Barbette Gun-Carriage utilised this force by causing it to raise a counter-weight, while the gun descended below the parapet into safety and concealment from the enemy. This was effected by interposing between the gun and counter-weight a *moving* fulcrum. Any fixed fulcrum, such as a pivot, was found, no matter how strong, incapable of resisting the almost inconceivably rapid action of exploding gunpowder; it was torn from its position before it had time to move. But in the moving fulcrum there is nothing to be broken. The recoil of the gun rolls back the elevators, which raise the counter-weight, and this is retained in its position when the recoil is exhausted, and when released and allowed to fall restores the gun to the firing position again. It should be further observed that the gun commences to move in the direction of the recoil, gradually descending on a cycloidal curve, and thus the force of the recoil is not suddenly checked, but guided. This is one of the conditions essential to its success.*

The invention, which it is the design of this paper to discuss, effects a similar object for naval gun-carriages to that accomplished on land by the Protected Barbette Gun-Carriage. By it the gun is gradually lowered in its recoil below the surface of the deck of the vessel, and the force of the recoil is stored up to raise the gun at pleasure to its firing position above the deck. But the means by which it is accomplished are wholly different. There is no counter-weight and there is no moving fulcrum. It is manifest that at sea the fall and rise of a counter-weight could not be used. The direction of the force of gravitation is fixed and invariable, but the platform of a ship's deck is not always horizontal, and is often rapidly changing its inclination. In the Hydro-pneumatic Carriage, advantage is taken of the elasticity of air to store up and utilise the force of the recoil. A volume of air is compressed by the recoil of the gun, and being retained at pleasure in its compressed state, it is able to lift the gun to the position it occupied before the discharge; and as the moving fulcrum transferred the force of the recoil to the counter-weight without any check or jar, so in this naval carriage a like office is performed by water, which smoothly and effectually conveys the force of the recoil to compress the air in its reservoir. This is accomplished in a very simple manner, which can be easily understood by the accompanying diagram. The lines represent the gun and carriage in the firing position, the dotted lines in the loading position, showing the effect of the recoil. The gun is carried in a small triangular carriage (A, B, C), and this moves down through a quarter circle by the parallel motion of four strong bars, jointed on the carriage and on a platform on the lower deck of the vessel. In the firing position this part of the apparatus is supported by a plunger (D, E) or piston, and by the descent of the carriage this plunger is forced into a cylinder filled with water. This cylinder communicates with an air vessel or reservoir; consequently by the recoil a volume of water equal in bulk to the cubic content of the plunger is forced into the air reservoir; the volume of air is diminished by that amount and the pressure increased. The valve at F is self-acting in one direction only; it allows the water to flow into the air reservoir, but not to return. Consequently, when the recoil has exhausted its force in compressing the air, the gun remains in the loading position. When the valve G is turned, the water is driven from the reservoir by the compressed air, rushes into the cylinder, raises the plunger, and with it the gun and its carriage into the firing position. It should be observed that there is a circular portion of the upper deck, which, with the platform on the lower deck, to which the parallel bars are attached, traverses round on the plunger as a pivot, and so enables the gun to be pointed in any direction. In this rotating circular portion of the upper deck there is a rectangular opening which opens and closes by a pair of self-acting shutters with the rise and fall of the gun. A minute description of these minor arrangements is not here necessary.

One of the most remarkable features of this invention is the extraordinary power of adjusting the force employed to meet the recoil of the gun. By the descent of the plunger the air space is reduced by the cubic content of the plunger; and as the air space can be varied by admitting more or less water into the reservoir, so can the elastic force be varied to meet the recoil. For instance, did the air space in the reservoir equal the volume of the plunger, then the plunger could not possibly descend entirely into the cylinder, as that would compress the air to nothing. On the other hand, were the air space three or four times the volume of the plunger, then a small force of recoil would be sufficient to bring it completely down. The resisting force may thus be adjusted within almost any limits to meet the force of the recoil. It will be further observed that as in the Protected Barbette Carriage with counterweight, the recoil is met by a very slight resistance at the commencement, and is allowed to start in motion in its own direction. The first backward motion of the gun depresses the plunger very slightly, but as the recoil goes on it causes an increasingly rapid descent. For instance, the rollers must travel over two-thirds of the quadrant A H, to send the plunger half way down into the cylinder; the remaining one-third would send it down to the bottom. Thus the resistance to the recoil goes on increasing in a double progression, both from the increased pressure of the air as its volume is diminished, and also from the fact that the motion of the gun produces an increasing diminution of that volume.

Let us go through the process of adjusting the machine into working order. The reservoir and cylinder are both empty, the plunger is at its lowest descent, the gun lies down in the loading position. By a pump communicating with the reservoir, water is driven into the reservoir until the air space is reduced to one-half or one-third, as the case may be, of the volume of the plunger. This will raise but very slightly the plunger and its load. Now air must be pumped in till its pressure in the air space is sufficient to raise the plunger with the gun and its carriage into the firing position. The gun may then be brought down to the loading position.

This entire process need not be literally gone through in every case to adjust the machine. When once (if the expression may be borrowed) the "constants" of the carriage have been determined, *i.e.*, the amounts of air and water required in the reservoir, those quantities can be pumped in, keeping the valve G closed, and the gun remaining quiescent in the loading position. Water should be pumped in so as to leave a fixed air space, and then an amount of air, such that, with the added volume of the plunger, the pressure would still be sufficient to sustain the gun in the firing position. For a twenty-five ton gun the weight to be raised, including that of the plunger and the moveable part of the carriage, would be about thirty tons. Supposing the sectional area of the plunger to be two square feet, this would require a pressure of air of a little over 230lbs. on the square inch, or a little under sixteen atmospheres. When once adjusted, the carriage would remain in complete working order for days or weeks, in fact, until the water was allowed to run off.

While the main object and purpose to be accomplished

* While this article was going through the press, an attempt to make a gun descend an inclined plane by recoil and raise a weight, and so to form a protected Barbette carriage, was tried in the Royal Arsenal, and failed for this reason: The horizontal force of the recoil was not met in its own direction, but at an angle. The gun would not descend the inclined plane beyond a foot or two, and the violent concussion destroyed the elevating gear at the second shot.

by the hydro-pneumatic gun-carriage has been sketched, it is evident that all the applications of the principle of utilising the recoil as embodied in this engine have not been exhausted. The force of the recoil which must be exhausted in bringing the gun down to the loading position is very much greater than the force that would be required simply to raise the gun again to the firing position. The recoil takes place very rapidly, much more rapidly than it is desirable that the gun should rise again. If in the Protected Barbette Carriage it was allowed to return freely to its firing position, it would come up with an inconvenient or even a dangerous violence. The superfluous energy of the recoil stored up in the counter-weight must, therefore, be controlled and exhausted by friction bands. In the hydro-pneumatic carriage the return of the gun can be completely controlled by the valve or stopcock G, so as to bring it to the loading position as gently as desired, and the superfluous energy of the recoil will take the form of heat developed in the compressed air of the reservoir. But this superfluous energy may be seized and utilised. If a second and smaller plunger is attached to the cross head of the main plunger, which supports the gun and its carriage, with a cylinder and reservoir of its own, the power there accumulated may be used for any other purpose, as training the gun and carriage. In this case also, though the pressure produced and the heat generated in the main reservoir will not be so great as if there was no second plunger, still it alone will contain an ample store of force to bring the gun again into its firing position.

To discuss the military advantage of this invention, as a substitute on board ships of war for a turret weighing 300 tons of wrought iron, affording more complete protection to gun and gunners, and not weighing for a twenty-five ton gun more than sixteen tons altogether, would be travelling out of the realm of NATURE.

We have only endeavoured to show in this example with how great efficiency and docility Nature obeys those who understand how to direct her forces, and that all her work is not only efficient but instructive. If we can persuade her to undertake a new task she will teach us a new lesson. In the hydro-pneumatic gun-carriage a means supplies itself for measuring the exact amount of work done by the recoil. The compression of the air in the reservoir, and the heat generated in the process, will give accurate data for measuring the force exerted, and by this a step will be made towards measurements of the power of explosives with a precision hitherto unattainable.

Nature, like the great ancient fabulist, if she is compelled to be our slave, is resolved also to be our teacher.

NOTES

THERE is one part which neutrals may take in the Continental war. With no sympathy for those who have caused the war on either side, our sympathy is all the more due to those who innocently suffer from it on both sides. The following appeal, posted on the walls of every *mairie* in France, will touch other hearts than those of Frenchmen :—"*Appel à la France.*—Au nom de Dieu, au nom de la patrie, au nom de nos fils, de nos frères, de nos braves soldats tombés avec honneur sur le champ de bataille, et toujours héroïques quoique vaincus aujourd'hui, nous faisons un appel à tous les cœurs français. De grâce, donnez-nous de l'argent, du linge, des chemises, des couvertures, des vêtements, de flanelle, etc. Là-bas, sur nos frontières, l'élan des villes, les offrandes touchantes des villages ne suffisent déjà plus à nos chers blessés.—Les besoins sont immenses.—Le temps presse.—Donnez, oh! donnez vite! Envoyez les dons en nature et en argent au siége de la société à Paris, Palais de l'Industrie, porte No. IV." Here is a work in which all may unite—French, Germans, and neutrals, men of science, men of literature, men of business; and above all, our women. Nobly already have English, Irish, and Americans, surgeons, nurses, sisters of charity, come forward in the good work, but still it can only be as a drop in the ocean. To offer succour to the wounded and sufferers on both sides, to assuage as far as we can, the horrors of war, never exhibited on a more fearful scale than within the last few weeks, is now the duty of our more fortunate countrymen and countrywomen.

ANOTHER sacrifice of science to the war! The Congress of Alpine Geologists, the meeting of which we announced to take place on the 31st of this month, is adjourned to a more favourable time. It is probable also that the Congress of Anthropology and Pre-historic Archæology which it was proposed to hold at Bologna, and that of German naturalists to take place at Rostock, will not be held.

THE following sectional arrangements of the British Association are now announced :—A—MATHEMATICAL AND PHYSICAL SCIENCE (in the Crown Court, St. George's Hall) : President—J. Clerk Maxwell, F.R.S. L. and E. ; Secretaries—Prof. W. G. Adams ; W. K. Clifford ; Prof. G. C. Foster, F.R.S. ; Rev. W. Allen Whitworth. B—CHEMICAL SCIENCE (in the Royal Institution, Moore Street) : President—Prof. Henry E. Roscoe, PhD., F.R.S., F.C.S. ; Secretaries—Prof. A. Crum Brown, F.R.S.E., F.C.S. ; A. E. Fletcher, F.C.S. ; Dr. W. J. Russell, F.C.S. C—GEOLOGY (in the Concert Hall, Lord Nelson Street) : President—Sir Philip de Malpas Grey Egerton, Bart., M.P., F.R.S., F.G.S. ; Secretaries—W. Pengelly, F.R.S., F.G.S. ; Rev. H. H. Winwood, F.G.S. ; W. Boyd Dawkins, F.R.S., F.G.S. ; G. H. Morton, F.G.S. D—BIOLOGY (in the Reading Room and Lecture Room of the Free Public Library) : President—Prof. G. Rolleston, M.D., F.R.S., F.L.S. ; Vice-Presidents—John Evans, F.R.S., F.G.S., F.S.A. ; Prof. Michael Foster, M.D., F.L.S. ; Secretaries—Dr. T. S. Cobbold, F.R.S., F.L.S. ; Thos. J. Moore ; H.T. Stainton, F.R.S., F.L.S., F.G.S. ; Rev. H. B. Tristram, LL.D., F.R.S. E—GEOGRAPHY (in the Small Concert Room, St. George's Hall) : President—Sir Roderick I. Murchison, Bart., K.C.B., D.C.L., LL.D., F.R.S., F.G.S. ; Secretaries—H. W. Bates, Assist. Sec. R.G.S. ; Clements R. Markham, F.R.G.S. ; Albert J. Mott ; J. H. Thomas, F.R.G.S. F—ECONOMIC SCIENCE AND STATISTICS (in the Council Chamber, Town Hall) : President—Prof. Jevons ; Secretaries—E. Macrory ; J. Miles Moss. G—MECHANICAL SCIENCE (in the Civil Court, St. George's Hall) : President—Charles Vignoles, C.E., F.R.S., M.R.I.A., F.R.A.S. ; Secretaries—P. Le Neve Foster ; J. T. King.

THE Dutch Society of Sciences, of Haarlem, instituted last year, in addition to its ordinary prizes, two large gold medals, each of the value of 500 florins, one of which bears the name and effigy of Huyghens, the other of Boerhaave. These medals are to be awarded alternately, once in two years, to the *savant*, Dutch or foreigner, who shall have contributed the most, during the previous twenty years, to the progress of one particular branch of mathematical physics or of natural science. The Huyghens medal is to be devoted in 1874 to chemistry, in 1878 to astronomy, in 1882 to meteorology, in 1886 to mathematics, pure and applied. The Boerhaave medal is to be granted in 1872 to mineralogy and geology, in 1876 to botany, in 1882 to zoology, in 1884 to physiology, in 1888 to anthropology. The series will then recur. At their recent annual meeting the society made the first award of the Huyghens medal to M. Clausius for his discoveries in thermo-dynamics.

SIR FREDERICK POLLOCK, late Chief Baron, whose death is announced as having taken place on Tuesday last, in the 87th year of his age, was an amateur photographer of no mean ability, and had been President of the London Photographic Society ; he was an occasional contributor of articles on photography to the Philosophical Proceedings of the Royal Society.

He received his education at St. Paul's School and Trinity College, Cambridge, and was Senior Wrangler and First Smith's Prizeman in 1806.

THE Duke of Argyll writes to the *Times* to say that a remarkable meteor which was visible in the north of England on the 15th inst., was also seen at Inveraray. "It burst," the Duke says, "about 50 degrees above the horizon in the N.N.W., and ts great peculiarity was in the appearance presented by the luminous vapour which was the product of its explosion. This vapour was brighter than the tail of any comet—at first linear in shape—with sharp irregular projections. It was soon, however, curled up, as if by an atmospheric current, into the form of a horse-shoe, and in this form seemed to drift very slowly before the north-east wind in a south-west direction. It gradually, but very slowly, lost its brilliancy, remaining visible for more han a quarter of an hour." Two other correspondents of the *Times* describe a very brilliant meteor which was seen in Cambridgeshire on Saturday night.

A WATERSPOUT was observed off Calais on Saturday evening. From the edge of a thick black thunder-cloud two funnel-shaped projections were seen to depend, until they gradually reached the surface of the sea, on which they created a great disturbance, masses of foam rising up to a considerable height around the foot of each waterspout. It was calculated that the long streamers hanging down from the cloud to the sea were nearly a mile in length. The wind caused them to wave about gently and alter their form slightly from time to time. One of the waterspouts lasted about ten minutes, and the other about a quarter of an hour. During this time they moved rapidly along the sea.

ON Saturday evening, August 20, between 11 P.M. and midnight, a very beautiful aurora borealis was seen near Weobley, in Herefordshire, stretching from N.N.E. to N.W., and visible, with more or less distinctness, for about three hours.

THE *Engineer* states that an exhibition is about to be opened in Tromso, the capital of Finmark. The exhibition will contain the products and appliances used in the several fisheries, those of agriculture, and of mechanical and domestic industry, together with objects and products illustrative of the mode of life and state of civilisation of the inhabitants of those regions.

WE recorded recently the purchase by the Belgian Government of the Martius herbarium as the nucleus of a national collection. The same Government has now also purchased the Brussels Botanic Gardens from the Belgian Horticultural Society. The capital of Belgium has thus laid the foundation of a national establishment comparable to those of Paris and London.

THE Treasurer's report of the British Medical Congress, which has just been sitting for four days at Newcastle-on-Tyne, shows that out of an income of 5,000*l.* per annum it spends just 15*l.* on scientific research. It is stated that the greater part of the funds are required to keep afloat its own journal, and that a proposition from some of the members to publish an annual volume of Transactions found but little favour.

TWO instances are recorded in *Les Mondes* of somnambulism being perfectly cured by the administration of bromide of potassium. In one case, a woman of the age of twenty-four who had been subject to attacks two or three times a week for ten years, was operated upon; the dose given was two grammes of the bromide in seventy-five of water per diem, gradually increased to six grammes; the attacks became at once less and less frequent, and entirely ceased at the end of two months. In the other case, a girl of eight was the subject; one gramme was given morning and evening, and the cure was complete and immediate.

WE have received a specimen of paper manufactured entirely from wood, which is at least equal in colour and texture to the cheaper kinds of ordinary printing paper. There is no doubt that the pulp from the fibre of the fir and some other kinds of wood makes excellent material for paper, which can be prepared at a low price, the only practical difficulty being the high temperature and consequently the high pressure required to decompose the non-fibrous matter. Another material now actually employed for the manufacture of paper, is the husk and seeds of the cotton-pod from which the oil has been expressed, the fibrous pulp resulting from this operation is said to be an excellent paper-making material. The larger portion of the cheaper printing-papers used for newspapers, magazines, &c., is now made entirely from the Spanish Esparto grass, a name given to two distinct species, *Macrochloa tenacissima*, and *Lygeum spartum*, both growing abundantly on the shores of the Mediterranean; but the comparatively high price of this material, more than double what it was a few years since, affords a favourable opening for the introduction of other paper-making fibres.

PROFESSOR ORTON does not give a very encouraging account of the intellectual condition of Ecuador. He says:—"Ecuador boasts one university and eleven colleges, yet the people are not educated. Literature, science, philosophy, law, and medicine, are only names: there is not a single book-store in the city of Quito, and there are only four newspapers published in the whole of the Republic. In the schools the pupils study in concert aloud, Arab fashion." Yet Professor Orton adds that Chile has thought it worth her while lately to sign a convention with Ecuador "for an exchange of literary productions!"

THE Government of Nicaragua has sent an expedition under Mr. Sonnenstern, a civil engineer, to examine whether the River Coco can be made navigable. The report of Mr. Sonnenstern, which is favourable, has been published in the *Gazette* of Nicaragua. The river has hitherto been little known. The Indians are stated to be indolent and docile, and might, by contact with settlers, be civilised.

THERE is a rumour in California that a large quicksilver deposit has been discovered in the coast mountains eastward of San José.

THE Ecuador Government has decreed that in the capital and suburbs no house constructed of cane and straw shall be permitted, and that three months after the date of the decree all those existing shall be demolished. There was a former decree to this effect, which is thus fully enforced.

THE old Palace of Government at Lima, in Peru, is condemned, and a new one, which is to be a stone palace from the designs of M. Zoiles, architect and engineer, is to be built. In preparation, the ministerial departments have been removed from the old building.

THE Federal Government of the United States of Columbia has paid a debt to the state of Panama by the transfer of house property in Panama, which is to be converted into a college for that city.

THE Rev. W. A. Leighton, of Shrewsbury, author of the "Flora of Shropshire," is preparing for publication "A Lichen Flora of Great Britain, Ireland, and the Channel Islands."

WE have to acknowledge the receipt of "Hogg's Secret Code for Letters or Telegrams," with instructions for converting a message into ciphers, and for converting ciphers into a message.

THE Rev. Prof. Haughton reprints from the *Dublin Quarterly Journal of Medical Science* his paper "On the Muscular Forces employed in Parturition, their amount and mode of application."

KARL FRITSCH'S "Phänologische Beobachtungen aus dem Pflanzen und Theirreiche" contains an immense mass of observations taken in the neighbourhood of Vienna and other districts of Austria, in the year 1857 (but now for the first time published), on what may be termed periodical natural history, that is, the period of the first flowering of plants, and the first appearance of migratory birds, insects, and other animals of the summer season.

THE last volume (XIX.) of the Transactions of the Imperial Zoological-Botanical Society of Vienna contains, among its more important articles, contributions to the flora of Greece and Crete, by Dr. E. Weiss; a monograph of the genus *Botrychium*, by Dr. J. Milde (reducing the thirteen species in Moore's Index Filicum to ten); anatomical investigation of *Pleurophyllidia formosa*, by R. Bergh; a second contribution to the flora of Lower Austria, by Dr. A. Neilreich; observations on the metamorphosis of insects in the light of the theory of descent, by F. Brauer (a thoroughly Darwinian article); contributions to Hymenopterology, by Dr. J. Kriechbaumer; descriptions of several Myriapods in the Museum of Vienna, by MM. A. Humbert and H. de Saussure; the Lichens of the Tyrol, by F. Arnold; zoological notes, by G. Ritter von Frauenfeld; contributions to the Fish-fauna of Trans-baikal, by B. N. Dybowski.

IN the "Arbeiten aus der Kiel Institut" we observe that Klünder has been making further investigations into the time occupied in muscular contraction. His experiments have been conducted with a pendulum chronoscope constructed by Hensen. The contraction is traced on a reddened glass plate attached to the arm of a tuning fork, with which it therefore vibrates when this is sounded. The curve described is consequently a sinuous line, its ascending and descending portion decussating. If a vertical median line be drawn on the plate when at rest, the measurements can be examined and compared. These give for the stage of latent excitation a value of $\frac{3}{400}$ths of a second, which, when the muscle is weighted or exhausted, may rise to more than 0·01 sec. Antecedent extension diminishes the duration of this period, as Helmholtz had already remarked. The proper curve of contraction exhibits itself in its middle part as a curved line modified by the elasticity of the muscle. The muscle is quite inactive towards the end of contraction, as shown by the form of the extremities of the curve. The greatest increase in rapidity occurs in the ascending portion of the curve, which corresponds to the greatest development of force in the muscle which is between the 3rd and 4th 1-400 of a sec., the absolute greatest rapidity of the ascent is in the 8th 1-400 sec. The form of the curve is, considerably changed if a heavy weight is appended to the muscle, the period of elevation as well as the fall being both longer. The retardation occurs principally at the commencement of the elevation, at which period the rapidity only slowly increases, as compared with its usual rate.

THE COMING TRANSITS OF VENUS*

TRANSITS of Venus over the disc of the sun have more than any other celestial phenomena occupied the attention and called forth the energies of the astronomical world. In the last century they furnished the only means known of learning the distance of the sun with an approach to accuracy, and were therefore looked for with an interest corresponding to the importance of this element. Although other methods of arriving at this knowledge with equal accuracy are now known, the rarity of the phenomenon in question insures for it an amount of attention which no other system of observation can command. As the rival method, that of observations of Mars at favourable times, requires, equally with this, the general co-operation of astronomers, the power of securing this co-operation does in itself give the Transits of Venus an advantage they would not otherwise possess.

Although the next transit does not occur for four years, the preliminary arrangements for its observation are already being made by the governmental and scientific organisations of Europe. It is not likely that our Government will be backward in furnishing the means to enable its astronomers to take part in this work. The principal dangers are, I apprehend, those of setting out with insufficient preparation, with unmatured plans of observation, and without a good system of co-operation among the several parties. For this reason I beg leave to call the attention of the Academy to a discussion of the measures by which we may hope for an accurate result.

In planning determinations of the solar parallax from the Transits of Venus, it has hitherto been the custom to depend entirely upon the observations of the internal contact of the limbs of the sun and planet proposed by Halley. It is a little remarkable, that while astronomical observations in general have attained a degree of accuracy wholly unthought of in the time of Halley, this particular observation has never been made with a precision at all approaching that which Halley believed that he himself had actually attained. In his paper he states that he was sure of the time of the internal contact of Mercury and the sun within a second. The latest observations of a transit of Mercury, made in November 1868, are, as we shall presently see, uncertain by several seconds. It is also well known that the observations of the last transit of Venus, that of June 1769, failed to fix the solar parallax with the certainty which was looked for, the result of the standard discussion being now known to be erroneous by one-thirtieth of its entire amount. One of the first steps to carry out the object of the present paper will be an inquiry into the causes of this failure, and into the different views which have been held respecting it.

The discrepancies which have always been found in the class of observations referred to, when the results of different observers have been compared, has been generally attributed to the effect of irradiation. The phenomenon of irradiation presents itself in this form: When we view a bright body, projected upon a dark-ground, the apparent contour of the bright body projects beyond its actual contour. The highest phenomenal generalisation of irradiation which I am aware of having been reached is this: A lucid point, however viewed, presents itself to the sense, not as a mathematical point, but as a surface of appreciable extent. A bright body being composed of an infinity of lucid points, its apparent enlargement is an evident result of the law just cited.

[The speaker here drew a number of diagrams for the purpose of illustrating his theory.]

The following diagrams show the effect of this law upon the time of interval contact of a planet with the disc of the sun. The planet being supposed to approach the solar disc, Fig. 1 shows the geometrical form of a portion of the apparent surface of the sun, or the phenomenon as it would be if there were no irradiation immediately before the moment of internal contact. Fig. 2 shows the corresponding appearance immediately after the contact. To indicate the effect of irradiation, or to show the phenomenon as it will actually appear on the theory of irradiation, we have only to draw an infinity of minute circles for each point of the sun's disc visible around the planet to indicate the apparent phenomenon. The effect of this is shown in Figs. 1*a* and 2*a*. The exceedingly thin thread shown in Fig. 1 is thus thickened as in 1*a*, and the sharp cusps of Fig. 2 are rounded off as shown in Fig. 2*a*. The apparent radius of the planet is diminished by an amount equal to the radius of the circle of irradiation, and the radius of the sun is increased by the same amount. Comparing Figs. 1*a* and 2*a*, it will be seen that the moment of internal contact is marked by the formation of a ligament, or "black drop," between the limbs of the sun and the planet. This formation is of so marked a character that it has been generally supposed there could be little doubt of the moment of its occurrence. The remarks of the observers have given colour to this supposition, the black drop being generally described as appearing suddenly at a definite moment.

Examining Fig. 2*a*, it will be seen that the planet still appears entirely within the disc of the sun. The geometrical circle which bounds the latter, and that which bounds the planet, instead of touching, are separated by an amount equal to double the irradiation. And, when they finally do touch, neither of them will be visible at the point of contact. The estimate of the moment of contact must therefore be very rough, the means of estimating being far less accurate than those afforded by a common filar micrometer. In the actual case the eye has to continue the two circles to the point of contact by estimation, through a distance depending on the amount of irradiation, while measures with a micrometer are made by actual contact of a wire with a disc. Such estimates have, therefore, been

* Substance of a paper read before the Thirteenth Annual Session of the American Academy of Sciences, held at Washington, by Prof. Simon Newcomb. (The original paper was illustrated by diagrams.)

generally rejected by investigators, not only from their necessary inaccuracy, but because the time of "apparent contact" depends upon the amount of irradiation, which varies with the observer and the telescope. If there is no irradiation at all, the time of apparent contact and that of true contact will be the same, as shown in Fig. 2, while, when the cusps are enlarged by irradiation, apparent contact will not occur until the planet has moved through a space equal to double the irradiation.

Let us return to the phenomenon at actual contact. According to the theory as it has been presented, the formation or rupture of the black ligament connecting the dark body of Venus with the dark ground of the sky is a well-marked phenomenon, occurring at the moment of true internal contact. This was, I believe, the received theory until Wolf and André made their experiments on artificial transits in the autumn and winter of 1868 and 1869. They announced, as a result of these experiments, that the formation of the ligament was not contemporaneous with the occurrence of internal contact, but followed it at the ingress of the planet, and preceded it at egress. In other words, it appeared while the thread of light was still complete. They furthermore announced that with a good telescope the ligament did not appear at all, but the thread of light between Venus and the sun broke off by becoming indefinitely thin.

The result is not difficult to account for. Irradiation has already been described as a spreading of the light emitted from each point of the surface viewed, so that every such point appears as a small circle. The obvious effect of this spreading is a dilution of the light emitted by a luminous thread, whenever the diameter of the thread is less than that of the circle of irradiation. In consequence of this dilution, the thread may be invisible while it is really of sensible thickness, a given amount of light producing a greater effect on the eye the more it is concentrated. Since the thread of light must seem to break when it becomes invisible at its thinnest point, the formation or rupture of the thread marks, not the moment of actual contact, but the moment at which the thread of light becomes so thick as to be visible, or so thin as to be invisible. The greater the irradiation, and the worse the definition, the thicker will be the thread at this moment.

An interesting observation, illustrative of this point, was made by Liais at Rio Janeiro, during the transit of Mercury of November 1, 1868. He had two telescopes, one much smaller than the other. He watched the planet in the small one till it seemed to touch the disc of the sun, then looking into the large one, he saw a thread of light distinctly between the planet and the sun, and they did not really touch until several seconds later.

Reference to the figures will make it clear that there is no generic difference between the phenomenon commonly called the rupture of the black drop and that of the formation of the thread of light. If the bright cusps are much rounded, as in Fig. 1*a*, the appearance between them is necessarily that of a drop, while if they are seen in their true sharpness, as in Fig. 1, the form of the drop will not appear. It has been shown that with different instruments the phenomenon of contact may exhibit every gradation between these extremes. The only well-defined phenomenon which all can see is the meeting of the bright cusps and the consequent formation of the thread of light at ingress, and the rupture of the thread at egress.

To recapitulate our conclusions—

1. The movement of observed internal contact at ingress is that at which the thread of light between Venus and the sun becomes thick enough to be visible.

2. The least visible thickness varies with the observer and the instrument, and, perhaps, with the state of the atmosphere.

3. The apparent initial thickness of the thread varies with the irradiation of the telescope.

Two questions are now to be discussed. The observed times varying with the observer and the instrument, we must know how wide the variation may be. If it be wide enough to render uncertain the results of observation, we shall inquire how its injurious effects may be obviated.

The first question can be decided only by comparison of the observations of different observers upon one and the same phenomenon. For such comparison I shall select the observations of the egress of Mercury on the occasion of its last transit over the disc of the sun. This selection is made for the reason that this egress was observed by a great number of experienced observers with the best instruments, while former transits, whether of Venus or Mercury, have been observed less extensively or at a time when practical astronomy was far from its present state of perfection, and that the transit in question would therefore furnish much better data of judging what we might expect in future observations. The comparison was made in the following way:—I selected from the "Astronomische Nachrichten," the "Monthly Notices of the Royal Astronomical Society," and the "Comptes Rendus," all the observations of internal contact at egress which there was reason to believe related to the breaking of the thread of light, and which were made at stations of known longitude. Each observation was then reduced to Greenwich time, and to the centre of the earth.

From these comparisons it appears that the contact was first seen by Le Verrier, at Marseilles, at two seconds before nine o'clock, Greenwich time. In one second more it was seen by Rayet at Paris, Oppolzer at Vienna, Lynn at Greenwich, and Kaiser at Leyden. The times, noted by twenty other observers, are scattered very evenly over the following fifteen seconds. Kam and Kaiser, at Leyden, did not see the contact until nineteen and twenty-four seconds past nine.

It thus appears that among the best observers, using the best instruments, there is a difference exceeding twenty seconds between the times of noting contact. This difference corresponds to more than a second of arc, so that really these observations were scarcely made with more accuracy than measures under favourable circumstances with a micrometer, and are not therefore to be relied on. But a great addition to the accuracy of the determination could be made by measures of the distance of the cusps, while the planet was entering upon the disc of the sun. It would tend greatly to the accuracy of the results, if the observers should meet beforehand with the telescopes they were actually to use in observing the transit and make observations in common on artificial transits. It would be a comparatively simple operation to erect an artificial representation of the sun's disc at the distance of a few hundred yards, and to have an artificial planet moved over it by clock-work. The actual time of contact could be determined by electricity, and the relative positions of the planet and the disc by actual measurement. With this apparatus it would be easy to determine the personal errors to which each observer was liable, and these errors would approximately represent those of the observations of actual transit.

Still it would be very unsafe to trust mainly to any determination of internal contact. Understanding the uncertainty of such determinations, the German astronomers have proposed to trust to measures with a heliometer, made while the planet is crossing the disc. The use of a sufficient number of heliometers would be both difficult and expensive, and I think we have an entirely satisfactory substitute in photography. Indeed, Mr. De la Rue has proposed to determine the moment of internal contact by photography. But the result would be subject to the same uncertainty which affects optical observations—the photograph which first shows contact will not be that taken when the thread of light between Venus and the sun's disc was first completed, but the first taken after it became thick enough to affect the plate, and this thickness is more variable and uncertain than the thickness necessary to affect the eye. We know very well that a haziness of the sky which very slightly diminishes the apparent brilliancy of the sun, will very materially cut off the actinic rays, and the photographic plate has not the power of adjustment which the eye has.

But, although we cannot determine contacts by photography, I conceive that we may thereby be able to measure the distance of the centres of Venus and the sun with great accuracy. Having a photograph of the sun with Venus on its disc, we can, with a suitable micrometer, fix the position of the centre of each body with great precision. We can then measure the distance of the centres in inches with corresponding precision. All we then want is the value in arc of an inch on the photograph plate. This determination is not without difficulty. It will not do to trust the measured diameters of the images of the sun, because they are affected by irradiation, just as the optical image is. If the plates were nearly of the same size, and the ratio of the diameters of Venus and the sun the same in both plates, it would be safe to assume that they were equally affected by irradiation. But should any show itself, it would not be safe to assume that the light of the sun encroached equally upon the dark ground of Venus and upon the sky, because it is so much fainter near the border.

If the photographic telescope were furnished with clock-work, it would be advisable to take several photographs of the Pleiades belt, before and after the transit, to furnish an accurate standard of comparison free from the danger of systematic error. There is little doubt that if the telescopes and operators practise together, either before or after the transit, data may be obtained for a satisfactory solution of the problem in question.

To attain the object of the present paper, it is not necessary to enter into details respecting choice of stations and plans of observation. I have endeavoured to show that no valuable result is to be expected from hastily-organised and hurriedly-equipped expeditions; that every step in planning the observations requires careful consideration, and that in all the preparatory arrangements we should make haste very slowly. I make this presentation with the hope that the Academy will take such action in the matter as may seem proper and desirable.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS—MEETING AT GLASGOW

AFTER having had an existence of some fifteen or sixteen years, during which it has done a large amount of scientific and thoroughgoing practical work, this North Country Institute has just deviated from its usual practice of holding its meetings in Newcastle-on-Tyne, and, with the co-operation of the Scottish Engineers and Shipbuilders' Association, has held a very successful meeting in Glasgow, the centre of the great Scottish coal-field, and the head-quarters of the mining and engineering industries of Scotland, and of the shipbuilding industry of the United Kingdom. The meeting began on Tuesday, the 9th of August, and extended over four days. On the opening day the Lord Provost of the City of Glasgow received and formally welcomed the members of the North of England Institute in name of the citizens and the Institution of Engineers and Shipbuilders; and thereafter the chair was taken by Mr. E. F. Boyd, President of the North of England Institute, and the business of the meeting commenced.

There were set down for reading and discussion no fewer than eighteen papers, the subjects treated of being all directly connected with mining and mechanical engineering. Only three papers were overtaken on the first day, when it was found that the time for adjournment had arrived. The afternoon was spent by the members in visiting various engineering and shipbuilding works, and other manufacturing establishments, which were freely thrown open to inspection by their respective proprietors.

We shall here briefly indicate the nature of the papers read and discussed at Tuesday's sitting of the Institute.

1. "On the Geology of the Coal Measures of Scotland," by Mr. James Geikie, district surveyor of the Geological Survey of Scotland. The author described, first, the calciferous sandstone series, which, when typically developed, consists of two groups of strata, the lower pointing to the prevalence of marine conditions during the deposition of the red sandstones and conglomerates, and the upper showing that during its accumulation marine and brackish water conditions alternated with the occasional appearance of land surfaces. Volcanoes were somewhat prevalent during the deposition of both groups. Second: The carboniferous limestone series, consisting of a lower group indicating marine conditions and occasional old land surfaces; a middle group indicating frequent land surfaces, and alternate brackish water and marine conditions; and an upper group pointing chiefly to lower marine conditions, with occasional brackish water deposits and a few old land surfaces: both submarine and subaërial volcanoes very active during the deposition of the whole series. Third: The millstone grit, deposited under almost exclusively marine conditions. Fourth: The coal measures, showing a prevalence of brackish or freshwater conditions, with abundant land surfaces, and speaking also of occasional inroads of the sea. No igneous rocks contemporary with the coal measures or millstone grit. Fifth: Intrusive rocks of three classes, namely, intrusive sheets, referable to close of "coal measures" group; bosses or pipes of tuff or agglomerate, probably of Permian age; and dykes of dolerite of Miocene ages. Sixth: Two systems of faults of different ages; the oldest striking N.E. and S.W., and the other, a double set, striking approximately E. and W. and N. and S. Mr. Geikie, in concluding, referred to the exceeding richness of the variety shown by the phenomena of the Scottish carboniferous formation, and said he had no hesitation in affirming that, when the palæontological and geological history of the carboniferous rocks of Scotland were worked out, there would be prepared one of the most important chapters in the physical history of the country.

2. "On the Magnetic Ironstone of Rosedale Abbey, Cleveland," by Mr. John Marley, M.E. This paper treated of the extraordinary deposit of magnetic ironstone which occurs at Rosedale West, and forms a very peculiar feature in the famous Cleveland ironstone, regarding which various papers have been published since 1857, when Mr. Marley first drew the attention of scientific men to it. The magnetic stone occurs quite isolated in two troughs, one of which is 90 feet deep, and it contains, in the best specimens, from 42 to 50 per cent. of metallic iron. In 1857 its extent was unproved, but it was believed to be very great, but this is now known not to be the case, from the results of recent borings and explorings which Mr. Marley fully detailed. The author explained the curious geological relationship which the magnetic stone bears to the top bed of the lias ironstone of Cleveland. The troughs lie east and west. Icebergs and glacial action were, in his opinion, in no way connected with the induction of the magnetic state, nor yet with the formation of the troughs. The deposits are not two beds of regular strata, nor are they veins, as no fissures have yet been found in the bottom of the troughs, although they have been diligently looked for. Mr. Isaac Lowthian Bell supplemented Mr. Marley's description by giving the results of a visit which he had paid to Rosedale, and stated that the magnetic ore could not be the result of volcanic action, as carbon was always contained in the analysis, as also water of hydration and a notable quantity of carbon.

3. "On the Duty of Cornish and other Pumping Engines," by Mr. J. B. Simpson. This paper was of especial interest on account of the subject treated of in it having a most intimate connection with the economy of fuel and the duration of the coal supply. After describing fully a Cornish engine recently erected in the Newcastle district, the author entered upon an examination of the details of twelve different kinds of engines, and compared their merits with those of the Cornish engine. In conclusion, he said that taking those engines into consideration, their average duty corresponded to a consumption of 14lb. of coal per horse-power per hour. Were a duty of 4lb. obtained, the saving in these engines alone would represent 40,000 tons of coal per annum, or, at 3*s*. per ton, 6,000*l*. The assumed total horse-power of pumping-engines in the Newcastle district is about 10,000, and from this the amount of the possible annual saving may easily be calculated. In many places coal may not be worth 3*s*. per ton at the pit mouth, but in the majority of cases its value is much greater. It is too much the practice to regard coal at the colliery as of little or no value, and that the extra 10lb. or 12lb. per horse-power per hour is not worthy of consideration. But fuel is not the only pecuniary part of the question, as extra consumption of coal means additional water, additional repairs, additional wear and tear, and additional manual labour—and these in the aggregate are very serious items of cost. The time does not seem far off when, in pumping and other colliery engines, the effective duty of 2lb. or 3lb. of coal per horse-power per hour will be considered as important as in the engines of London water-works and ocean steam-ships.

In the evening of Tuesday a *conversazione* was held in the Corporation Galleries. The east and west halls were occupied by numerous collections of objects—geological, palæontological, mineralogical, metallurgical, chemical, mechanical, engineering, mining, &c., together with a magnificent display of photographs, by Annan, of the Old Glasgow College, and various engineering works and Clyde-built ships. This exhibition was of immense scientific and industrial interest, and was at once the most extensive and valuable that has been held in Glasgow for many years. Advantage was taken of this evening's meeting to perform an interesting ceremony, namely, the presentation of a marble bust to Professor W. J. Macquorn Rankine, C.E., F.R.S., first president of the Institution of Engineers in Scotland, as a token of the appreciation and esteem of the members. A duplicate copy of the bust was also presented to the institution as a memorial of the Professor's labours in promoting the success of the institution. In the Large Upper Gallery there was an exceedingly interesting exhibition by means of the oxy-hydrogen light, of sections of fossil corals, by Mr. James Thomson, F.G.S., a gentleman who has of late years gone most extensively and enthusiastically into the study of fossil corals, and made it almost entirely his own; and so fully persuaded are palæontologists of the great value of his investigations, that Mr. Thomson is assisted by a grant from the British Association, at the forthcoming meeting of which he is to present a second report and exhibit his wonderful series of specimens.

On Wednesday morning the reading of papers was resumed, Mr. E. F. Boyd again presiding. The following is a brief notice of the papers overtaken :—

1. "On the Economical Advantages of Mechanical Ventilation," by Mr. D. P. Morison. The author stated that tabulated results of experiments recently made showed that the saving effected in the consumption of fuel varied in most cases from 40 to 80 per cent. in favour of mechanical ventilation as compared with furnace ventilation. The latter had other disadvantages, such as (1) the danger of an open fire in a fiery seam ; (2) in order to avoid that danger, the necessity and serious cost of constructing a dumb drift to convey the return air to the upcast shaft, and the fact that a large amount of fresh air is required to feed the furnaces, while it is of no value in the workings themselves ; (3) the serious fact that the upcast shaft, being usually heated to nearly its practical maximum, cannot, in cases of necessity (such as a sudden fall of the barometer, an unexpected occurrence of a large discharge of fire-damp, or a block in the air-ways), be made at once available for an increased duty ; (4) the inordinate wear and tear upon furnaces, arches, bars, and the shaft lining, whether brick-casing or tubbing, and in case of a coal-drawing upcast shaft, the deterioration of the ropes, guides, cages, and other plant. In no case could the furnace compete successfully with mechanical ventilation. Even in the deepest of English mines the advantage of mechanical ventilation is shown by the economy in fuel being from 35 to 40 per cent. over that required for furnace ventilation. Mr. Morison described various mechanical ventilators, including those of Struve, Nasmyth, Lemielle, Waddle, Guibal, and others. He expressed himself as most in favour of the Guibal ventilating fan, the one most in use both on the Continent and in this country. An interesting discussion followed Mr. Morison's paper, remarks being made by Messrs. Lupton (Leeds), Steavenson (Durham), William Cochrane and Simpson (Newcastle), Barclay (Kilmarnock), Marley (Darlington), Harvey (Glasgow), and others.

2. "On J. Grafton Jones's Coal-getting Machine," by Mr. Arnold Lupton, Leeds. After describing the machine in question, and specially dwelling upon its involving the use of the hydraulic wedge and a drilling apparatus, Mr. Lupton claimed for it the following advantages :—1st, The safety with which mines can be worked by it as a substitute for gunpowder ; 2nd, The superior shape of coal got by the wedge as compared with that got by blowing, and the less amount of slack made ; 3rd, The improvement in the health of the miners likely to ensue on the disuse of gunpowder ; 4th, The saving in labour by using the hydraulic wedge instead of hammer-driven wedges ; 5th, The saving in labour and diminution in the amount of slack made by using the hydraulic machine to push the coal out of the solid, in working those seams whose nature is such as to render it possible. Mr. Lupton stated that Jones's powerful machine is now in use, pushing coal out of the solid without any holing or natural breaks in the seam, at Kiveton Park Colliery, in South Yorkshire. The seam is five feet thick, and the coal is very hard, but by the use of the hydraulic wedge blocks are got four yards long and four feet wide—each about eight tons weight—at one application of the machine. In the course of the discussion which followed various other important and interesting facts were evoked.

3. "On an Expansive Double-cylinder Pumping Machine," by Mr. Andrew Barclay, Kilmarnock.

4. "On an Expansive, High-pressure, Cut-off Slide Valve," by the same.

5. "On a New Coal-getting Machine," by Mr. George Simpson, Glasgow. The author of this paper dwelt at some length on the working of coal on the "long-wall" system by machinery, and then explained the nature of the machinery which he thought most suitable for it. The essential feature of the machine, exhibited and described by Mr. Simpson, is a somewhat saw-like blade which works into the face of the coal seam in a horizontal manner. Mr. Simpson said it was indispensable that the tool to be used should be durable and easily removed and replaced in case of blunting or breakage, and he claimed that his cutter possessed those qualifications. He also showed an application of an endless chain for driving the proposed machinery, and which might be worked by an engine on the drawing road at the face of the coal, or from the bottom of the shaft or other convenient point.

6. "On the Utilisation of Blast Furnace Gases, Coal being used as the Fuel," by Mr. William Ferrie, Monklands, Iron and Steel Works, Lanarkshire. The author stated that it had occurred to him that if raw coal could be coked in the blast furnace as in a common gas retort, the difficulty of withdrawing the furnace gases for use would be overcome, and he immediately commenced experiments with a small blast furnace, one-fifteenth of the capacity of a 50-feet furnace. The upper part was divided into two compartments or retorts into which the coal, ores, and limestone flux were charged ; and the top of the furnaces was closed in by the ordinary bell and cone arrangement, as in the Cleveland district. The gases passed off into a main which communicated by two pipes, one to each side of the furnace, to the entrance of the flues at the bottom of the retorts, and were ignited by the aid of atmospheric air. These flues were spiral, in order that the heat from the burning gases might permeate the materials inside the retorts, while the exhaust gases were thrown off by chimneys at the top of the retorts. This small furnace was worked for about two months with raw coal only as fuel, and the results were highly satisfactory, notwithstanding that the furnace was so small in size. Being convinced that this plan of working a furnace was practicable, Mr. Ferrie had forthwith commenced the alteration of one of the ordinary furnaces at Monkland Works, which he said would be ready for operating with at the end of the month of August.

7. "On Mineral Oil Works," by Mr. David Cowan. The author referred to the manufacture of mineral oils as one of the leading industries of Scotland ; to the nature and extent of the oil yielding materials, namely, bituminous shales and cannel coals, distributed throughout the Scottish coal measures ; and to the quantity and quality of the produce from those materials. He afterwards described the mode of treating the raw materials, referring to the horizontal and the vertical retorts used in Scotland, comparing their advantages and disadvantages, and then described an arrangement of apparatus designed to combine the advantages of both kinds of retorts, and which would at the same time admit of improved facilities of workings. In order to improve the mode of firing, Mr. Cowan suggested that instead of coal the retorts should be heated with gas flame, and further, that the system of first converting the fuel into gas (as successfully worked out by Siemens) should be adopted. He estimated that the mode of heating by gas in this way would effect a saving of from 40 to 50 per cent. of the fuel.

The time allotted for reading and discussing papers having now arrived, the president announced that those papers which had not been overtaken, would become the joint property of the two institutions. They will doubtless be published along with the others in the transactions to be issued by each institution. The afternoon was spent in the same way as that of the preceding day ; and in the evening a grand banquet was held, at which the members of the North of England Institute were the principal guests. Thursday was occupied in visiting collieries, ironworks, engineering, ship-building, chemical, and other manufacturing establishments at a distance from Glasgow ; and on Friday there was an excursion on the saloon steamer Chancellor down the Clyde to Dunoon, and thence up Lochlong to Arrochar, from which the party walked or rode over to Tarbet, on Loch Lomond, a distance of about two miles. The visitors were then conveyed by one of the Loch Lomond Company's steamers to the top of that loch, "The Queen of Scottish lakes," where dinner was served. In the afternoon the whole length of the loch was traversed to Balloch, where the party took train and returned by the Dumbartonshire Railway to Glasgow. All the visitors were greatly delighted with the magnificent scenery along this route, as well as with the kindness, attention, and hospitality shown to them during their four days' sojourn in the "land o' cakes." Altogether, a very great degree of pleasure was experienced both by the members of the North of England Institute and by the members of the Scottish Institution. Not unlikely a return visit will soon be paid to the "Coaly Tyne."

JOHN MAYER

SCIENTIFIC SERIALS

THE *Revue des Cours Scientifiques*, for August 13, commences with a translation of Dr. Carpenter's lecture on the Temperature and Animal Life of the Deep Sea. This is followed by a report of Prof. Milne-Edwards's address in *comité secret* of the Academy in favour of the election of Mr. Darwin as corresponding member, the substance of which we gave last week. The last paper is M. Ed. von Beneden's very important and interesting article on *commensalisme*, or "fellow-boarding," as it has been termed, in the animal kingdom, extracted from the proceedings of the Belgian Academy of Sciences, a translation of which has already been published in this country. The current number for August 20 opens with an article *à propos* of the war, a translation of Prof. Shaw's address to the Military College at Sandhurst on the war establishments of Great Britain. We have then the continuation of M. Marey's paper on the Flight of Birds; and, in conclusion, under the head of "Bibliography," a translation of Mr. Wallace's review of Mr. J. J. Murphy's "Habit and Intelligence," which appeared in our columns.

THE *American Entomologist and Botanist* publishes a double number for July and August, which is occupied by short descriptive articles of interest and value principally to American collectors and students. The article of chief general interest is one on the "Origin of Prairie Vegetation," consisting of an able criticism of Prof. Winchell's theory that the prairies are of lacustrine origin, and that we must look to the source of the prairie vegetation from without,—probably the remains of a pre-glacial flora, the germs of which have remained stored up during subsequent epochs, and come again to life whenever the diluvial surface is again exposed. The writer of the article maintains that there is no need to go so far back as the diluvial period for the origin of the prairie vegetation. Dr. Hale, of Chicago, mentions the interesting fact that the *Ranunculus cymbalaria*, an abundant plant of the eastern sea coast and of the salt springs in the State of New York, is found in great abundance at Chicago, and for several miles along the shores of Lake Michigan, though nowhere else on the Great Lakes. It appears, however, that it also grows on the muddy banks of some of the western rivers.

THE *Geological Magazine* for the present month (No. 74), contains only three original articles, namely, one by Mr. D. Mackintosh on the Dispersion of Shapfell Boulders, and Origin of Boulder Clay; a second by Mr. John Hopkinson on the structure and affinities of *Dicranograptus* (with a plate), including descriptions and figures of the British species of that genus, two of which (*D. formosus* and *D. nicholsoni*) are described as new; and a memoir, with two plates, by Mr. T. Davidson, on Italian Tertiary Brachiopoda, with an important table of the species and their geological distribution. Among the abstracts and notices of memoirs, is a report of an interesting lecture on the Primæval Rivers of Britain, by Professor T. Rupert Jones.

Mittheilungen aus Justus Perthes' Geographischer Anstalt (vol. xvi., No. 8) opens with a remarkably interesting paper —illustrated by a map—by Dr. G. Nachtigal, on his travels in Tibesti. He says that, in spite of Barth's philological investigations, he regards the question as to the nature of the Tibbu as still undecided. They are of middle height, are very well built, and possess elegant yet muscular limbs. The majority of them are of a deep bronze colour, but without a trace of what is usually termed the negro physiognomy. On the whole, their physical and psychical peculiarities, their social and political arrangements, and their manners and customs, resemble those of the Berber infinitely more than those of the Negro. Amongst other things, Dr. Nachtigal records some careful observations of the rivers Zuar and Marmar, the former of which he regards as incomparably the finest river in Tibesti. In M. Lejean's article on his own travels in European Turkey in 1869, he corrects the existing maps in several points, embodying in an elaborate map the results of his investigations. He expresses the greatest contempt for the modern Turks, intimating that those who believe they have recently made real progress are deceived by mere appearances. He says he has gathered full materials for a work or works on the ethnography and archæology of the districts he describes. Professor Pellegrino Strobel describes a journey from the Planchar Pass to Mendoza; and the rest of the number is made up of "Geographical Notices" and translations of extracts from Mr. Robert Brown's "Physical Geography of the Queen Charlotte Islands," and from reports published in the "South Australian Register," on Mr. G. W. Gogden's Measuring Expedition to North Australia.

SOCIETIES AND ACADEMIES

BRISTOL

Observing Astronomical Society.—Report of observations made by the members during the period from July 7th to August 6th, 1870, inclusive:—*Solar Phenomena.*—Mr. Thomas G. E. Elger, of Bedford, reports that the sun spots observed in July exceeded in number those recorded during the previous month, but they were, with a few exceptions, small (less than 30" in diameter), and although pretty equally distributed between the two hemispheres, those to the south of the sun's equator presented a remarkable contrast, both in type and size, to those observed to the north of it; the former, as in June, included some large scattered groups and moderately sized spots of the normal class, while the latter consisted chiefly of solitary specks without penumbræ, and clusters of minute black punctures which frequently assumed very grotesque configurations. A striking feature of the large groups observed during the early part of the month was an evident tendency either to close up or to become dissociated upon reaching a certain position on the disc—about half way between the E. limb and the centre. On the 25th one of the largest groups observed this year appeared at the E. limb; on the 28th it measured nearly 5' in length, and consisted of a large preceding spot 1' 10" in diameter, followed by a straggling train of "wispy" penumbræ enclosing several small spots. This group dwindled away very rapidly after the 28th. Another large spot, about 50" in diameter, was observed from July 13th—25th.

Fresh groups observed in the sun's N. hemisphere during July	9
Fresh groups observed in the sun's S. hemisphere during July	12
Maximum number of groups on disc	12 (July 13, $5^h\ 30^m$)
Minimum number of groups on disc	4 (July 28, $5^h\ 10^m$)

Mr. Albert P. Holden, of London, says, "I observed a very interesting spot on June 21, at 7 A.M. The penumbra was unusually pale, and the umbra of a decided light brown hue. Four darker openings arranged in a square were observed in the umbra, and were readily seen with a very small aperture. A very remarkable circumstance in connection with the sun spots during the last two months has been their extremely light colour. The light brown tints of the umbra have been very marked, and totally different from the dark hues they usually present; while, at times, the penumbræ have been so light as to be scarcely visible. In most of them, however, the nucleus (which is ordinarily so difficult to detect) has been very easily seen, as in the case of the foregoing observation. The fact proves the phenomenon seen to be due to the actual lightening of the spots themselves, because if it were merely an optical or atmospheric effect, the whole spot would be lighter and the nucleus would be quite as difficult to detect as before. It is probable that these appearances may be a necessary result of the maximum of sun-spot activity, and are due (as suggested by Mr. Lockyer) to the thinness of the solar envelope at the present time. This would certainly account for the light hues of the umbræ and penumbræ, and also for the frequency and blackness of the nucleus." Mr. Henry Ormesher, of Manchester, writes, "On the 31st of July, from $2^h\ 15^m$ to $3^h\ 0^m$, while looking at the sun with my 3 in. refractor, I saw a beautiful large cluster of spots occupying an almost central position on the disc. It occurred to me that the umbra in the largest spot appeared more dense on the western side. I therefore determined to examine it with my $5\frac{1}{4}$ in. refractor. I did so, using a power of 181. The result was that it resolved itself into a very fine nucleus of a somewhat oval shape. After making myself sure that the above was the case I examined the cluster generally, and was struck with the beautiful appearance of the brighter part of the sun's atmosphere. A very bright stream ran across the cluster, in a zigzag direction, separating the penumbra. Some parts of this stream, and particularly the upper part, appeared brighter than others, presenting a very mottled appearance."—Mr. William F. Denning, of Bristol, observed the sun, with his 3 in. refractor, on July 14, from $5^h\ 30^m$ to $6^h\ 10^m$. He noticed nine large well-defined *maculæ* on various parts of the disc. A particularly large and interesting group of spots was visible in the N. hemisphere. On July 22, at 8 P.M., a spot was observed in the same hemisphere, which was divided by two bridges of light. He noticed that the penumbra was invaded by numerous minute lines of light, and that the bridges seemed to present the appearance of running matter. This observation was made with power 100 and $10\frac{1}{4}$ in. reflector by Browning.

The Lunar Eclipse of July 12.—The Rev. Ralph Prowde, of Northallerton, Yorkshire, observed this phenomenon, and has forwarded the following:—"I observed the eclipse of the moon on the 12th, but the only thing remarkable was the great contrast of shade between the darker and brighter penumbræ. I say penumbræ, for I suppose the real umbra of the earth's shadow falls within the moon's orbit. The darker interior cone of shadow obscured the edge of the moon and the object on its surface as it passed over them almost entirely, but its own edge did not seem to be nearly so regularly round as the lighter enveloping cone of shade."—The Rev. J. J. Johnson, of Crediton, reports:—"On the evening of the 12th I had a very favourable view of the lunar eclipse. The sky was clear at first, with a small amount of stratus near the horizon. I first caught sight of the moon at 8.41, but it was 8.49 before it got clear of the clouds. I paid particular attention to the degree of distinctness with which the eclipsed portion could be seen. When about four digits were covered I just noticed the copper tin through the telescope. I fancy this would be a little sooner than in the last eclipse I observed (September 1867) but in that of October 4, 1865, which was only of 4 digits, the copper tint was very decided in the telescope at the time of the greatest obscuration. When about six digits, or half the disc, was covered, the copper colour could be clearly seen with the naked eye. I could not make out any particular parts of the moon's surface until 9.35, when I noticed the *Mare Tranquillitatis* and the *Mare Serenitatis* showed with beautiful distinctness through the earth's shadow in the telescope. A few minutes after the total was attained, I was struck with the obscurity of the eastern side of the moon being so much more than I had expected. At 9.55 at least half of its surface was as if blotted out even when seen through the telescope, although I applied two different powers—70 and 150. Three of the *seas* at the western side were all I could make out. Possibly a thin coating of cirrus cloud which covered all the sky about this time might account in some measure for the invisibility of the moon. By 10.30 this had entirely cleared away, and the sky was everywhere covered with stars. The Milky Way very near the moon was about as distinct as it usually appears on a dark clear night. At this period, being the middle of the eclipse, the upper portion of the moon was the invisible part, all those regions lying round the margin of the disc being alone to be seen, except at the vertex, where the margin itself was not discernible. At 11.23 the first streak of light was breaking forth at the eastern edge. At 11.45 the red colour was nearly gone, and the eclipsed part appeared of a grey colour. At 11.58 I noticed there was no trace of the Milky Way; at 12.24 the lunar circle was again complete."—Mr. Oliver J. Lodge, of Hanley, reports that "the colour of the moon during the totality was of a most peculiar copper hue, giving very little light indeed. But during the egress of the shadow it was almost as white and silvery as it usually is, although still under the penumbra." Mr. Edmund Neison, of London, says:—"The colour of the eclipsed disc was during the whole time a dull, yellowish olive-green, both in the telescope and out, but was never dark enough to prevent many of the chief markings and craters being seen. From 10.44, when the lunar disc was fairly above the fog-banks, *Aristarchus* was quite distinct as a bright crater, and even before eleven *Grimaldi* was plainly discernible." At Bristol, Mr. William F. Denning observed the phenomenon, and remarks that even at the time of totality many of the most conspicuous objects on the disc were distinctly visible. The copper tint was also very evident. During a portion of the time the moon was over cast with clouds.

Venus.—Mr. Henry Ormesher, of Manchester, observed this planet with $5\frac{1}{4}$ in. equatorial refractor, on July 23, at 5^h P.M. "The definition was excellent. I observed three dusky spots on the disc, one of which was of very considerable magnitude."

Saturn.—Mr. H. Michell Whitley, of Penarth, writes:—"July 7th, 10^h 11^m, power 208—the ball of the planet dull yellow colour. N. equatorial ruddy belt conspicuous, and another of same colour between it and pole; pole bluish grey; edges of disc fainter than centre; sky in ansæ much blacker than around planet; crape ring across ball nearly as dark as Ball's dension, pale purple; crape ring very easy in ansæ. No line of light between it and B."

Occultation.—Mr. J. C. Lambert, of Sleaford, witnessed the occultation of B.A.C. 5954 on July 10, and found the exact time of disappearance to be 12^h 40^m 41^s mean time.

Meteors.—Mr. J. C. Lambert "observed a very brilliant meteor at 11^h 40^m, July 21. Course from a little below γ Cassiopeiæ to ξ Persei. Nucleus appeared as a star of 1.5 mag.; tail nearly 2° long; colour, yellowish white; duration 2^s. During the time of observation (11^h to 12^h 30^m) observed no less than eleven small meteorites. The course of one of these was from ϵ Bootis to 43 Comæ Berenicis, and immediately afterwards one from a little below 43 Comæ Berenicis to η Bootis. Could this have been one and the same meteor describing an arc?"

Lunar Observations.—Mr. H. Michell Whitley has very carefully examined many interesting lunar objects, and the results he obtained have been forwarded to Mr. W. R. Birt.

PARIS

Academy of Sciences, Aug. 16.—M. Yvon Villarceau communicated some remarks on the decimal division of angles and of time, in reference to M. l'Abbadie's communication of the previous week.—M. Sainte-Claire Deville made a final reply to M. Jamn on the subject of the sepecific heat of mixtures.—M. Wurtz presented a note by MM. Ad. Lieben and A. Rossi on normal amyl alcohol. The same authors recorded last year the manufacture of a new butyl alcohol differing from the alcohol of fermentation, and representing the fourth term in the homologous series of normal alcohols. Taking this alcohol for a point of departure, and applying the same synthetical methods, they succeeded in obtaining a new amyl alcohol, which they call normal, and bearing the same relation to the amyl alcohol already known as the new butyl alcohol does to the butyl alcohol of fermentation. In order to obtain it cyanide of normal butyl is first obtained, and the valeric acid corresponding to it made by the oxidation of ordinary amyl alcohol. The lime-salt of normal valeric acid is mixed with the formiate, and the mixture submitted to dry distillation. Valeric aldehyde is thus obtained, boiling at about 102°, and isomeric with valeral. This aldehyde, treated with nascent hydrogen, yields the alcohol. Normal amyl alcohol bears a strong resemblance to the amyl alcohol of fermentation. It is distinguished by its higher boiling point, 137°. By oxidation it yields valeric acid.—M. Wurtz also presented a note by M. F. Papillon on modifications in the immediate composition of bones, proving that the normal lime contained in the bones of animals may be partially replaced by alumina, magnesia, or strontia, by including these substances in their food.—M. Cave contributed a note on the formative zone of the foliar organs in monocotyledonous vegetables. This he found to occupy the same position as in his previous researches on dicotyledonous plants. In the leaves of endogenous plants the inferior tissue is the older; the layer nearer to the superior epidermis is the younger. In the fruits, also, the author has invariably found the formative zone occupy the same place in those belonging to the two divisions of flowering plants.—M. Jamin presented a note by M. W. de Fonvielle on the astronomical discoveries of the ancients.

THE MEDICAL SCHOOLS OF ENGLAND AND GERMANY

I.

IN the region of scientific medicine the Germans enjoy at the present time an undisputed pre-eminence. Their medical books have taken possession of the markets of the world, and their larger schools are themselves like markets in which representatives of all countries appear, in order to exchange gold for the higher culture. Next to German books, those published in Great Britain have the best programme and apparently the widest geographical distribution. But here the enormous territory of the English language plays a very prominent part. To professional men who do not speak the English tongue, English books are but little known and still less read. In like manner, the extent to which foreigners avail themselves of the English schools is exceedingly small. It is very significant that even Americans pass by their natural market, England namely, for the acquisition of higher medical education, and resort annually in troops to Germany, where they have to contend with the disadvantage of a foreign language.

If we now attempt to ascertain the causes of this phenomenon, we must arrive at once at the conclusion that local conditions have nothing to do with it. Great Britain can number nearly as many medical schools as exist in Germany, and their local position is extremely favourable for visits from foreigners. In this respect the larger cities enjoy an enormous advantage over smaller towns, for medical students do not, as a rule, despise good living, and therefore prefer to live in great cities. Hence the medical schools of Vienna and Berlin are rendezvous for travelling physicians, while many a small German town with no less distinguished a teaching power, is visited only by those foreigners who prefer to taste the treasures of a teacher drop by drop, far from the battle of the metropolis. London alone possesses eleven medical schools. Here are also offered to the travelling disciple of science the advantages of the metropolis, and something besides which can only be obtained on the Continent by an expenditure of time and money, and then not altogether, the opportunity, namely, of changing the school, and especially of discovering the one which it will best answer his purpose to visit.

If, in spite of all this, the schools of London form no open market, the cause must be sought for in their quality. It does not, in fact, require much criticism to discover that the construction of the medical schools here is so entirely different from that of the corresponding schools in Germany, that the defectiveness of our language is the only excuse for designating the two by the same name. In the majority of the medical schools of London instruction is only a subsidiary product of the general charity. The hospitals are supported by voluntary contributions, and at one and the same time medical assistance is given to the sick and medical instruction to youths eager for knowledge. The subscribers elect officers for this purpose; and both the electors and the elected are agreed in considering the treatment of the sick as the primary office, instruction as a secondary office. Professional men on the Continent are obliged to bear this relationship constantly in mind, if they would understand how it comes to pass that a nation of such sound judgment in practical life as the English, can act in a manner which, to those who look at such hospitals from the stand-point of the development of science, appears so opposed to every modern theory of work.

In these hospitals, founded and supported by voluntary contributions, the teachers, in the course of their lives, change several times the subject of their lectures. The teacher generally begins with botany, and abandons it after he has acquired a moderate knowledge by several years' instruction, in order to take up another important branch of human knowledge; and perhaps again exchanges this for something else, just at the time when he can say with Faust:—

Und sehe dass wir nichts wissen können.

The final object of such a course is the position of hospital physician or surgeon, with which, as a rule, a profitable practice is also combined. The hospitals attain in this manner the best result which they can attain. They obtain physicians who for several years have given their attention more or less assiduously to reading scientific literature. In so far as these physicians are at the same time in a wider sense useful to the community, this system performs good service in educating a large number of well-read medical men. For the development of these officers into distinguished original investigators, the mosaic-work of their course of study is altogether destructive. From the haste with which they rush through great departments of knowledge, they can give no time or leisure to assist in drawing up the endless chain of causes to the light of day. Such an undertaking, moreover, is entirely outside the aim for which the charitable contributions were given.

Among the numerous London schools, some three or four stand out conspicuously, and one of these is so constituted, from its connection with other non-medical chairs, as well as from the history of its establishment, that one may conclude the fostering of science is not in this case a secondary aim. Let us observe now what assistance is afforded by this school for this purpose; and let us compare these means with those provided by a great German school, for instance, that of Vienna. The writer of this article has chosen this example, chiefly because he is familiar with the interior arrangements of the Vienna school. The consideration also that this is the oldest of the prominent German schools, and that its eventful history can exhibit many points of interest which stand prominently forward, has its influence. Other examples might be brought forward which would equally illustrate the contrast.

It must, in the first place, be borne in mind that the London school just referred to, that of University College, is, like all her sisters, a private institution, while the Vienna Medical School is a State institution; the Government builds or rents the building, directs it, and provides it with officers. The means for this object flow from the provisions of the budget of the Ministry for Public Instruction; and the Government therefore possesses the power of granting the means of diminishing or enlarging them according to circumstances. Since many German schools, which are still State institutions, are yet entirely or partially self-supported, some words of criticism must be devoted to this system. The independent means of the Universities are not only means for the protection of their independence, but at the same time are a bulwark against the attacks of an absolute Government, hostile to science. In those states, however, where a protection against violence is provided by distinct legislation, and especially in those in which the people has a share in the Government, every other bulwark than that which the law offers is only antiquated trumpery; the independent foundations of the Universities are no better than a means for the maintenance of the spirit of caste, and for the fostering of nepotism. In Austria the independent foundations of the Universities have fallen a prey to the insatiability of the State treasury. The freedom which has so rapidly developed itself in Austria during the last few years, found the doors of the Universities open, and forthwith established herself there. Well might their noble spirit be envied by those institutions which have used their independent means for enclosing the school and the church within a common wall!

It will not require many words to prove that the state institution enjoys an advantageous position with respect to the private institution. For while, on the one hand, the State can calculate on future revenues in laying out money for the establishment of scientific institutions, the private institution must regulate itself in accordance with its actual means, and can only reckon upon much narrower materials and temporary factors. This contrast cannot be illustrated in a more striking manner than by comparing the palace which the Saxon Government has built in Leipzig for instruction in physiology, with the one or two rooms which University College, London, is able to devote to the same purpose.

It must, however, not be forgotten that it is only recently that such institutions as that at Leipzig have been established. There are, indeed, at the present moment, only three other institutions in Germany which can be compared to it, viz., the Physiological Institute at Breslau, the splendid Anatomical Institute at Berlin, and the Pathological Institute at Vienna, all of which occupy separate spacious buildings. In these and other universities, establishments of a similar kind, and on a similar scale of completeness, are either projected or are now in course of construction.

S. STRICKER

THE EARLY HISTORY OF MANKIND

Researches into the Early History of Mankind and the Development of Civilisation. By Edward B. Tylor. Second Edition. (London: Murray, 1870.)

MR. TYLOR has devoted himself to a branch of Anthropology of which there are very few students in this country, that namely which treats of the mental development of man as elucidated by his arts and customs, and especially by his myths, his superstitions, and his language. More than a third of this volume is devoted to an elaborate account of the gesture-language used by deaf mutes and savages, and to picture-writing, word-writing, and the influence of names and images, as illustrative of various phases in the development of the human mind. After this we have chapters on the growth and decline of culture, as illustrated by the use of stone implements of various degrees of perfection, by weapons, by modes of procuring fire, and by modifications in various domestic utensils. Then follow accounts of remarkable savage customs, such as the curing of disease by the extraction of foreign substances from the body of the patient, the prohibition of marriage with certain relations or namesakes, tabooing the names, and even avoiding the sight, of certain relations, and the extraordinary custom of the *couvade*. Myths, their origin and geographical distribution, are then discussed; and these varied subjects are all treated from a twofold point of view, either as giving us an insight into the laws of the development of the human mind and the growth of civilisation, or as furnishing, by their similarity over extensive areas and in widely separated countries, an argument for the common origin of the different races of man.

The work is throughout carefully written, and is illustrated by abundance of curious and little-known facts and a critical examination of their bearings. The author is very cautious in drawing any general conclusions, and when he does so carefully indicates all sources of error and uncertainty. The character of such a book cannot be fairly shown by extracts; we shall, therefore, briefly summarise one or two of the more interesting subjects and arguments.

Many persons are, no doubt, under the impression that the deaf and dumb talk to each other by means of the finger alphabet; but the use of this pre-supposes a knowledge of the meaning of words and letters, which the deaf and dumb child can hardly be taught till intelligible communication has been established with it. Alphabetical speech is slow and clumsy, whereas the deaf mute speaks to his comrades as rapidly, if not as precisely, as we do by means of vocal speech. He uses a copious and expressive language of signs, indicating words and ideas by means of simple motions and gestures. This language has the advantage of being natural and universal. English, French, and German children to a great extent understand each other, and even a North American Indian would be able to talk with them all, it being a curious fact that many of the signs used by the Indian tribes are identical with those of the deaf and dumb schools of Europe; and Mr. Tylor states that a Sandwich islander and a Chinese both made themselves understood in an American deaf and dumb institution. The "gesture language" is also connected with spoken language in two remarkable ways. Among low savage tribes there are cases in which speech has to be supplemented by gesture to make it intelligible, and it is, perhaps, reasonable to suppose that at an earlier stage of civilisation the proportion of gestures to words would be greater than it is now. There is also an agreement in some fundamental idioms. In the Aryan languages many substantives have verbal roots descriptive of some of their essential attributes. "Thus, the horse is the *neigher;* stone is what *stands*, is *stable;* water is that which *waves, undulates;* the mouse is the *stealer;* and age is what *goes on;* the oar is what *makes to go;* the serpent is the *creeper;* and so on." Now the deaf and dumb who have no means of communication but by signs, express themselves in the same way. To them the bird is what *flies*, the fish what *swims*, the plant what *sprouts out of the earth*, &c., and the motions of flying, swimming, and sprouting up, are used as the signs for bird, fish, and plant.

Mr. Tylor is usually very cautious in concluding that any art or custom found among distant peoples has had a common origin, or can be used to measure the comparative antiquity of the migrations of races. Yet, in one case, in which he considers that it can be so used, he arrives at conclusions which hardly seem warranted by the facts. The Madagascans smelt iron, as do also the natives of Africa and of the western islands of the Malay Archipelago, but the bellows used in Madagascar is the peculiar Malay form—an upright bamboo, with piston formed of a bunch of feathers, and entirely different rom the inflated skin-bellows of Africa. This curious fact, taken in conjunction with many others, and with the presence of a considerable Malay element in the Malagasi language, as well as some physical resemblance between the Hovas and Malays, conclusively proves that there has been a Malay immigration to Madagascar, and also that it took place subsequent to the introduction of the art of working iron. So far the facts lead us safely; but Mr. Tylor, if we understand him rightly, goes further than this, and holds it to be proved that the art of smelting iron was first introduced from Malaisia rather than from Africa, and also that the Malay migration to Madagascar was a much later event than the Malay migration to Poynesia, where the use of iron was unknown till introduced by Europeans. Now, for all that the facts tell us, iron working may have been known in Madagascar before the Malays came, they merely introducing the bamboo bellows, which would be especially adapted to a country in which bamboos were abundant, but cattle, deer, and all large animals which could furnish suitable skins, *entirely absent.* They certainly might have introduced iron-working also, but the fact of their introducing a more useful form of bellows does not prove it. So, with regard to Polynesia, there are two sufficient reasons why iron-working should not have been introduced there, even if the Malay immigration had been long subsequent to that which invaded Madagascar. The only Malay iron-smelters are certain tribes of Borneo, Sumatra, and the Malay peninsula, while among the Javanese and Coast Malays who are the chief navigators, as well as among the whole of the Moluccan tribes, the art is entirely unknown. But the Malay element in the Polynesian languages is composed of pure Malay and Javanese words, and there is every reason to believe that wandering traders of these nations introduced the Malay language into Polynesia. Added to this the fact that the volcanic and coralline islands of the Pacific contain no iron ore, and we need not wonder at iron workers not being found among them, or that the tribes who still more recently peopled New Zealand should not know how to make use of the iron ore that occurs there. The evidence of language on the other hand would seem to be in favour of the Madagascar migration being the most ancient, because the Malay and Javanese words are generally more changed in the Malagasi than in the Polynesian languages. In the latter, scores of words are slightly modified but intelligible Malay, as *pua* for *bua* (fruit), *ika* for *ikan* (fish), while in the former many equally common words have been greatly altered, as *ravina* for *ron*, Jav. (leaf), *lanitra* for *langit* (sky); and the word *lima* or *rima* (five), which extends almost unchanged over the whole of Polynesia, becomes the hardly recognisable *dimi* in Malagasi. The Hovas are undoubtedly much nearer the true Malays in both physical and mental characteristics, than are the Maories or Tahitians, and this would indicate that a larger and more compact body had reached Madagascar than Polynesia. This is what we might expect, for the chances are so much against a safe canoe voyage across the open Indian Ocean, a distance of nearly 3,000 miles with scarcely an intervening island, that we can hardly suppose it to have occurred more than once; while the numerous islands in every part of the Pacific render it much more probable that canoes accidentally blown out of their course from the Moluccas or New Guinea, might repeatedly reach some islands tenanted by the Polynesian race. But a compact body which ultimately conquered much of the country and established a dominant race, would have a greater tendency to preserve their language unchanged; and the fact that so much change has taken place is an additional argument for the comparative antiquity of the Madagascar immigration. The ignorance of making pottery in Polynesia, an art which has certainly been known to the Malays and Javanese from a very early period, seems at first sight opposed to the theory of a late communication; but this fact may, I think, be easily understood when we consider that the immigrants were most probably traders, and of the male sex, and therefore ignorant of an art which in their native country is almost entirely practised by women. While treating of this subject, Mr. Tylor falls into some confusion by speaking of the "Malayo-Polynesian culture," and "the pure Malayo-Polynesian race," things which can have no existence, if, as I believe, Malays and Polynesians are almost as distinct as Malays and Africans.

The geographical distribution of customs, beliefs, and myths, furnishes our author with materials for some of his most curious and interesting chapters; but, still less than the arts of savage life, do they appear to afford any safe ground for conclusions as to the affinities or early migrations of the races of mankind. We cannot conclude without expressing our admiration of Mr. Tylor's industry and research in so little trodden and comparatively unproductive a field. He has carefully brought together a vast number of interesting phenomena illustrative of the mental condition of savage man, but we cannot help feeling that a satisfactory explanation of them has not yet been arrived at, and that we require researches of a very different nature before we can form any adequate conception of the various causes that have influenced the early mental development of the human race.

A. R. WALLACE

KARL KOCH ON TREE-CULTIVATION

Dendrologie: Bäume, Sträucher und Halbsträucher, welche in Mittel- und Nord-Europa im Freien kultivirt werden. By Prof. Karl Koch. 8vo. Vol. I. 735 pp., without illustrations. (Erlangen: F. Enke, 1869. London: Asher and Co.; Williams and Norgate.)

THE work of Prof. Karl Koch is a valuable addition to the literature of applied Botany; and no doubt throughout German-speaking countries it must early become the volume of all others most redolent of Nicotian essence on the shelves of people who concern themselves about tree-cultivation and general nursery-work. It has a considerable value, too, as a contribution to Scientific Botany, for its author has had long experience, with very favourable opportunities, in connection with everything woody,* hardy enough to bear exposure in the open air in Prussia. He is a good botanist and an enthusiast in his speciality, so that his book includes much useful information, especially of that kind, too seldom put on record, possessed by workers in the open air, or so scattered through periodical botanical and gardening literature, as to be hardly available at a pinch. To English botanists and nursery-folk it offers many interesting features. One amongst many others is the opportunity it affords of comparing the climatic differences between Britain and Central Europe, as deducible from the copious data which the "Dendrology" gives relating to the capacity of the various species to resist the severity of continental winters.

Here is an example of the author's plan of treatment. We take the common Aucuba, or so-called "variegated laurel," of every English shrubbery. *Aukuba*, not *Aucuba* Prof. Koch says it must stand :—

A. Japonica, Thunb. Fl. Japon. 64, tab. 11 and 13 (1784).

THE JAPANESE AUKUBA.

Japan.

Flowers in May and June.

Leaves varying in form, mostly elliptical or elongate-lanceolate, usually sharply toothed above the lower third, glabrous: inflorescence with appressed hairs; petals ovate-lanceolate, dark brown-red; berries coral-red.

One of the most beautiful of evergreen shrubs, unfortunately scarcely hardy in north-eastern Germany, even when protected in winter, though thriving in the open air in France and Rhine-land. In England it is a prime favourite.

Then follows a general account of the habit of the plant.

Until quite recently we have had only the bright-yellow-spotted female shrub in our gardens, but since Von Siebold and Fortune have introduced the unspotted male plant, and a number of new forms, *Aukuba japonica* promises to compete with the Holly in variety. In the last catalogue (1867) of the Siebold-Garden, Witte has published no fewer than twenty-four forms as already in the trade.

Here are enumerated some of the more important of these, arranged according (1) to form of leaf, (2) kind or mode of variegation, and (3) toothing of the leaf-margin.

Altogether more than a page is devoted to this *Aucuba*. To its less-known Himalayan congener, *A. himalaica*, about half as much. The common Barberry extends over nearly five pages, but it is an extreme case of a variable and much-cultivated plant.

Throughout the plan is pretty much the same as is followed in *Aucuba*. After the name follows synonymy so far as may be needed; then frequently some explanation of the origin of the name, whether generic or specific, often including a biographical paragraph in the case of plants commemorating some person. Then follows the geographical distribution of the species. Here we may remark, what this book is especially apt to recall, the curious fact familiar to every botanist, how many well-known species of tree and shrub, even such as are not likely to have undergone material modification under culture, are of doubtful origin,—the horse-chestnut and walnut for example. Persia and the Central Asiatic plateau generally are credited with these trees, and probably the guess is in the right direction, though no wild specimens exist of either species in our herbaria.

There are some things we cannot agree with in the book, of course. For example, we should not undo *Cratægus*, and make all our thorns into medlars (*Mespilus*); nor do we consider the reasons given suffice to justify a renaming of our common lime-trees (*Tilia*); but these are matters too technical for discussion here, and after all of subordinate importance.

The first volume only, including the Polypetalous Natural Orders, is as yet published. Just at present German gardens are left pretty much to take care of themselves, and we fear there is no chance of the second volume until we have this miserable war settled. D. OLIVER

* Down indeed to *Alyssum saxatile* and *Iberis saxatilis*.

OUR BOOK SHELF

Travels of a Naturalist in Japan and Manchuria. By Arthur Adams, F.L.S., Staff-Surgeon R.N. (London: Hurst and Blackett, 1870.)

THOSE who wish to see what a world of pleasure may be opened up to one by an adequate knowledge of some department of Natural Science, ought to read this book. Mr. Adams is an enthusiastic naturalist, with a special "weakness," as he terms it, for insects, and the delight he has experienced in the hunt for specimens, and the close observation of his favourites in different parts of the world, have been simply endless. We should hope that some of his readers will find his eagerness "catching," and be led to feel new interest in objects which they have hitherto regarded with indifference, or perhaps treated as a nuisance. Among other animals observed by Mr. Adams with more or less care, was one of two specimens of the scaly ant-eater (*Manis Javanica*)—a female—which came under his notice. During the day she remained coiled up in a ball, but grew lively as night approached. In walking "she trod gingerly on the bent under-claws of her fore-feet, and more firmly on the palms of her hind-feet." One of her favourite attitudes was that of her gigantic extinct analogue, the Mylodon, as seen in the model of Waterhouse Hawkins in the gardens of the Crystal Palace. Supported on her hind limbs and "the firm, flattened, powerful, muscular tail," she would raise her fore-feet, moving her head and body from side to side, and peering cautiously about with her "little round prominent eyes." On the least alarm she tucked in her head between her fore legs. On one occasion she was coiled up in a strong net and supposed to be properly secured; when night approached, however, she easily burst her trammels, and was discovered by the violent barking of a little dog who was puzzled and alarmed by the apparition of so strange a visitor. Both specimens were fed on raw eggs and chopped raw beef, and seemed to thrive. Besides observations of this sort, Mr. Adams's readers will find scattered throughout his work some pleasant sketches of natural scenery, a few descriptions of amusing personal adventures, and occasional glimpses into the different customs of the countries he has visited.

Echinides du Départemente de la Sarthe considérés au point de Vue zoologique et stratigraphique. Par MM. Cotteau et Triger. Avec 65 planches de fossiles, dessinées et lithographiées d'après nature par MM. Levasseur et Humbert, 10 planches de coupes géologiques, et 2 tableaux. Williams and Norgate, 1855—1869.)

NOTHING can afford better evidence of the zeal and assiduity with which palæontology is now pursued than the fact mentioned by M. Cotteau in the preface to this work, that whereas MM. Agassiz and Desor, in their

Catalogue raisonné of 1845, indicated the number of Echinidæ discovered in the department of Sarthe at forty-one, and D'Orbigny in his Prodrome Stratigraphique at forty-four, the result of the joint labours of the authors, and other naturalists of the district, has raised the number to no less than two hundred and two. The discrimination, description, and illustration of the different species have been performed by M. Cotteau, whilst their stratigraphical arrangement and position have been accomplished by M. Triger. Some of the more remarkable forms discovered by them are the large *Heterocidaris trigeri*, with its peculiar arrangement of tubercles and its singular ambulacral pores, a species of which has recently been obtained by Mr. Wright from the inferior oolite of Yorkshire; the *Metaporhinus sarthacensis*, a curious and exceptional form representing in the Jurassic series the great family of *Spatangidæ*, which only make their appearance at the commencement of the cretaceous period; the *Echinocyphus tenui striatus*, which the authors are inclined to regard as the type of a new genus; the *Cidaris vendocinensis*, which presents such beauty of form and markings, with many others we have no space to particularise. The lithographic drawings are clearly drawn, and comprehend all the species discovered.

Progress of Chemistry. Jahresbericht über die Fortschritte der Chemie und verwandter Theile anderer Wissenschaften. Unter Mitwirkung von Th. Engelbach, Al. Naumann, W. Städel; herausgegeben von A. Strecker. Für 1868. 2tes Heft. (Williams and Norgate, 1870.)

THIS part, like the first, which we noticed a short time since, contains 480 pages; Organic Chemistry, continued from the first part, occupies 354, 13 of which are devoted to Animal Chemistry. Analysis fills 71 pages, the remainder being set apart for Technical Chemistry.

The section on Organic Chemistry contains accounts of Perkin's investigations on the hydrides of sodium and benzyl-salicyl, on butyric coumarin, and butyrocumaric acid, as well as Fittig's criticism of Perkin's views of the constitution of coumarin, which has since given rise to a lively discussion. Notices of Schützenberger's researches on triacetiodol, and of those of Perkin and Duppa on the constitution of glyoxylic acid are given. Stenhouse's experiments on benzol sulphuric acid are described, besides several papers by different chemists on the sulpho acids of the benzol series. Hofmann contributes, as usual, several valuable papers, the most important being those on the cyanide of naphthyl and its derivatives, and on the artificial mustard oils containing the radicals ethyl, methyl, amyl, tolyl, and benzyl, in the place of the allyl existing in the natural essence. The constitution of these compounds is also discussed. Gautier's researches on the carbylamines are continued, and also those of Lossen on hydroxylamine, which are noticed at considerable length. The action on organic bases is concluded by an account of Crum Brown and Fraser's experiments on the physiological effects of the compounds produced by the union of methylic iodide with the poisonous alkaloids.

Under Analysis we find the methods proposed by Frankland and Armstrong for the examination of potable waters, and which have since given rise to some controversy. Russell's apparatus for gas analysis is also described. The section on technical chemistry (only a portion of which appears in this part), contains papers by Rosenstiehl and Kopp, and by Schaffner on the preparation of sulphur from alkali waste, a subject of much importance, especially in this country, where the heaps of residues, which usually evolve sulphuretted hydrogen, and often pollute rivers in their neighbourhood, accumulate in immense quantities; this material, thanks to the study of scientific chemistry, may now be made to yield pure sulphur to such an extent as to make it worth the while of the manufacturer to extract it, while its removal renders the residues innocuous.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Gulf-Stream

I SEND for the perusal of your readers an extract from a note sent to me by Mr. King Groom of Stornoway. The facts he mentioned may be interesting. The beans I have received. When I was in the Hebrides some time since, I was assured that clubs, paddles, and drinking vessels of wood were sometimes found on the shores of the islands, and that these things were supposed to float in the Gulf-Stream from Mexico, but I never saw any. Some of your readers will doubtless be able to say where these beans grow, and to give their opinion as to the probability of their floating from the Mexican Coast, or from some other tropical country or island whose shores are washed by the Gulf-Stream. If these beans are brought over by the Gulf-Stream, it is probable that they may also be found on the west coast of Ireland and on the coasts of Devon and Cornwall. If so it would be interesting to hear from your correspondents in those parts whether any particular virtue is attributed to them by the inhabitants.

Board of Trade, Aug. 25. THOMAS GRAY

"Upon travelling on the shore of Illery I found a, to me, curious bean, known as '*dolichos mens*,' or horse-eye bean. I was told that every year a few are found along the shores of the Outer Hebrides, and they are supposed to be carried by the Gulf-Stream from the Gulf of Mexico. These beans are much sought after, as they are superstitiously supposed by the South Uist and Barra people to be a charm in child-bearing; if at that time the woman has one in her hand she will have little pain in her labour. I was much interested in the story as told me by a Mr. Arbuckle, at Barra, the parish schoolmaster, and confirmed by Dr. M'Donald of North Uist. It is said the curious have a small band of silver wire placed round the bean that has travelled so far of itself, and a silver cross put on the side by a silversmith in the south. The inhabitants state they are sure the bean is brought to the shore of the Gulf-Stream from Mexico, as they have been thus found from time immemorial. Another bean is also brought by the same means—viz., 'Eig autea Mi: Mosa,' a large brown seed."

The British Medical Association

THE reference to the income and expenditure of the British Medical Association last week requires correction. The income of the association, from subscription, is not 5,000*l.* but 3,471*l.*; the subscription annually only one guinea. The association is one which includes an important political and social organisation. For the annual guinea the associates are enabled not only to supply themselves with a journal weekly, which stands on the same footing as those published at a higher price than their total annual subscription, but in addition they keep also an active and important organisation, with branches in every part of the kingdom, which protects medical and public interests and advances medical science. Many think with you that it would be desirable to make larger grants for special researches. But for this purpose it would be necessary to start a special fund. The annual mass of scientific matter published in the journal is treble what could be contained in any volume of Transactions, and has the advantage of being published at the opportune moments of discussion. You would confer a benefit by urging the propriety of a special fund for original research. But the members are so well pleased with the large return for their annual guinea, that their numbers have risen in four years from two to four thousand; and the weekly journal, which now takes the lead in periodical medical literature, is the essential condition of the political and professional authority of the association. To publish in its place an annual volume of Transactions would, it is universally felt, be a suicidal act of retrogression. Among the 4,000 members there are not a dozen who are not aware of this. X.

The Intended Engineering College

"Look not a gift horse in the mouth"

I WAS very sorry to see in NATURE for 18th August a letter from Mr. G. C. Foster complaining of a supposed intention of the Government to aid the teaching of science, and basing this complaint upon what appears to me most narrow and unreasonable grounds. The representatives of science have been tolerably unanimous in demanding of the Government further aid to science, and I think they should with equal unanimity protest against any such grumbling at a promised instalment before its nature and conditions are known.

Mr. Foster says "that it is fair to assume that Government," &c., &c., and then having stated the details of his assumption, proceeds to criticise it. I think (and surely shall not be alone in this opinion) that it is most unfair to assume anything of the kind as the basis of criticism. When the details of the Government scheme appear, will be the proper time to discuss them.

Being as ignorant of these details as Mr. Foster appears to be, I can say nothing about them, but must protest against the principle upon which Mr. Foster's complaint is based. It is this, that Government must initiate no scientific effort, give no special aid or patronage to any college or scientific institution, lest it should assail the vested interests of "institutions like University College and King's College in London, and Owens College in Manchester." According to this shopkeeping view of the interests of these institutions, they themselves should never have come into existence, and all endowments or other extraneous aids to new institutions must be regarded as attacks upon the vested interests of their more venerable competitors.

In the classic period when Munro Primus, Munro Secundus, and Munro Tertius occupied successively the anatomical chair of the University of Edinburgh, its medical school was the most flourishing in Great Britain; students journeyed from London and all parts of England to attend its classes. At about the culminating period of its rising fame the London University was founded, and among its most active promoters were Lord Brougham and other Scotchmen. According to Mr. Foster, these Scotchmen were traitors to their own University, for undoubtedly the medical schools of University College, King's College, and the provincial colleges affiliated to the London University, have, by the competition of their metropolitan *prestige*, patronage, endowments, and local facilities, seriously rivalled their northern predecessor; and if the University of Edinburgh were merely established for the purpose of providing class-fees for its professors, the Scotch promoters of the London University were traitors to their own *alma mater*; but if the objects of the Edinburgh University are the promotion of science and diffusion of general knowledge, then the founders of the London University were co-operating with the Edinburgh University, even though they thinned the attendance in some of its class-rooms.

The other institution whose vested interests Mr. Foster specially pleads to conserve, should rather be suppressed, if his principle were accepted, for by its rich endowment and *prestige*. Owens College competes unfairly with the less-favoured institutions of Manchester and the private science teachers there who have no share in its endowments. Mr. Oliver Mason is about to build and endow with princely munificence a great educational establishment in Birmingham, and has bought the ground within a stone's throw of the Birmingham and Midland Institute. If the council and friends of the Midland Institute accepted Mr. Foster's views, they would denounce Mr. Mason's project as the founding of an opposition shop, which, by its rich endowment, might undersell their own and take away their customers. If they regarded the existing institute as merely established and maintained for the purpose of providing certain professors with their present moderate salaries, for supporting a secretary and his assistant, and for the comfortable maintenance of the porter and his wife, they might consistently do so; but speaking from direct personal knowledge, I can affirm that, on the contrary, they of all others are the most rejoiced by Mr. Mason's munificence, because they are the most deeply interested in the intellectual progress of their town. I recommend Mr. Foster to imbibe some of their spirit, and to rest assured that no revolutionary disturbances are likely to result from excessive endowment or patronage of scientific institutions, either by the present or any other British Government of this generation. Even if Mr. Lowe's next financial surprise should consist in devoting a portion of the national surplus to the elevation of the national intellect, let generous acceptance accompany our amazement.

W. MATTIEU WILLIAMS

Scientific Research

DURING the last century every branch of scientific research has undergone gigantic strides towards perfection. Great credit is due, ay, even in greater proportions than is given, to those talented minds, who, although on every hand impeded by obstacles, have successfully overcome every difficulty, and solved problems which excite the wonder and admiration of the universe. Within the limits in which I am compelled to restrain myself, it will not be necessary to pursue my idea with elaborate detail; but if I generalise with sufficient skill, abler hands can take up the thread and unwind it to the extremest minutiæ.

The means required for the prosecution of scientific research in a systematic manner, have never been at all adequate to the requirements. Various branches of science, such for example as astronomy, chemistry, &c., require an immense outlay in order to enable the philosopher to pursue his investigations with any prospects of a successful result. Others again, such as botany, geology, &c., require the devotion of long periods of time for the collection of specimens and their classification. Our societies certainly have, by their energy and emulative inducements, succeeded in extending scientific research far beyond the point which the most sanguine mind desired a century ago. But might not these societies be made much more useful; would it not be possible to distribute more widely their published transactions? Many gentlemen who take a great interest in scientific questions, but who do not live in London, are prevented from joining the societies by their exclusiveness. To them the valuable libraries, the periodical meetings, are useless, they therefore do not subscribe, and the high price of the publications prevents many from becoming purchasers. It seems to have become a settled opinion amongst scientific bodies, that everybody is able to spend 1*l*., or even more, just when he pleases, upon a luxury.

Unconnected with any society—not because of their own wish, but from their misfortune—hundreds of steadfast, able minds are working, adding, or being forestalled in, as the case may be, their mite here and there, in the onward march of progress. It is by unknown, frequently penniless searches after truth, that the great and complex problems have been solved. These great minds exist among us still. As examples, let me cite one or two instances, before suggesting an idea whereby we might hear more of such people. Whilst residing at Oxford, I became acquainted with a policeman, W. S., whose geological collection and information would have been worthy of one of our greatest and richest savants. A young gentleman, now a dissenting minister, and an undergraduate of that excellent institution, the London University, collected and classified some hundred species of the flora of his native county, Yorkshire. A third gentleman is assiduous in his botanical researches, and has, I believe, collected and classified the whole of the flora of another county. Now, it is such minds as these that, judiciously directed, make the greatest discoveries. Their only incentive to labour is a fixed inherent desire to know more of certain things; they have really no aim but the satisfying of the natural tendency to move in this direction. The published text-books upon various scientific subjects are not adapted for self-taught students, the authors presuppose the aid of a master. There is no meeting together to discuss what this or that one has done, but each laboriously pursues his own path, often wasting valuable time in going over ground already fully explored.

I would suggest that local societies in connection with the central bodies, be formed in *every* county. The nucleus to these bodies already exists in clergymen, doctors, solicitors, and above all, tutors and schoolmasters. There is a yearning amongst many of these men for more information, and, as previously stated, they are debarred from reaping any benefits from the central bodies as conducted at the present moment. The government of these branches should be somewhat similar to that of the older societies; each member ought to contribute an annual subscription, in return for which he would receive—

- α. Free admission to all meetings of the local and of the central society.
- β. The transactions of the society also free.
- γ. Any other benefits as the committee might determine, or which could be obtained.

Thus far the scheme I advocate is simple, but it may be said, this necessitates the formation of as many branches as there are societies. Not so, however; the country members within each district would be too few to allow of this; but they might *all* congregate under one roof, be subject to one government, and reap the advantages of communion. Every member might upon election signify the particular transactions he wished to obtain; his subscription, after deducting a certain per-centage for local expenses, could be sent to the society publishing them, and he should be enrolled upon its books as a *bonâ fide* member. The information to be obtained of one science is generally so closely connected with another, or others, that no difficulty would be found in getting the greater part of the local members together for the purpose of hearing an address upon any scientific subject. The large libraries of the various central societies could be utilised by sending a parcel of books to the local library, such books to be exchanged monthly. It may be asked, would the parent bodies, and science generally, gain by such an arrangement? Are the British Islands too well explored? Is there no more celestial or terrestrial object remaining unknown? Have mathematicians, mechanicians, &c., reached the bounds of their studies? I say to these, and a score of other similar questions, No! Then the watchword should be Onward. By the above means the face of the whole country would be covered by earnest and interested searchers. Botanists might discover new species; astronomers would be joined into an immense circle, closely watching every phenomenon which occurred in the heavens; one statement would be verified by others; geologists would be at the side of every quarry or well, seeking specimens; antiquaries would be at hand to receive "finds," whenever historical ground or old buildings were being moved. Monthly statements of work performed would be forwarded to the general Secretary, to be printed in the Transactions. Lectures would be multiplied a hundredfold. Book-worms would find treasures hitting about in family mansions, and even in village cottages, which would satisfy even their craving appetite. But I am not writing for readers unable to understand. All will admit the feasibility of the plan, if only it were tried. Probably other correspondents may wish to be heard upon the subject, therefore I leave the suggestion in their hands.

Reading C. H. W. BIGGS

Kant's Transcendental Distinction between Sensibility and Understanding

As Dr. Ingleby's letter cannot well be answered, except by me, will you kindly insert the following observations? I am very sorry the form of the controversy compels me to refer to myself; you will see that the point at issue concerns an important question in Kant's philosophy. He said a certain question of mine was badly worded. As a question set out of a prescribed book, he concedes it to have been accurate enough, but he still denies the precision of the statement in that book. I think he is right, and that I was guilty of an error, though by no means so grave an error as he imputes to me. But his imputation is again partly my fault, for I did not write clearly enough. Here are the words which misled him; "we must not confuse the empirical distinction between real object and merely subjective appearance with the transcendental distinction on which Kant's doctrine of Space and Time is based."

In the first place I do not think there is any ambiguity in the term *real object*, when I am speaking of an *empirical distinction*, for then it cannot possibly be a noumenon; and the meaning of *subjective appearance* follows upon its correlative. Dr. Ingleby should, therefore, have found no difficulty in interpreting me rightly so far, and, indeed, he has done so. But he understands the rest of the sentence as if I had written "we must not confuse the empirical distinction between real object and merely subjective appearance with the transcendental distinction *between the same two things* on which Kant's doctrine of Space and Time is based." This I did not say, though I am afraid my words are open to such a construction. He justly adds that Kant's Æsthetic is founded on no such distinction, and he points out the fact that Kant has in the previous page (p. 78 of Hartenstein's Ed.) spoken of his broad distinction in kind between Sensibility and Understanding, as a transcendental distinction.

I perfectly agree with him that this was the point referred to by Kant, and perhaps he is right that the philosopher meant nothing more. But what I had in my head when I wrote the passage, was a special phase or aspect of this same distinction, the aspect which insists, that *it is not merely the ordinary empirical sensibility* (such as tastes and odours), *but the a priori and necessary sensibility which his doctrine contrasts with the understanding*. Of course he has not yet considered, and therefore leaves undetermined, whether the understanding can cognize things, *per se*: but as to sensibility, the most obvious illustration which a superficial teacher would select, in expounding the so-called subjectivity of space and time, would be contingent, as opposed to necessary, data of sense. He would show how colour and taste and warmth were apparently perceived in the object; but were really modifications of the subject, while other qualities (extension, figure, &c.), were really necessary to the object. Kant protests repeatedly against this empirical distinction being used to illustrate his doctrine, which depends on a transcendental distinction—a distinction (I thought) not of mere contingent, but of pure *a priori*, and therefore necessary, sensibility from understanding. The passages which I indicated and translated in the sequel of the note, preach this peculiar aspect of his doctrine, and were cited for this reason alone.

I confess I was led to search them out by overlooking, stupidly enough, his employment of the phrase "transcendental distinction" in the previous page; and the fact, that Professor K. Fischer had omitted to mention so important a point, made me all the more anxious to notice it. But when my language was so ambiguous as to mislead a really competent critic, like Dr. Ingleby, I must only acknowledge my fault, and promise to make amends in my next edition. I trust, however, that in this instance, your readers will absolve me from having blundered in the principles of the Critical Philosophy, even if I gave too much meaning to the *transcendental distinction*. I cannot conclude without thanking your able correspondent for his valuable criticism.

Trinity College, Dublin, Aug. 15 J. P. MAHAFFY

Colour Blindness

To the remarks in Mr. Hayward's letter in NATURE of August 18, may I add my own observations? I have often noticed that my right eye has much greater defining power than my left; as, for instance, in reading print; but when I look at a check pattern of white and black, the white looks much whiter and the black much blacker to my left than to my right eye. Is not this somewhat analogous to Mr. Hayward's case?

St. Peter's, York, Aug. 20 LEONARD MARSHALL

Cross Fertilisation

THERE could perhaps be found no more striking illustration of the law which seems to demand, from all species of living things, frequent crossing as a condition of their continued existence, than is afforded in the structure and development of the flowers of *Lobelia*. A hasty examination of a few specimens of this plant might seem to refute this idea; and I can imagine an anti-Darwinian, unacquainted with the life-history of the flower, pointing triumphantly to it, not only as an instance of pepetual self-fertilisation, but also as an incontrovertible example of an organism specially adapted to the use and convenience of a different species, without itself deriving any advantage from the circumstance. For while the flowers of this genus are furnished with a broad and brilliantly-coloured lip, forming an attractive lure on which insects may alight to feed on the nectar provided for them, the introrse anthers are connected together, so as to form a rigid case completely enclosing the style and imbedding its summit in pollen. In this case, then, insect agency appears to be worse than useless; for though a few grains of pollen may be, and are, shaken out, through a small orifice between the extremities of the anthers, upon the back of every moderate-sized insect which enters the flower; such grains can apparently never be brought into contact with the stigma, and consequently must perish and be wasted. How completely, however, would such a reasoner find the tables turned by more continued observation. *Lobelia* is one of those genera which might be more correctly described as *versisexual* than, as strictly speaking, hermaphrodite. Its flowers are at first entirely male, the female organs not being fully developed till after all the pollen has been removed. Then the style forces its way between the extremities of the anthers, and expands into a broad stigma, so situated as to rub the backs of the bees and other insects that enter the flower, and brush off any pollen that they may bring. Thus, self-fertilisation, instead of being, as it at first seemed, inevitable, is in fact impossible; and insect agency, which appeared at best useless, is absolutely necessary to the survival of the species.

"Versisexuality" seems also to be the rule among the species of *Ranunculaceæ*, *Geraniaceæ*, *Saxifragaceæ*, and probably many other families. It is evident that in such species the pollen of the earliest and the ovules of the latest flowers will be wasted; and since natural selection tends always to prevent any waste, it is conceivable that such species might in the course of many generations give rise to monœcious or diœcious descendants.

Kilderry, Co. Donegal W. E. HART

The "English Cyclopædia"

IN answer to Nemo's letter in your issue of August 11, I do not wish to prolong the correspondence. An index will be added as soon as possible to the Natural History Supplement, in which cross references will be given. I am not the editor of the "English Cyclopædia," but I was

EDITOR NATURAL HISTORY SUPPLEMENT

Holly-berries obnoxious to Birds

ALLOW me to thank Mr. Hart for his remarks on my note, with reference to this subject; and, at the same time endeavour, as briefly as possible, to explain my meaning more fully.

I take it that a holly-tree, standing in a favourable situation for the growth of young plants, and bearing its berries until perfectly ripe (and I noticed a tree loaded with berries on August 1st), would stand a better chance of propagating and increasing that variety than a tree which has been robbed of all its berries by birds during the preceding winter. I am quite aware that the local distribution of some plants is, in a great measure dependent on birds; but, with regard to holly-berries so disseminated by the migratory thrushes, &c., the great majority would be deposited on arable or pasture land, where the young plants would be speedily eradicated by the plough or scythe, and consequently the parent tree would stand a worse chance of propagating itself from seed, than the variety from which the berries had fallen on ground adapted to their growth. Perhaps Mr. Hart will kindly point out where this hypothesis is "so different" from the theory of Messrs. Darwin and Wallace; a theory with which I, as well as most working zoologists, entirely agree.

East Woodhay, Aug. 8 HENRY REEKS

Solar Spots

I EXTRACT the following from NATURE of 28th July, p. 267:—"Mr. T. W. Backhouse, of Sunderland, reports that in May there was a remarkable case of a Solar Spot making a revolution round another. It occurred with respect to the two largest spots of a group which was half way across the northern zone, on May 9th. The smaller spot was south of the larger on the 7th at 3^h, but preceded it on the 12th at 21^h, the line joining the two spots having rotated through an angle of 80° or 90° in $5\frac{3}{4}$ days."

It is interesting to observe that the direction of this rotation, from south to east, is the same as that in which cyclones rotate in the earth's northern hemisphere; in the southern hemisphere they rotate in the opposite direction. This coincidence gives some support to the theory of the solar spots being produced by cyclones. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Aug. 6

Noises Caused by Fish

YOUR issues for May 12 and 19, 1870 contain sundry notices of noises supposed to be produced at sea by various fish. The localities are mostly tropical. But it is not necessary to go so far afield for examples of the noises in question. While on board a steamer at anchor for two or three days in the Tagus off Lisbon in the spring of 1869 (April), I heard noises of the kind referred to, which were attributed by the ship's officers to a fish (whose name I now forget), the sound being produced, it was asserted, only at particular states of the tide. Disposed to consider the explanation a mere sailor's "yarn," or superstition, I did not give to the subject the attention it may have deserved.

Perth W. LAUDER LINDSAY

The Kingfisher's Meal

RETURNING from my morning's round on a pleasant summer's day, I observed a kingfisher perched on a hazel bough close to a pretty little trout-stream; my attention was instantly aroused, for one does not often see these pretty creatures, even during prolonged country excursions, in such a position; and moreover his attitude was peculiar—perfect stillness, with an inclination of the head to the left pinion—just the posture in fact that I have seen a fatally wounded bird take previous to dropping from its resting-place; indeed so close was the resemblance that I expected every moment to see the bird I was watching drop into the water, believing it to have been wounded; guess my astonishment when the supposed invalid was seen to dart with amazing swiftness into the curling stream, rise, and continue its rapid flight without apparent interruption, to the rails surrounding a hay-stack close by, where I saw it making most energetic movements of the head and neck, and first became aware, from observing a silvery, glittering, and writhing little fish in its beak, that, instead of being ill as I supposed, and suddenly determined on trying the effects of a bath, he was actually at dinner. After gorging this lively mouthful, the active and dexterous little fisher-bird returned to his hazel bough looking quite as invalidish as before; but now I was aware of his intentions. "Natura est dux optima." PHILALETHEIAN

Ancient Egyptian Forests

A NOTE in the *Academy* for July speaks of ancient forests now turned to chalcedony, *e.g.* at Cairo, thus indicating a profuse vegetation in former days.

Let it not be forgotten that the hieroglyphs represent Egypt as the "land of trees," Khem having been the god of gardens. On the Rosetta stone Egypt is indicated by "a tree and the sign of land" (*vide* Wilkinson's Ancient Egyptians, ii., 184-7). It seems that the destruction of trees is an unvarying accompaniment of dense population. A. HALL

Poisoning by Œnanthe crocata

IN your comments on the rapidly fatal poisoning case, recorded by me, where a man and cart-horse quickly died after eating a small portion of the roots of this plant, you remark "it seems strange that the horse, as well as the man, should not have rejected a plant of so acrid and suspicious a flavour." Now the flavour of the *root* of this plant is known to be mild and pleasant, and not acrid. I can confirm the truth of its mild taste from experience, as I have twice eaten portions of the root for experiment: the taste is intermediate between that of a turnip and the stalk of celery. The poison did not act as an irritant, but the deaths resulted from paralysis of the heart.

WORTHINGTON G. SMITH

BARON HUGEL

THE death is announced of Baron Charles Hügel, well known as a scientific explorer and a cultivated man of letters. He was born 25th April, 1796, and, after completing his education at Heidelberg, was for some time engaged in the wars in the early part of this century between Prussia and France, and in 1814 he took part in the triumphal entry into Paris. In 1824 he relinquished military pursuits, and returning to Vienna, entered with great earnestness into the study of Natural Science, for which he had always shown a decided taste. For many years he studied assiduously, preparing himself for an expedition he had planned round the world. In 1831, on the 2nd of May, he set sail from Toulon, and was away six years. His ship was fitted out with every appliance for a scientific voyage, and in all the various localities he visited in Asia, Africa, and the then unknown field of Australia, he amassed large and valuable collections. These were, on his return, purchased by the Austrian Government, and to them the Vienna Museum owes its great importance, especially in the botanical treasures he had so lavishly accumulated.

The materials he brought back with him, and the abundant notes he had taken, were utilised in several elaborate scientific publications, such as Endlicher's "Plants of the Swan River District (Australia)," and Heckel's "Fishes of Cashmere."

The baron also delivered two learned and interesting addresses to the meeting of German Naturalists in 1838 and 1843, and besides these he sent many valuable scientific papers, especially on botany, to the Vienna scientific publications.

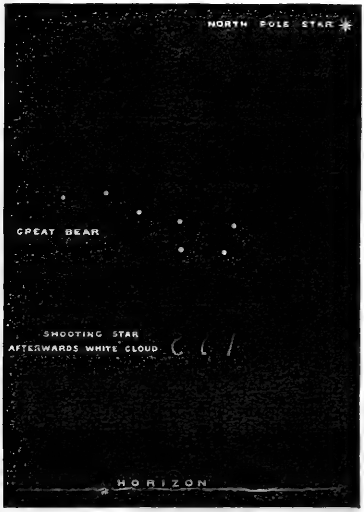
He is also the author of two works in German, "The Basin of Cabul" (Vienna, 1851), and "Cashmere and the Empire of the Sikhs" (Stuttgardt, 1840).

For many years he continued to take a very active part in all the scientific progress of his native country and of Italy. At the time of his death, in his seventy-fifth year, he was Austrian Minister at Brussels.

THE METEOR OF AUGUST 15

We have received descriptions from several correspondents of the remarkable meteor seen on the evening of August 15 over the north of England and Ireland and south of Scotland, to which we referred in our last number.

A correspondent from Portrush sends the following description and sketch:—"At 8.50, on August 15, when stars of first magnitude were only faintly visible, a shooting star was seen in the north-west. I have shown its position in the heavens in the accompanying sketch. It was observed to leave behind it a white thin cloud which

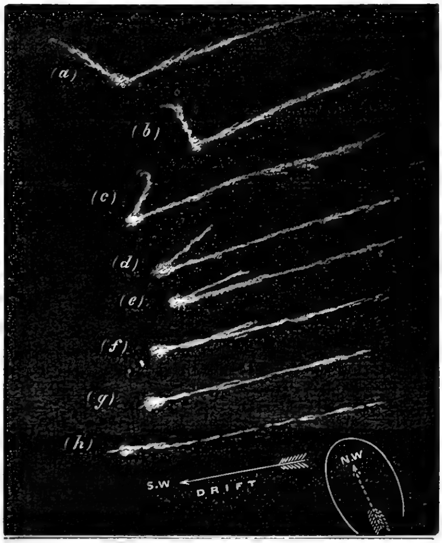


Shooting star, 8.50 P.M., August 15.—N.N.W. 25 deg. above the horizon, left behind it a streak of white cloud, which was clearly visible for ten minutes, drifting with the wind.

drifted a little to the west, and altered its shape from a straight line to a crescent. It was evidently illuminated by the light of the setting sun, and disappeared gradually in ten or fifteen minutes. Was the white thin streak of cloud, vapour, or dust? I observe by the newspaper that this cloud was seen in the neighbourhood of Belfast some forty miles distant, from which I infer that the phenomenon took place at a considerable altitude."

At Dunbar it is described by an observer in the following language:—"A remarkable atmospheric phenomenon was witnessed at Dunbar on Monday night. The phenomenon was first seen about a quarter before nine o'clock, and at that time it was more than half-way up the northern horizon. When first observed it had the appearance of a ball eight or ten inches in diameter, of a bright sparkling white colour tinged with blue, hanging suspended in mid-air. The colour, indeed, throughout was much the same as that of a star of the first magnitude. From the head or ball there issued a tail of the same bright colour, apparently three or four yards in length, and pointing in a north-easterly direction. By-and-by, however, a second tail seemed to branch off from the middle of the first one, at an angle of forty-five degrees, thus giving to the tail of the figure a cleft or forked appearance. This second tail seemed to come and go, being occasionally detached for a few seconds, sometimes indeed being lost sight of altogether, then suddenly coming into view, and appearing to unite again. The phenomenon lasted with little variation for fully twenty minutes, and then proceeded very slowly in a south-westerly direction."

At Kirkbank, near Burntisland, it presented the following appearance:—"A brilliant shooting-star appeared in the north-west on a bright evening sky, and darted out of sight northwards. Its path was precisely that of a body obliquely reflected from an air-cushion. It left a trail like a nebulous haze. At the point of reflection a vivid spot remained, and fainter trails before and behind; corresponding to head or ball and tails noticed at Dunbar. The nucleus drifted towards south-west, and the branches gradually folded together behind, all disappearing as a



faint streak. Duration estimated fully ten minutes, terminating about 9.5 P.M., as Dunbar notice has it." The successive aspects were sketched by the writer and annexed.

And at Arran the appearance presented appears to have been very similar:—"On Monday night about half-past nine o'clock, there was a peculiar manifestation of what appeared to be electrical agency in the sky, at Whiting Bay. At that hour a bright light was seen to flash out from the north-west, near the horizon. It suddenly spread upwards in the form of a long ribbon, the upper half of which afterwards doubled down, when the whole assumed a horse-shoe form, and then gradually faded away. The sky was at the time perfectly clear, and a number of stars were visible, but the brightness of the meteoric appearance completely outshone them."

We should be glad to receive further descriptions of this remarkable meteor from some of our astronomical correspondents.

SCIENCE OF WAR

II.

MACHINE GUNS

THE Machine Gun has for a good many years, in one form or another, excited the attention of the military authorities of Europe and America, and recent events have made it the subject of a great deal of popular interest. The best known guns of this class are the Gatling Battery and the Mitrailleur. The first (of which Figs. 1 and 2, taken from photographs of the original in the possession of the British Government, present a front and rear view) is an American invention, and did good service on many occasions during the late civil war. Three sizes of this gun are constructed. The smallest has ten steel rifled barrels, the calibre being suited to the musket cartridges

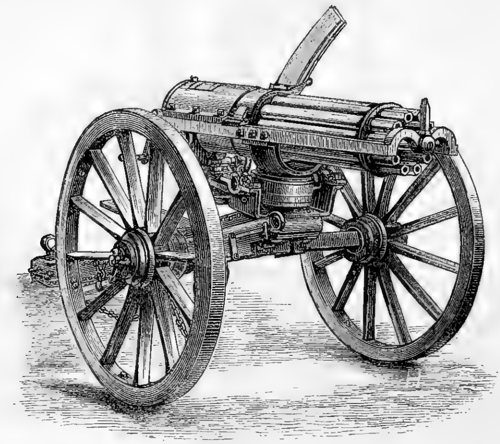


Fig. 1.

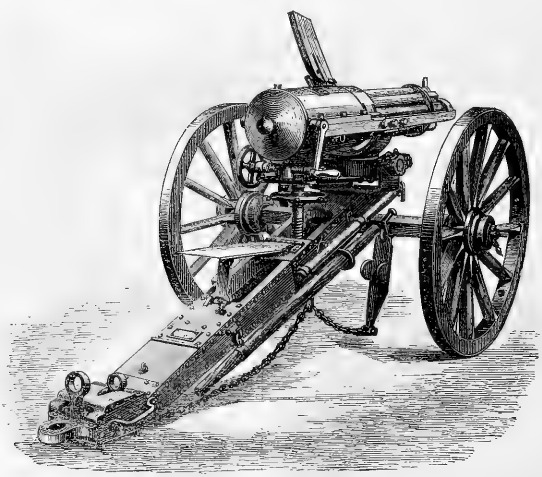

Fig. 2.

used by different Governments. The second-sized gun is constructed with the same number of barrels, but is invariably of three-fourths inch calibre, and discharges solid lead balls of $4\frac{1}{2}$ oz. in weight. The largest sized gun, which is of one inch calibre, has sometimes ten, but generally six barrels. It is provided with solid lead balls half-a-pound in weight, and can also use explosive projectiles. One of the main features of the gun is that it has as many locks as barrels, each barrel and its lock revolving together. Its success, therefore, as a whole, does not depend upon that of each of its parts, for if any of the barrels or their locks are injured, the remaining ones continue to work as well as ever. The weapon is supplied with cartridges by means of "feed-cases," through the hopper—the upward projection rising at the end of the breech-covering nearest the barrels. When it is in operation the cartridges are placed in the rear ends of the barrels, and the breech is closed at the time of each discharge by a forward motion of the locks. A return movement extracts the shells when the cartridges have been fired. In the ten-barrelled gun five cartridges are being loaded and fired whilst as many shells are in different stages of being extracted. The locks are not attached to any part of the gun, and operate on a line with the axes of the barrels. Whilst the gun is revolving, "they play," to quote the words of the manufacturers, "back and forth in the cavities in which they work, like a weaver's shuttle, performing their functions of loading and firing by their impingement on stationary inclined planes or spiral projecting surfaces." The weapon can be loaded and fired only when the barrels, inner breech, locks, &c., are being revolved, all of which operations are set going by a man simply turning the crank. In the most recent guns the covering and back diaphragm in the outer casing are perforated, the apertures being closed by

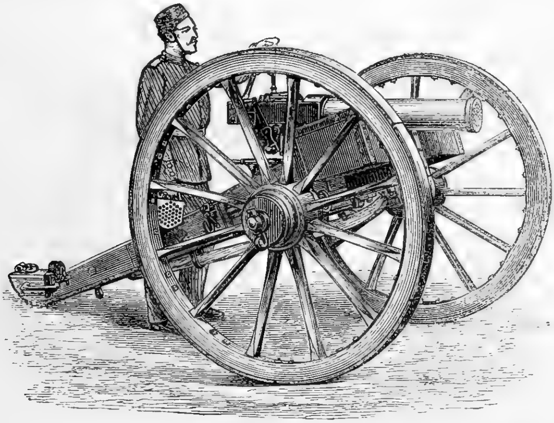

Fig. 3.

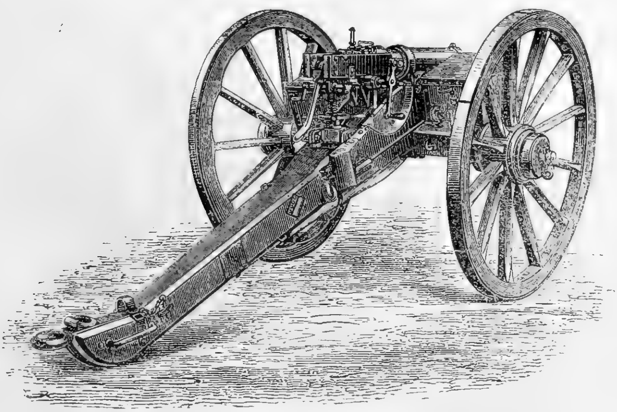

Fig. 4

means of a single removable plug. In this way the locks may be inserted and removed without taking off the caseable plate, obviously a great improvement, as it renders the inspection and repairing of the locks much simpler. The newest guns are also cocked by means of a knob placed at a point on the right side of the weapon. When turned, this knob permits the gun to be revolved without being snapped while not in use. If its position is reversed, the gun can be made to snap or fire at once. The carriage on which the gun is mounted is so constructed that the latter may receive, when being fired, a lateral motion, "so as to sweep the sector of a circle of more than twelve degrees, without moving the wheels or the trail of the carriage." Five hundred yards or more may thus be covered without the continuous fire of the gun being interrupted.

We turn now to the Mitrailleur Gun, of which there are two kinds, the French Mitrailleur and the Belgian, that of Montigny. The gun of which in Figs. 3 and 4 (also taken from photographs of the original) we present views from different points, is that which is at present being made the subject of a great variety of experiments at Shoeburyness. It was constructed under the superintendence of Major Fosbery, and, although improved in detail, in all essential points resembles the Montigny gun. It is the latter that we shall describe in what follows, making free use of the careful report on the subject presented by Major Fosbery about two years ago to the Government.

Like the Gatling gun, the Montigny Mitrailleur is made of three sizes, the smallest containing nineteen guns and the largest thirty-seven. Major Fosbery's gun is of the latter size, is of ·534 inch calibre, and weighs 400 lbs. The barrels are planed exteriorly to an hexagonal form, those of Major Fosbery's gun being rifled on the Metford system. They are fitted and soldered together, and to the wrought-iron tube which surrounds them and forms the barrel of the weapon. To this barrel, it will be seen, are screwed at the breech end two broad plates of wrought-iron. They are placed vertically, and are connected together at the end nearest the barrel by the ring into which the latter is screwed, and near the other end by a transverse bar. These plates form what is called the breech attachment. Placed between them are the breech-block and the lever, of which the long arm forms a handle—in Fig. 3 raised, depressed in Fig. 4. Attached to the short arm of the lever is a cylindrical mass of gun metal, confined to a box or recess of similar shape, in which it can be played freely to and fro. Short tubes are bored in the metal of this cylinder, corresponding in number and position with the barrels of the gun, and in each of these are placed a spiral spring and a small steel piston. On the face of the cylinder a perforated steel plate is screwed, through which the pistons project. They also pass through corresponding holes at the bottom of the recess in which the cylinder moves. In a vacant space which now occurs slides a vertical steel plate or shutter, and beyond we come to a second plate, screwed to the face of the main breech-block, containing a small point or striker, corresponding with each barrel, and therefore with each spring and piston in the movable cylinder. The vertical plate or shutter by which the strikers and pistons are separated, is moved by a transverse axle by means of two ratchet wheels, which take into tooth racks placed on the back of the plate. The axle is kept in position by a coiled spring, and is provided with a handle, which may be seen in both Figs. 3 and 4, on the right of the gun.

Turning back to the lever, we find that it is secured to the breech attachment by trunnions working in brass bearings attached to the side plates, and forming its fulcra. Its short arm is connected with the breech-block by a link formed of two pieces, furnished with left-handed screws, and united by a screwed collar, by turning which the link can be lengthened so as to compensate for any wear and tear in the working parts. By raising the handle of the lever the breech-block is drawn back by means of the link, and by the same means it is pushed forward and forced against the rear end of the barrels when the handle is depressed. As the lever, when the handle is depressed, rests against the bar uniting the plates of the breech attachment, it is obvious that the breech-block could be removed from its place only by a force sufficient to fracture the bar or the trunnions of the lever. No force is ever applied to it greater than that which arises from the explosion of a single cartridge.

The only remaining part of the gun is the cartridge-holder. It is a steel plate about half an inch thick, in which holes are bored, corresponding in position with the strikers and barrels of the gun, and made to fit accurately the heads of the cartridges. On either side of the gun is an ammunition-box, plates being carried ready filled in one, and boxes of cartridges occupying the other. Flanges forming perpendicular grooves are attached to the face of the breech-block, and in these the cartridge holder and extractor is made to slide vertically.

If the gun is to be loaded the lever is raised, when the breech-block is withdrawn to its utmost limit, the lock springs are freed from compression, and the points of the pistons rest lightly against the steel shutter behind which they are placed. A full cartridge-plate is dropped into its place, the strikers being pushed back by its bevelled edges as it descends. Next, the lever is depressed, when the breech-block advances, the cartridges are forced into their barrels, all the springs are compressed, and the pistons are urged against the steel shutter in front of them. When the gun is to be fired the handle to the right is turned. The shutter which is connected with the axle to which the handle is attached at once begins to descend, and as a vacant space is thus left for the pistons, they shoot, one after the other, across it, and come into contact with the strikers. The latter communicate the blow to the cartridges, which are immediately fired. To avoid friction between it and the pistons, the upper edge of the steel shutter is bevelled, and it is so cut into steps that two contiguous barrels are never fired consecutively. The whole thirty-seven are fired by $1\frac{1}{4}$ turns of the handle. At any point the firing may be stopped, and the fired cartridges be replaced, or the whole may be fired by a rapid motion of the handle. When the cartridges are exhausted, the lever is raised, the breech-block is drawn back, and the plate containing the empty cases is taken away. A fresh loaded plate is substituted, when the breech is again closed and the firing renewed.

Neither in the Gatling nor Montigny do the barrels radiate, as is generally supposed; they are arranged perfectly parallel. That such must be the case is indeed evident on slight consideration. For were it desirable to render the tubes in any way divergent it would be necessary, in the first place, to fix upon a specific range at which the arm should be used, as upon the locality of the target would depend the degree of radiation; thus, if the charge were regulated to spread in the most advantageous manner at a hundred yards, its effect would be very insignificant at ten times that distance, by reason of its very scattered nature at a point so remote from the gun. On the other hand a sufficient separation of the bullets is always brought about by the unavoidable discrepancies inherent even to a well-finished arm with parallel barrels; for even if the tubes were all mathematically true—a condition practically impossible to fulfil—very slight variations in the powder charge of the cartridges would always prevent the whole series of projectiles from pursuing a perfectly parallel course and lodging in the target within the same limits as those whence they started. As a matter of experience we may mention that the shooting is considered to be exceedingly correct, when at a fair range the whole thirty-seven bullets from the Montigny are lodged in a target measuring twelve feet square.

We need not here enter into the disputed question how far machine guns are capable of competing with the ordinary field guns. There can be no doubt that if the former be well constructed, they ought to be much more easily worked in the field than the latter. It is in their favour, too, that the effect of their projectiles does not, as is largely the case with field guns, depend upon the proper action of a fuze; and the extraordinary rapidity of their fire (the Gatling gun may be fired, when well manned, from 400 to 500 times per minute, and the Mitrailleur 379 times, or more) is a decided advantage. The absence of recoil by which they are distinguished is also noteworthy. The weak point of the Mitrailleur is its comparatively small range. There is no evidence that it can be fired with effect much over 800 or 900 yards, so that it is comparatively useless at distances which a field gun commands with ease. Moreover, its trajectory at short distances is said to be rather high, and hitherto the cartridges have manifested a tendency to stick after having been fired. These facts alone would be decisive against trusting solely to the Mitrailleur. But it does not follow, because it is not good for all purposes, that it may not be useful for some. There are obviously many positions in which it might inflict great damage on an enemy. Doubtless much light will be thrown on its capabilities by the tests to which it is being submitted at Shoeburyness, and by the manner in which it bears itself among the fearful scenes in which it is at present playing a prominent part on the Continent.

NOTES

DR. C. H. SCHAIBLE has published a little pamphlet of 16 pages, entitled "Self-help on the Battle-field" (*Selbsthülfe auf dem Schlachtfelde*: Trübner), for gratuitous distribution among the German troops, and solicits its reprint in Germany. In spite of the great care now bestowed upon wounded soldiers, it is practically impossible, in great engagements, for all to receive immediate attention; and immense suffering is caused by their lying as much as two days on the battle-field without being removed. In these cases the wounded soldier is thrown entirely on his own resources; presence of mind and quiet judgment are indispensable at such a moment; but both are the result of a knowledge of the proper remedies. This knowledge the author undertakes to teach in a concise and simple way, intelligible to every understanding. He first points out the articles required for immediate dressing, which might be carried by every soldier. He then explains the mode of arresting bleeding; the different steps in dressing the various kinds of wounds; the treatment of fractures; and concludes with some general rules. We earnestly hope it may afford some alleviation of the terrible sufferings caused by the present war.

NOTWITHSTANDING the announcement which was made to the contrary, the International Metric Commission met in Paris from the 8th to the 13th of August, for the purpose of some preliminary business, and then adjourned to a more favourable opportunity. Of the 25 foreign States which accepted the invitation of France, 20 were represented, viz., Austria, Chile, Colombia, Spain, the Roman States, the United States of N. America, Ecuador, Great Britain, Greece, Italy, Nicaragua, Peru, Portugal, Russia, San Salvador, Norway, Sweden, Switzerland, and Turkey. The bureau was constituted as follows:—President, M. Mathieu, of the Institute of France; Vice-presidents, M. Struve, of the Academy of Sciences of St. Petersburg; Prof. W. H. Miller, of the Royal Society of London; Prof. Henry, Secretary of the Smithsonian Institute of Washington; M. Herr, Prof. of Geodesy and Astronomy in the Polytechnic School of Vienna; and General Morin, of the Institute of France; Secretaries, M. Tresca, sub-director of the Conservatoire des Arts et Métiers; and M. Hirsch, director of the Observatory at Neufchâtel. The commission decided that the question to be proposed at a future time should be of two kinds, the first relating to the metre itself, the second to the kilogramme. A committee was appointed to carry out the needful arrangements in the interval before the next meeting, consisting of Prof. Airy assisted by Mr. Chisholm, Baron Wrède, and MM. Wild, Hirsch, Ibanez, Steinheil, Förster, Lang, and Hilgard.

WE regret to learn the death of Dr. Bolley, the celebrated professor of chemistry at the Polytechnic School, Zurich, which took place suddenly on the 3rd of August. He was a native of Heidelberg, where he was born in 1812, and had held positions as assistant and professor in the University of his native town, at the Cantonal School of Aargau, and the Federal Polytechnic School at Zurich. From 1859 to 1866 he was director of this school, and during that time the number of students increased greatly, being attracted from all the civilised countries of the world. He was a commissioner from the Federal Government to the London Exhibition of 1851 and 1862, and to that at Paris in 1867. The works by which he will be best known are his "Manual of Technico-Chemical Research," and his contributions to the most complete and valuable work on chemical technology. To his efforts is greatly due the foremost position which the Polytechnic School at Zurich enjoys among the technical schools of the Continent.

THE Dutch Scientific Society of Haarlem has proposed a series of questions to be answered by the 1st of January, 1872, among which the following are the most important:—1. To define, by anatomical and chemical researches, the mode of origin and the function of wax in living plants. 2. To explain, as much as possible by the aid of original researches, the history of the development of certain malformations and excrescences produced in the oak by different gall-making Hymenoptera. 3. To decide experimentally whether the roots of plants give rise to particular excretions, and in that case to establish the nature of the excreted matters. 4. To study the works of Huyghens, both with reference to the state of knowledge at his time, and with reference to its actual state. 5. The value of the constant of aberration, deduced by Delambre from the eclipse of the first satellite of Jupiter, and that which results from the more recent astronomical measurements, present a difference at present inexplicable. The observations respecting the eclipses of the first satellite of Jupiter are required to be collated, and a new determination of the constant of aberration to be deduced. 6. To make a new series of researches on the influence which the different colours of the spectrum exercise on the respiration of the green parts of plants. 7. To give a monograph of the flora of the sandhills of Holland. 8. To give a systematic description of the marine Phanerogamia.

WE have to announce that Dr. Debus, F.R.S., has been elected Lecturer on Chemistry in the medical school of Guy's Hospital; and that the practical classes of the institution will be under his direction.

DR. T. E. THORPE, of Owens College, Manchester, has been elected by the trustees of Anderson's University, Glasgow, professor of scientific chemistry in the room of the late Dr. Penny.

ON the 1st August severe shocks of earthquake were felt, about two in the morning, in several provinces of Greece, and were attended with disastrous results in the Parnasside and in Livadia. The town of Galaxidi and the villages of Khrusso and Arakhora suffered the most. The latter are nothing more than a mass of ruins; six of the people lost their lives, and all were more or less hurt. At Galaxidi all the houses were injured and some have crumbled to ruins; six children were crushed to death and about 150 adults were injured. Amphissa, the chief town of the province of the Parnasside, also suffered, but in a less degree. There seem to have been additional shocks the next day, but the dates are indistinct.

FROM official statements and from private letters received in London, we learn that Guatemala is suffering from the frequent occurrence and great destructiveness of earthquakes. The chief ravages are in the district of Cuajiniquilapa. The earthquakes have been daily from the 14th April to the last date, the 18th June, with the exception that after the 3rd May there was no shock for three days. The greatest shock was on the 12th June at 3 P.M. The motion was from S.E. to N.E., preceded by hollow rumbling. The church and chapel of the town were nearly destroyed. The principal parochial and municipal buildings, the prisons and custom-houses are in ruins. All the tiled private houses have suffered, especially those built of adobes or sunburnt bricks, only the straw huts escaped. The buildings in the coffee farms are destroyed, as also the fences and ditches. We suppose the fences are built of adobes or tapia. More damage has been inflicted in other parts of the country. The hills of Izquatan, Esclavos, and all about Cuajiniquilapa, exhibit extraordinary effects of the earthquakes. The earth has opened in deep rents, the most prominent of which run from S.E. to N.E. This, it will be seen, was the direction of the great earthquake of the 12th June. This shock lasted from ten to fifteen seconds. Some of the shocks have been tremulous, and others oscillating (*sic* in the Spanish). On the 18th June there were four shocks, between 6 A.M. and 4 P.M. The cause of the commotion is imagined to be in the volcanoes of Trocuamburro and Moyato, as it is known that great rocky precipices covered with trees have been thrown down, rivers dried, and roads blocked.

ON the night of the 12th July, in Salvador, Central America, the sky was dusky and overcast, but cleared off after some electric discharges. Next morning, at 4.50, there was an earthquake. This earthquake seems to have been felt in Guatemala on the same day, causing considerable damage in the departments of Santa Rosa and Jutiapa, particularly to farms, but attended with no loss of life.

IN a recent number of *Les Mondes* Dr. A. Boué calls attention to the fact that a great many scientific publications of the northern and easterly parts of Europe remain almost unknown, except in the countries where the languages (Swedish, Danish, Finnish, Lithuanian, Russian, Czech, Slavonic, Magyar, Polish, Neo-Greek, and Roumanian, and even Dutch) in which they are published are spoken. The author suggests that it would be an advantage if, for each of these publications, either a full translation or an abstract of the papers were simultaneously published in French, English, or German.

WE wish to call attention to a circular respecting the proposed Natural History Museum in connection with Clifton College. It is intended that the museum shall be essentially a British one, and contributions to illustrate the natural history and antiquities of our land are invited. We hope to revert to this admirable effort on an early occasion.

WE have received Sydney papers of May 28, containing a report of an interesting lecture delivered before the Royal Society of New South Wales, by the Rev. W. B. Clarke, on the progress of science during the past year in the Australian colonies.

THE Imperial Academy of Sciences of St. Petersburg has issued the first three parts of Vol. XIV. of their Bulletin; the contents are as follows:—Sur le dégagement d'ammoniaque par les champignons, El. Borscow; Quelques observations faites à 'Observatoire de Pekin—Lettre à M. Wild—M. Fritsche; Sur le genre Dinotherium, réuni à la famille des Elephants, et sur la craniologie comparée des genres de cette famille (Extrait), J. F. Brandt; Sur l'acide urinylique, nouveau produit de l'action de l'acide nitreux sur l'acide urique, N. Sokolof; Manuscrits orientaux de la Bibliothèque Impériale Publique, provenant de la succession de M. le Comte Simonitch, B. Dorn; La houille de Malewka; G. v. Helmersen; Appareil servant à fermer les stigmates chez la Blatte (*Periplaneta orientalis*), O. v. Grimm; Influence de la température sur la conductibilité de la chaleur de quelques métaux (Extrait), R. Lenz; Observations faites à l'Observatoire astronomique de l'Académie en 1868, A. Savitch; Recherches embryologiques sur le *Gyrodactylus*, E. Metchnikof; Recherches anatomiques sur les antennes des insectes, O. v. Grimm; Les canaux sémicirculaires du chat (avec une planche), O. v. Grimm; Une rectification de la table des forces élastiques de la vapeur aqueuse de M. Regnault—Lettre à M. Wild—H. Moritz; Etudes faites à l'aide d'un astro-photomètre de M. Zöllner, P. G. Rosén; Manuscrits orientaux achetés par le Musée asiatique de l'Académie aux hérétiers de M. Graf, B. Dorn; Sur une nouvelle construction de mon Polaristrobomètre (Saccharimètre Diabetomètre) (avec une planche), H. Wild; Sur les aurores boréales du 15-16 Avril et du 13-14 Mai, 1869, H. Wild; Sur l'orage magnétique du 15-16 Avril, 1869, H. Wild; Quelques mots sur les Sturionides européens et asiatiques, J. F. Brandt; Nouvelles recherches embryologiques sur le *Bothriocephalus latus*, Dr. Knoch; Sur deux envois de monnaies, reçus au Musée asiatique, B. Dorn; Sur une méthode d'exprimer les perturbations d'une comète au moyen de séries rapidement convergentes, Dr. H. Gyldén; Propositions concernant la réorganisation du système des observations météorologiques en Russie—Rapport d'une commission, nommée par l'Académie; Réapparition de la comète de Winnecke et découverte de nouvelles nébuleuses, O. Struve; Notice sur l'absorption de l'hydrogène par le fer galvanique, M. H. v. Jacobi; Propriétés générales des polyèdres, qui, sous une étendue superficielle donnée, renferment le plus grand volume, L. Lindelöf; Sur les dérivés chlorés du toluol, F. Beilstein et A. Kuhlberg; La coupole de Mélik-el-Aschraf Abou-l-Nassr-Birsbay, M. Mehren; De quelques versions orientales du conte du trésor de Rhampsinite, A. Schiefner; Histoire de la génération des esturgeons—Communication préalable—A. Kowalewsky, Ph. Owsiannikow, et N. Wagner; Histoire de la génération du *Petromyzon fluviatilis*—Communication préalable—Ph. Owsiannikow; Nouvelles acquisitions de monnaies au Musée Asiatique. B. Dorn. From the same energetic and enterprising society we have the first part of Ruprecht's "Flora Caucasi," carrying down as far as Ampelideæ.

FROM *Cosmos* we obtain the information that M. Böttger has produced a new test-paper which is highly sensitive towards the alkalies and alkaline earths. The reagent is a magnificent colouring matter, obtained from the leaves of an exotic plant (*Coleus verschaffelti*), upon digestion for twenty-four hours with absolute alcohol, to which a few drops of sulphuric acid have been added. The paper is prepared for use by the usual process. The colour is a splendid red, which passes more or less rapidly into a fine shade of green, by the action of the alkalies or the alkaline earths. It is far more sensitive than turmeric; it is unaffected by carbonic acid, and will indicate the presence of the least traces of the carbonates of the alkaline earths in water. A moistened strip of the paper, when held at the opening of a gas jet, immediately assumes a green colour, if ammonia be present.

IT is proposed to erect a statue of Harvey, the discoverer of the circulation of the blood, in the Central Park, New York, and large subscriptions have been received for that purpose. It is to be of bronze, of colossal proportions, "representing Harvey at the moment he felt convinced he had made the great discovery that has immortalised his name." Verily the American sculptors have a pleasant task before them. How does a philosopher usually look under such circumstances?

AT a recent auction sale in New York, the finest known copy of "Elliott's Indian Bible" (Cambridge, 1663), printed in the Indian language, was sold for 1,050 dollars, about 210*l*. There is one copy of this celebrated Bible in the British Museum, one in the Island of Nantucket, and a third on Gardiner's Island, or Long Island Sound.

THE second part of Drs. A. and Th. Husemann's "Pflanzenstoffe," the first part of which we reviewed some time since, is still entirely occupied with the vegetable alkalies or bases, the most important treated of being Coniin, Chinin, Cinchonin, Coffein, Strychnin, Atropin, Nicotin, Hyoscyanin, and Veratrin. The third part, completing the work, is promised in September.

M. AUG. DUMERIL publishes, under the title of "Suites à Buffon," a second volume of his "Natural History of Fishes or General Ichthyology," comprising the *Ganoidei*, *Dipnoi*, and *Lophobranchii*, with an accompanying atlas of plates.

PAPERS ON IRON AND STEEL

I.—A VERY COSTLY AND VEXATIOUS FALLACY

II.

THE greatest enemy to steel is phosphorus; one-tenth per cent. is sufficient to produce serious deterioration, and even to render the harder varieties of steel utterly worthless. As our common English pig-iron is made from clay iron-stones, many of the nodules of which contain, as nuclei or otherwise, the remains of fishes and other animal matter, they are exceptionally rich in phosphorus; and thus all the difficulties of steel-making are greatly increased in this country. There are few results in connection with the progress of British industry of which we have better reason to be proud than our pre-eminence as steel-makers, in spite of the greatest natural disadvantages; and this is the more remarkable from the fact that so great a triumph has been gained by illiterate men who have achieved it by following out with a remarkably sound though unaided sagacity the strict method of true Baconian inductive investigation. Whenever I meet a formulating book-stuffed pedant, I love to tell him of the great unconsidered fact, that while the learned men of the middle ages were muddling their intellects with worthless disputations, the artizans of that period were true inductive philosophers, and that the revival of science only commenced when the men of the universities adopted the method which had always been followed by the men of the workshop.

If the men of the universities have outstripped the men of the workshop in recent times, it is simply due to the fact that science has kept systematic record of its achievements, by means of which each worker has the full benefit of the labours of his predecessors and fellow-workers, and is able to start from the point where these left off; whereas the workshop observers and experimentalists have worked with little or no systematic co-operation. If such co-operation only among one set of investigators has done so much, what may we not expect when it shall not only be extended to the other, but when both sections shall co-operate with each other. This technical and scientific co-operation is the great want of the present age. The artizan needs scientific education, and the professors of science have much to learn from the great mass of facts included in the practical experience of the workshop.

But I must not at present be carried further away into this tempting digression, but return to my main subject by anticipating an objection which will probably be made. The manufacture of puddled steel may be supposed to refute all I have said respecting the impracticability of producing steel directly from English pig-iron. If steel fit for the manufacture of files, chisels, &c., could be made from ordinary English pig-iron by this process, all my statements certainly would be refuted, for puddled steel is simply made by checking the oxidation and arresting it at such a point that some of the carbon in the pig-iron shall remain unburnt.

The facts connected with the manufacture of puddled steel which bear upon the present subject, are as follows: First, puddled steel of merchantable quality cannot be made at all from *common* English pig-iron. Second, the manufacture of puddled steel has been much more successful on the Continent than in England. Third, only *mild* steel and that of an inferior quality is made by this process from English iron.

Referring to the first fact, I may mention that there is a great deal of mystery, and there have been a great many failures and much waste of labour, fuel, and iron in carrying out this process in England. In many forges where it has been tried it is now altogether abandoned, and where it is carried on with any degree of success there is usually much secresy maintained. Now the mystery is not in the puddling, as the necessary modifications in the supply of cinder and the working of the damper are well understood, and have been sufficiently explained in the specifications of abandoned patents and otherwise. The secret part of this process is in the selection of the pig-iron, or rather of the "blend" of pig-irons, for it is found that a mixture of certain brands of pig-iron is better than any single brand used alone.

My own experience in connection with this subject has been very interesting, and is, I think, worthy of record. When engaged as chemist in the works of Sir John Brown and Co. of Sheffield, I made careful analyses of all the numerous brands of pig-iron that are used for various purposes in these works. These I tabulated and kept continually before me, in order to compare their composition with the special uses to which they were applied, and the properties which they, or the material made from them, exhibited. The manager of the iron department was a remarkable example of one of those self-taught, unconscious Baconian philosophers I have above alluded to. He has, during many years, been observing, experimenting, and generalising his inductions consisting of a code of original rules for the manufacture of iron suitable for various purposes. Like the man who had talked prose all his life without knowing it, he has been following strictly the injunctions of the "Novum Organon" in discovering the best "blends" of pig-iron for manufacturing respectively armour-plates, rails, boiler-plates, angle irons, &c., &c.; and among his other mysteries were certain blends for making puddled steel. These he calls his "steel-irons." He selected these, like all the others, without having, or pretending to have, any knowledge of their chemical composition.

By quite a different path, *i.e.* upon purely theoretical chemical grounds, I had determined that certain brands among those I had analysed were the best fitted for making puddled steel, and was anxious to verify my theory. To have asked directly for a revelation of the iron manager's secrets would have been unreasonable, and therefore I simply gave him a statement of the analyses of these particular brands all arranged together, and called them "steel-irons," adding that for the best work I supposed that he mixed with them a proportion of a certain foreign brand. "Hush, don't talk so loud; I don't want these fellows to hear you. Who told you that I use these?" was the substance of Mr. Jevons's reply. My theoretical and his practical selection proved to be exactly the same in result. He had selected just those particular pigs which contained the smallest per-centage of phosphorus, and which relatively to their carbon contained the smallest proportion of silicon.

But this was not all. I had just concluded a number of experiments made for the express purpose of determining the function of manganese in the manufacture of iron and steel, and had come to the conclusion that its usefulness depends upon its readily oxidising, even before all the carbon is oxidised, and thereby affording a base with which the silica could unite and form a liquid and readily fusible silicate. Now this is just what is wanted in making puddled steel, and hence I suggested the addition of the highly manganiferous foreign ore. He had recently discovered that it did just what I expected, and supposed that his discovery was quite new. Such, however, was not the case, for this, like so many other trade mysteries, had been independently discovered by a number of other practical investigators.

The foreign manganiferous metal referred to is Spiegeleisen. Dr. Percy says "Spiegeleisen has been found admirably suited for the production of puddled steel of the best quality, and accordingly it is largely used for this purpose." Now spiegeleisen is remarkably free from those impurities which, as I have stated, cannot be removed from common English pig-iron without also taking out the carbon. I find that the average proportion of silicon to carbon in English pigs is about three-fourths; in spiegeleisen it is below one-fourth, and that the average proportion of phosphorus in the samples of spiegeleisen which I have analysed, is less than one-twentieth of the quantity contained in our Cleveland pigs. Three, four, and five hundredths per cent. is the quantity I ordinarily find in good German or Swedish spiegeleisen. The sulphur seldom exceeds one-tenth per cent., and the large quantity of manganese materially assists in the removal of the silicon. It is, in fact, very similar to the Styrian cast-iron, which, as I have already said, does not present the English difficulty of making steel by the direct process. Both are charcoal-irons, made from remarkably rich and pure ores. The manufacture of cast-iron from such ores, and steel from such cast-iron is mere child's-play compared with our native manufacture.

In reference to the second fact that the manufacture of puddled steel has been carried out more successfully on the Continent than in England, I need only say that this confirms my statements, as the puddlers there are less skilful than ours, and their raw material is a vastly superior charcoal-iron, such as I have already described.

The third fact, viz.: that only *mild* steel of inferior quality is made by this process, is further confirmation of what I have said respecting the necessity of removing the carbon from common pig-iron in order to purify it sufficiently to produce good steel; for even with all this skilful selection of the purest pigs, and the mixing of spiegeleisen with them, it is found in this country impracticable to make puddled steel containing more than one-half per cent. of carbon. Such steel is only fit for rails, tyres, for rubbish cutlery, and other purposes where a very soft steel, or rather steely iron, is used. If the puddling were stopped when the carbon was only reduced to about 1·75, or say 1·5 per cent. (the quantity contained in the best hard cast-steel), the puddled steel would be utterly rotten, it would crush under the hammer whether hot or cold; the reason of this being that even with the best English pigs, the selected "steel-irons," there would, with this amount of carbon, still retain a ruinous proportion of silicon, phosphorus, &c. It is necessary with all available advantages to bring down the carbon to within one half per cent. in order to produce a workable material. Even then it is worth only about one third of the price of good cast-steel.

I might illustrate this subject still further by entering into the details of the chemistry of the Bessemer process and of Bessemer steel, by the history of the nitrate of soda process, and of other attempts to manufacture steel directly from cast-iron; but I think the above is sufficient to expose the fundamental fallacy upon which all such attempts have been founded. I hope to have succeeded more particularly in demonstrating the very great error of those who, in their attempts to make such steel, have, like the friend of my correspondent whose letter opens this paper, deliberately chosen cinder-pig or other inferior iron upon which to make their demonstrative experiments. This was the case with the Heaton Company. They worked for a long time at Langley Mill with one of the worst classes of pig-iron they could have selected for their purpose. I pointed this out to them in a letter printed in the *Chemical News* of February 19, 1869. This effort, the most promising of any of the kind, on account of the action of the residual alkaline soda, was, through this serious mistake, never fairly tested. I witnessed some of their experiments, and analysed and otherwise tested the results. There can be little doubt that with properly selected pigs a material similar to puddled or Bessemer steel, may be made by this process, and by several others that have been tried and have failed; but with the common classes of English pig-irons, all such attempts to make steel directly by the partial oxidation of the carbon must of necessity fail, unless some entirely new, some hitherto utterly unknown method of removing the silicon, phosphorus, and sulphur of the pig-iron is also used. In such a case the novelty, the invention, the triumph, would consist not in the decarburisation of the cast-iron, but in the separation of the other ingredients.

I therefore recommend all inventors who seek to simplify or otherwise improve the manufacture of steel, to direct their attention first to the removal of phosphorus, next to the removal of silicon, thirdly to the removal of sulphur, and last and least of all to mere decarburisation, for that is a problem of the utmost simplicity, and already sufficiently understood.

My next paper will be "On the Chemistry of the Bessemer Process," and will include some original observations, the results of which I believe to be of considerable value to the numerous manufacturers who are now erecting or working Bessemer plant. W. MATTIEU WILLIAMS

SCIENTIFIC SERIALS

POGGENDORFF'S *Annalen der Physik und Chemie*, vol. cxl., part 2.—This number of Poggendorff's *Annalen* contains (1) the conclusion of Ketteler's paper on the theory of Chromatic Dispersion. (2.) The conclusion of Sondhaus's paper on the "tones of heated tubes, and on the vibrations of air in organ-pipes of various shapes." In this part the author compares his formula with Wertheim's experimental results, and shows that in most cases the agreement between them is very close. (3.) The conclusion of Freese's paper on chromates. (4.) "On the work done by gases in motion," by L. Boltzmann. In the first volume of the *Annalen* for 1869 (vol. cxxxvi.), a method of determining the specific heat of air under constant volume is described by F. Kohlrausch, the method consisting essentially in observing the cooling effect indicated by a delicate metallic thermometer enclosed in the receiver of an air-pump when the piston is raised. A few months afterwards (Pogg. *Annalen*, vol. cxxxviii.) Kohlrausch's experiments were criticised by A. Kurz, who objected to them that when the air in the receiver of a pump is expanded by drawing up the piston, it does no work; and that, therefore, theoretically, its temperature ought not to fall. This is of course an obvious blunder; and Boltzmann shows, by a strict mathematical discussion of the experiment, that although the pressure of the air against the piston, and therefore the work done by it, is not quite so great when the piston is raised quickly, as it would be if the movement were indefinitely slow, yet the difference is only a quantity of the same order as the ratio of the velocity of the piston to the velocity of sound, and therefore cannot have perceptibly affected Kohlrausch's results. (5.) "Calculation of the vibrations of a string, taking account of its rigidity," by R. Hoppe. (6.) "On asterism and corrosion-figures in crystals," by H. Baumhauer. (7.) "Comparison of the electrophorus with the electrical machine and the electrophorus-machine," by P. Riess. This paper contains some interesting historical notices of early electrical machines, both frictional and such as acted by induction, but we cannot see that it is of any importance as a contribution to the theory of electrical machines. (8.) "On the velocity of molecular motion and that of sound in gases," by E. Mulder. The author seeks to establish a relation between the velocity of sound in a gas and the mean velocity of translation of its molecules, as deduced by Clausius from the dynamical theory of heat. (9.) "On the production of stationary vibrations and sound-figures in liquidsand gases by solid sounding plates," by A. Kundt. (10.) "On elastic vibrations," by J. J. Müller. By a modification of Kundt's method of measuring the wave-lengths of vibrating columns of air, the author has succeeded in proving that the velocity of propagation of vibrations of great amplitude is perceptibly greater than that of vibrations of small amplitude, both in the case of columns of air and of elastic rods. (11.) "On Leclanché's Manganese battery," by J. Müller. The author finds that polarisation occurs to a considerable extent in galvanic cells of Leclanché's construction when they are employed in a circuit of small resistance, so that under these circumstances he found the electro-motive force of a Leclanché's cell to be only 0·896 of that of a Daniell's cell, whereas, according to Leclanché, it is equal to 1·38 times the electro-motive force of a Daniell's cell. (12.) "On the occurrence of augite-material in meteorites," by C. Rammelsberg. (13.) "On the Lodran meteorite," by G. Tschermak. (14.) "On acoustic attraction and repulsion," by K. H. Schellbach. Additional facts, but as yet no explanation of these curious phenomena. According to the author, the attraction of light bodies by a vibrating tuning-fork was observed and described by Guyot in 1834. (15.) "On the maximum-density and freezing point of mixtures of alcohol and water," by F. Rossetti. This is a short extract from the author's researches on the expansion of water and certain solutions, published in greater detail in the *Annales de Chimie et de Physique* for 1867 and 1869 (vols. x. and xv.). (16.) "A Method of Examining the Structure of Flames," by L. Dufour. The flame is cut across horizontally by a flat lamellar jet of water or of air, and can then be examined at leisure by looking down into it from above. (17.) "Remarks on the colour of iodine," by Carl Schultz-Sellack. The author calls attention to the different colour of iodine in the solid state, or when dissolved in water, alcohol, &c., from that which it shows in the state of vapour, or when dissolved in sulphide of carbon, stannic chloride &c., iodine transmitting in the former case chiefly the extreme red rays of the visible spectrum, and, in the latter case, chiefly the blue and violet rays. He argues that this difference of absorptive character between solid or liquid and gaseous iodine is analogous to the difference which exists, according to Magnus, between the absorptive action of liquid and gaseous water on invisible heat-rays. (18.) Prof. Nordenskiöld announces the discovery of *platinum* as well as gold in the sand of the river Ivalo in North Lapland. (19.) The genuine character of the diamond lately found in Bohemia has been proved by Prof Schafarik by burning a portion of it in oxygen.

Journal of the Chemical Society, July and August, 1870.—The whole of the July number and 22 pages of the August number of this periodical are occupied by the continuation of the very elaborate and exhaustive paper by Dr. Divers on the combinations of carbonic anhydride with water and ammonia. The half acid ammonium carbonate which was previously considered to be represented by the formula $(CO_2)_3\ (OH_2)_5\ (NH_3)_4$ is found by Dr. Divers to contain $(CO_2)_3\ (OH_2)_4\ (NH_3)_4$; when exposed to the air it loses water and ammonia, being transformed into the acid carbonate $CO_2\ OH_2\ NH_3$, of which 8 modes of preparation are described. Another compound obtained in an impure condition by Rose, is considered by the author to have the composition $(CO_2)_5\ (OH_2)_4\ (NH_3)_4$. He also thinks it probable that the orthocarbonate $CO_2\ (OH_2)_2\ (NH_3)_4$ or $CO_4\ (NH_4)_4$ exists. The modes of preparation and properties of ammonium carbamate $CO_2\ (NH_3)_2$ are fully described. The formula attributed to the commercial carbonate of ammonia is $(CO_2)_2\ OH_2\ (NH_3)_3$. The whole of this memoir bears evidence of most careful research and perseverance; the history of the compounds mentioned is traced out; the modes of preparation and properties are carefully described, and very numerous analyses have been made in order to ascertain their composition. Mr. Charles Griffin describes a new gas furnace for chemical operations at a white heat, which does not require a blowing machine. The gas is supplied to this furnace through a bundle of 16 Bunsen's burners, the upper ends of which are surrounded by a metal jacket fitting into a perforated clay plate supported on a tripod. When large crucibles are to be employed, a plumbago cylinder open at both ends and pierced with holes is placed on the clay plate, the conical crucible being supported by the upper end of the cylinder. The crucible and plumbago cylinder are surrounded by a fireclay cylinder resting on three bronze pennies placed on the lower plate. The cylinder is closed at the top by a clay plate, through which a flue is so made that the current of spent gases is bent twice at right angles before escaping into the sheet-iron chimney; the object of this flue is to check the stream of gas which would otherwise be so great as to cool the furnace very considerably. When small crucibles have to be heated, they must be supported on a grate consisting of a clay plate with a cusped aperture. By means of this furnace, ingots of cast iron 4lbs. in weight have been fused in 2½ hours, starting with a cold furnace; when the furnace is hot, 5lbs. could be fused in the same time; the quantity of gas used is 33 cubic feet per hour. The cylindrical body of the furnace may be replaced by one of an oval shape, and containing a muffle in which many operations may be performed, the temperature inside the muffle being sufficiently elevated to fuse silver, gold, and copper. The remainder of the August number is devoted to the proceedings of the society during the session of 1869-70, and a report of the anniversary meeting held on March 30, the latter including the President's address and obituaries of Mr. Brayley, F.R.S., Dr. Graham, F.R.S., Mr. A. B. Northcote, M.A., Dr. Penny, F.R.S.E., and of the late foreign members, Drs. Erdmann and Redtenbacher. These are followed by the list of papers read during the year; the balance-sheet, which shows the society to be in a prosperous condition; and the donations to the library.

SOCIETIES AND ACADEMIES

New Zealand

Wellington Philosophical Society, June 25.—W. B. D. Mantell, F.G.S., president, in his address, directed attention to the large additions made during the past year to the collection of fossil Reptilian remains in the Museum by the officers of the Geological Survey. Several genera are represented, but owing to the nature of the matrix, which exceeds in hardness the most refractory of the "Tilgate" beds, their development will be a work of great difficulty.—Walter Buller, F.L.S., exhibited and described a specimen of the now almost extinct New Zealand Rat or Kiori—in former days a highly valued article of food among the natives, and pointed out its striking resemblance to the ancient black rat of Britain.—T. H. Potts exhibited chicks a few days old of *Anarhynchus frontalis*, showing the characteristic crooked bill, and also the eggs and manner of nidification, along with those of *Charadrius bicinctus*; completely establishing the marked difference between the two birds.—W. T. L. Travers, F.L.S., gave an account of the habits of the Crested Grebe in New Zealand. He has reason to think that they pair for life, and stated that they make additions to the height of their nests, as inundation takes place, but that the eggs will retain their vitality though immersed in water for a considerable time, and inferred that this might have some connection with the coloured mucous layer with which the shell becomes coated during incubation.—Dr. Hector said he had found the nest containing eggs in a tidal lagoon, where it must have risen and fallen with the tide. The eggs were not discoloured. He also exhibited a dusky variety of the bird along with its chick, which is only found on unfrequented inland lakes.—Dr. F. J. Knox exhibited sections of the teeth of a *two-toothed Berardius*, and showed that, from the high state of development, they are not rudimentary as has been surmised, and yet they never appear to protrude through the gum.—John Buchanan exhibited a hybrid between the Australian *Acæna ovina*, which has been lately introduced with imported cattle, and the New Zealand *Acæna sanguisorbæ*.—Dr. Hector, F.R.S., called attention to the practical importance of knowing what fish belonging to the Salmonidæ are found in the New Zealand streams, as the English trout is being rapidly introduced throughout the country. Only one species, *Retropinna richardsonii* (the New Zealand smelt), is mentioned in the latest works as being found in New Zealand; but he exhibited in addition two very distinct forms, one having the same general character as that fish, but with dentition and form of head of an *Osmerus*. The third form is easily distinguished by its small head, forward position of the dorsal fin, small soft mouth devoid of teeth except a feeble row along the upper jaw. It is the common Opokororo of the natives, and grows to a very considerable size in some of the rivers and lakes. He also exhibited drawings of a specimen of *Scopelus* which he had obtained in Milford Sound, as a fourth fish related to the Salmonidæ.

Paris

Academy of Sciences, Aug. 22.—A note was read by General Morin on the first session of the international metric commission, held from the 8th to the 13th of August.—A letter was presented by Professor Newcomb of Washington to M. Delaunay on irregularities in the moon's motion due to the influence of the planets.—A note was read from M. Laranja e Oliveira on a remarkable atmospheric electric shock experienced at Porto-Alegre, Brazil, on June 9th.—M. Chapelas reported his observations on the August shooting-stars. He remarked that the year has been distinguished by a smaller number of shooting-stars than has been known for a long period. The periodic display commenced in the last days of July, but the determination of its maximum presented great difficulty, both from the almost constantly clouded condition of the sky, and from the moon being at her full. During the night of the 10th, in which there was an hour and a half favourable for observation, with an average clear sky amounting to 0·6, forty-six shooting stars were observed, among which were two meteors of the third magnitude. Their mean direction was (as is generally the case, and especially at that hour, $10^h\ 15^m$ to $11^h\ 45^m$) from

N.E. to N.N.E. The point of radiation was very difficult to determine owing to the small number of meteors. The constellations in which most appeared were Perseus, Cassiopeia, Camelopardus, and Aquila. Correcting the number observed for the influence of the moon, we get a mean at midnight of fifty-six shooting-stars per hour in a clear sky, or three more than last year; so that the phenomenon may be considered stationary. At 1 A.M. the sky was completely obscured, and the exact hour of maximum cannot be indicated; but during the time observed the phenomenon proceeded at the rate of ·6 stars per minute.—M. d'Avezac presented, in the name of the author, Don Salvador Clavijo, a general in the Spanish army, resident at the Canaries, a work entitled *Reflexiones sobrè el sistema planetario*, on the rotation on their axis of the bodies comprising the solar system, planets and comets.

Berlin

German Chemical Society, July 25.—M. Küchenmeister has obtained two different naphthoic acids corresponding to the two naphthols, by treating the two naphthylsulphates with cyanide of potassium and the cyanides with potash. One of the acids melts at 217°, the other at 230°.—C. Gräbe has continued his researches on the higher hydrocarbons of coal tar. After treating them with sulphide of carbon, which dissolves chrysen, there remains an impure substance which, when acted on by picric acid, forms a combination crystallising from alcohol in red needles. Decomposed with ammonia, they leave white scales of *pyrrhen*. To this hydrocarbon Laurent allotted the formula $C_{15} H_{12}$. Gräbe's determinations lead to the formula $C_{16}\ H_{10}$, borne out by the picrate $C_{16}\ H_{10}.\ C_6\ H_2\ (NO_2)_3\ OH$. Oxidation with bichromate of potassium and acetic acid yields the chinone $C_{16}\ H_8\ O_2$, from which zinc separates the hydrocarbon $C_{16}\ H_8$. The nitro-compound $C_{16} H_9\ (NO_2)$, and the two bromides in which two and three atoms of bromine take the place of hydrogen, have also been investigated. The author considers his hydrocarbon as phenylen naphthalin, $C_{16}\ H_{10} = C_{10}\ H_8 + C_6\ H_6 - H_4$.—Messrs. Gräbe and Caro have investigated the base contained in impure anthracene, to which, on account of its action on the mucous membrane, they have given the name of acridine. To obtain its sulphate, the impure hydrocarbon is treated with sulphuric acid, and some bichromate of potassium added to the filtrate. It shows a blue fluorescence, and its composition corresponds to the formula $C_{12}\ H_9\ N$, or a multiple of it.—M. Hofmeister publishes researches on phenylic ether and diphenylenic oxide. The former body is obtained by treating sulphate of diazobenzol with phenol, adding potash and distilling the insoluble residue, or by heating together sulphate of aniline, phenol, and nitric acid. It melts at 28°, distils at 240°, is not attacked by zinc, yields with PCl_5 a chloride (not yet analysed), and with sulphuric acid a conjugated acid $(C_6 H\ S_4O_4\ H)_2\ O$.—Lesimple has described a body obtained by distilling phosphate of phenyl, under the name of phenylic ether, ascribing to it the melting point 80° and the boiling point 273°. Hofmeister proves the real formula of this body to be not $(C_6\ H_5)_2\ O$ but $(C_6\ H_4)_2\ O$.—M. Beer has transformed benzophenon $(C_6\ H_5)_2\ CO$ into the chloride $(C_6\ H_5)_2\ C\ Cl_2$, and this by finely divided silver into the hydrocarbon $(C_6\ H_5)_2\ C = C\ (C_6\ H_5)_2$ tetra-phenylated ethylene. Products of substitution have been formed with NO_4, HSO_3 and Br. The bromide has the composition $C_{26}\ H_{17}\ Br_5$.—M. Schöne has obtained a combination of peroxide of barium and peroxide of hydrogen. This compound $Ba \left\{ \begin{array}{l} -O-OH \\ -O-OH \end{array} \right.$ is formed by mixing peroxide of barium with a solution of ½ per cent. of peroxide of hydrogen in water. At 10° it forms colourless monoclinohedric crystals resembling heavy-spar. At ordinary temperatures it becomes yellow, and yields water, oxygen, and peroxide of barium. This explains why alkaline solutions of peroxide of hydrogen are unstable.—V. Meyer communicated his views on the constitution of gallic acid.—Professor Hofmann then rose to report in his name and that of several of his pupils on the following researches partly unfinished, the war having called assistants and pupils from the laboratory into the field.—M. Bischoff, passing chlorine through an alcoholic solution of prussic acid, has obtained two crystalline substances $C_8\ H_{14}\ Cl_2\ N_2\ O_4$, already obtained by Stenhouse, and a new body $C_8\ H_{15}\ Cl\ N_2\ O_4$. Treated with acids or alkalis, they yield carbonic acid, ammonia, hydrochloric acid, and also ethylenic ammonia and a brown substance probably containing very complicated bases.—M. Melens, by treating acrolein with cyanic acid, has transformed it into a kind of trigenic acid.—M. Judson has transformed crotonchloral by oxidation into trichlorocrotonic acid and the salts and ethers of the same. The silver-salt boiled with water yields carbonic and hydrochloric acids, and the chloride $C_3H_2Cl_2$, identical or isomeric with chlorinated allylene. This body can also be obtained by treating crotonic chloral with alkalis. By treating the chloral with perchloride of phosphorus, O is replaced by Cl_2, hydrochloric acid being eliminated at the same time: $C_4\ H_3\ Cl_3\ Cl_2 - H\ Cl = C_4\ H_2\ Cl_4$.—M. Reimer has studied the butylamines. The bromide of tetrabutylamine can not be obtained. It yields at once butylene and hydrobromide of tributylamine.—M. Reiss has prepared butyl-benzol and butyl-anisol.—Professor A. W. Hofmann reported on his protracted researches on the green colouring substance obtained from rosaniline by the action of aldehyde and hyposulphite of sodium. Not forming any combinations and not crystallising, this substance could only be purified by frequent solution and reprecipitation. Numerous analyses lead to the formula $C_{22}\ H_{27}\ N_3\ S_2\ O$ corresponding to one molecule of rosaniline, one of aldehyde, and two of hydrosulphuric acid combined. Rosaniline treated with hyposulphite without the intervention of aldehyde yields a similar product from which acids reproduce rosaniline.—The same chemist, in treating bromide of ethylene with ammonia, has observed the formation of an insoluble white amorphous powder, exhibiting the strange property of absorbing large masses of water and swelling up to a voluminous gelatine. The substance (probably a mixture) corresponds to the formula $\left. \begin{array}{c} (C_2\ H_4)_4 \\ H \end{array} \right\} N_3$ combined with H Br, $H_2\ Br_2$ or $H_3\ Br_3$. But triamines being soluble, it is very likely that the formula should be multiplied.—The same chemist, when preparing cyaniline 25 years ago, observed that the mother-liquor treated with hydrochloric acid, yields dark red crystals. He has at last succeeded in purifying them, and establishing their formula $= C_{21}\ H_{17}\ N_5$. HCl—a triphenylated guanidine $N_3.\ C^{iv}.\ (C_6\ H_5)_3\ H_2$, in which two molecules of cyanogen have combined with two molecules of phenyl. If, however, triphenylated guanidine is treated with cyanogen, a body is formed of exactly the same composition, but of very different properties. The latter is colourless, and is transformed by acids into aniline, carbonic oxide, hydrogen, diphenyl oxamide, and diphenylated parabanic acid; whereas the former, when treated with acids, yields aniline, oxalic acid, and ammonia.—The same chemist has studied the action of triethyl phosphine on cyanate of phenyl, and found the resulting body to be not a cyanurate, but a new substance combining with alcohols, ammonia, &c.—A. Baeyer reported on some further derivatives of mellitic acid.—Mesohydro mellitic acid appears to be the first aldehyde of hydromellitic acid, and derives from it by the action of sulphuric acid and bromine. It is tetrabasic and beautifully crystallised. Only one acid is now wanting to complete the series, beginning with benzoic and ending with mellitic acid. The clue to obtain this acid appears to have been found. The same chemist has obtained a derivative from tetrahydrophthalic acid, which appears to be quinic acid.—Professor Rammelsberg then concluded the meeting by expressing his fervent hopes that a speedy victory of the German arms would allow all members of the society to resume their peaceful pursuits before the reassembling of the society in October.

New York

Lyceum of Natural History, April 4.—The President in the chair.—Dr. J. S. Newberry "On the Earliest Traces of Man found in North America." Dr. Newberry stated that the human relics for which the highest antiquity had been claimed were the Natchez bone and Table Mountain (California) skull. If it could be shown beyond question, that these bones really occurred in the positions to which they have been referred, we should have evidence that man existed on this continent as a contemporary with the mammoth, mastodon, and other extinct mammals, and at a period so remote that all the topographical features of the surface have since changed—in the case of Table Mountain the bottom of a valley having become a mountain summit. As regards the Natchez bone, geological changes have been effected since the date assigned it, which, in Sir Charles Lyell's judgment, must have required a hundred thousand years. In neither of these instances were the human remains actually found by credible persons in strata of high antiquity, and no dependence whatever can be placed upon inferences made from this material in the solution of the question of the antiquity of man. We may to-morrow obtain indubitable evidence of the occurrence of the remains of man in the Table Mountain tertiaries and the Vicksburg bluff; but until such evidence be discovered we must discuss the question leaving these hypothetical cases entirely out of view. No solid and enduring scientific fabric can be reared on doubtful premises. The caves of our country have as yet scarcely been entered upon as ground for archæological research. But one cavern has been examined with any care, that of Carlisle, Pa., by Professor Baird—and this may be said to have been but partially explored. Human remains were found in it, but not of special interest. The fauna represented by the great number of bones collected there, is essentially the same with that which occupied the country on the advent of the whites. This remarkable fact, however, is reported by Professor Baird, that all the species represented in the collections made in the Carlisle cave, have degenerated in size, and this modern degeneracy ranges from ten to twenty-five per cent. The shell mounds on the Atlantic coast, north and south, have been partially investigated by Prof. Wyman, Prof. Baird, and others. In these mounds human remains are constantly met with, but none which can serve as proof of great antiquity. Perhaps the best evidence that these shell mounds are of ancient date, is furnished by the facts reported by Prof. Baird, that those of Maine contain the bones of the great Auk (*Alca impennis*) and those of the walrus. Of these the first is supposed to be entirely extinct, and both in modern times have been confined to higher latitudes. The mounds of the western states, the copper mines of Lake Superior, the old oil wells of Pennsylvania, and the lead mines of Kentucky, really afford us the only traces of human occupation yet found within our territory which have a respectable antiquity, and one which can be measured even negatively in years. All these traces of the ancient semi-civilised people that once inhabited the Mississippi valley, are found overgrown by what we term the "primeval forest," in which are trees five hundred years old; and these trees, in some instances, are growing on the prostrate trunks of individuals of equal size, belonging to a preceding generation. This, then, is the record. We can positively assert that the works of the mound builders were abandoned and overgrown by forests a thousand years ago; how much before that time we have no means of knowing. We may fairly infer that some hundreds of years were consumed in the multiplication of this ancient people, in their spread over and subjugation of the country they occupied, in the substitution of cultivated farms for the pre-existent forest, in the construction of towns so numerous as to thickly dot all the surface, in the thorough exploration and extensive working of the mineral districts and oil fields, in the acquisition of the degree of civilisation they attained, in their gradual reduction in numbers to their total extinction. In New Mexico, Mexico, Central America, and Peru, we have countless monuments of a civilisation generically the same throughout this great area, and a civilisation which was indigenous to America. For the rise, culmination and decline of this civilisation—for it was in its decadence when Columbus first discovered America—we must allow two thousand or three thousand years. Perhaps they occupied much more time than this; but all these changes could hardly have been effected in less than two thousand years. Whether there was any relationship between the ancient Mexicans and the mound-builders is a question yet to be decided. They had this in common, that both were sedentary and agricultural; were miners and builders. But the Mexicans and the Incarial race were famous masons, and built huge structures of dressed stone which scarcely suffer in comparison with our finest architectural monuments. The mound-builders, on the contrary, build in earth and wood, and the structures they raised have little in common, so far as plan is concerned, with those of the southern nations. No geographical connection has been traced between these ancient civilisations. The one seems to have been strictly confined to the Valley of the Mississippi, the other to the high table lands lying between the Rocky Mountains and the Sierra Nevada. In answer to inquiries, Prof. Newberry stated that the inscriptions which covered the monuments of Central America and Peru, like the arrowhead characters of Assyria, and the hieroglyphics of Egypt, were destined to be read. Indeed, it might be said that many of these inscriptions could now be read. But little was to be expected, however, in the way of historical facts, from a perfect translation of all these records. They were apparently, for the most part, local and personal in character, and like the Egyptian and Assyrian records, consisted mostly of religious invocations, laudation of persons, or celebrations of local and temporary political triumphs, which to us have no special significance or value. The mining operations of our ancient Americans were so extensive, that most of the important deposits of copper on Lake Superior had been not only discovered, but worked by them. The working of the oil wells by the mound-builders had not perhaps been noticed by others, but Prof. Newberry asserted it from observations he had himself made. On the bottom lands of Oil Creek, below Titusville, he had, in 1860, noticed that the ground in the primeval forest was pitted in a peculiar way, the pits two or three feet deep, eight or ten feet in diameter, and almost contiguous. These were proved (by excavations made preparatory to boring oil wells) to be the remains of ancient wells or pits sunk in the alluvial clay. One of these, opened to the depth of twenty-seven feet, was cribbed up with timber, and contained a ladder like those found in the ancient mines of Lake Superior, formed from the trunk of a tree on which branches were left projecting six or eight inches. Prof. Newberry had subsequently seen similar pits to these, around the oil springs of Mecca and Grafton, Ohio, and at Enniskillen, Canada West. In the latter locality, a modern oil well cut into the circumference of an ancient one, and this was found to be filled with sticks and rubbish. A pair of deer's horns were taken out thirty-six feet below the surface. The lead vein in Kentucky, to which reference had been made, had been worked by an open cut several hundred yards in length. This was now a ditch some feet in depth, with a ridge of material thrown out on either side, the whole was covered by forest, and trees three feet in diameter were growing upon the ridges of rejected rubbish.

April 11.—The president in the chair. Mr. O. Loew "On Hydrogenium-Amalgam." He showed that when zinc-amalgam is agitated with a weak solution of bi-chloride of platinum, a spongy mass forms upon the surface of the zinc-amalgam, having buttery consistence, and strongly resembling in physical characters, the well-known ammonium-amalgam. This body he considers to be an amalgam of hydrogenium and mercury. To prepare it on a large scale, he shakes thoroughly zinc amalgam, containing three per cent. of zinc, with an equal volume of a solution of bi-chloride of platinum, containing ten per cent. of the salt. The mass becomes warm, and must be cooled from time to time, by plunging the flask, in which the reaction is carried on, into cold water, and also takes on a black colour from the finely divided platinum which is reduced. The mixture is then thrown into moderately dilute hydrochloric acid, by which the excess of zinc and oxychloride formed is dissolved. Unless thus treated, the amalgam is rapidly decomposed with evolution of hydrogen. The platinum is, for the most part, removed with the excess of mercury. The body thus prepared, has the consistency and appearance of ammonium-amalgam as obtained by acting upon an ammonium salt with sodium amalgam. At ordinary temperatures, several days are required for its complete decomposition. It possesses the marked reducing power peculiar to hydrogenium, reducing ferricyanides to ferrocyanides, per salts of iron to proto salts, decolourising permanganate of potassium, &c. This hydrogenium-amalgam also absorbs ammonia, and the resulting body resembles ammonium-amalgam as otherwise obtained. Since Graham compared hydrogenium with the active modification of oxygen, Mr. Loew proposed to consider the following series as parallel:—

Antozone.	Common Oxygen.	Ozone.
Nascent Hydrogen.	Common Hydrogen.	Hydrogenium.

And he further suggests the representing of these three states of hydrogen, by formulæ in the following manner,

[H]	[H H]	[H H] H
Nascent Hydrogen.	Common Hydrogen.	Hydrogenium.

He performed the experiment as described, in a most satisfactory manner, producing a large mass of the supposed hydrogenium-amalgam. The reading of this paper elicited considerable discussion. Dr. I. Walz, spoke in high terms of Mr. Loew's ingenious experiment, but opposed his theoretical views; especially the comparison of nascent hydrogen and antozone, the existence of which he denied. He exhibited the action of bi-chromate of potassium and zinc-amalgam when shaken together, whereby the former is reduced, and apparently a compound of hydrogenium and mercury obtained, which differed in characters somewhat from that exhibited by Mr. Loew. Prof. C. A. Joy referred to the experiments of Schönbein, which conclusively prove, he considered, the existence of Antozone. Schönbein agitated zinc-amalgam with water, and examined the solution obtained. This did not act upon iodide of potassium and starch, until a trace of a proto-salt of iron was added, when immediately the blue colour of iodide of starch appeared. The use of bi-chloride of platinum for assisting the evolution of hydrogen, originated with De la Rive. He thought that Mr. Loew had gone a step farther than either Schönbein or Graham in this most important discovery.

April 18.—The president in the chair. The president made some remarks on the metalliferous deposits of the West, stating it as his opinion, that the production of gold had passed its climax; giving his reasons for so believing. Gold is found disseminated over vast regions in the West; the accumulations in the placers having been worked for ages. He then entered into a description of the manner in which the accumulation of metal had taken place. There is still plenty of gold everywhere, but it is very difficult to separate it from the associated rock in which it is embedded. Those deposits where it could be readily procured, are beginning to be exhausted. The mountain system of the West, cnsidered with respect to the mineral wealth of that portion of the country, he considered divisible into belts, the westernmost or coast range producing mercury, the next eastward or Sierra Nevada Range, is very rich in gold. In the Rocky Mountains, the gold is associated with copper and iron pyrites. In Montana, the gold-bearing veins are extremely rich in that metal, but very difficult to work. Between the Rocky Mountains and the Sierra Nevada, there occurs an argentiferous belt stretching through Idaho, Nevada and Montana; it is in this region that the celebrated Comstock Lode is situated, which, up to the present time, has yielded 75,000,000 dollars. The agricultural portions of California, and the region eastward of the mountains, is of little value except for its mineral wealth, and, if it ever becomes important, it will be by the development of these deposits.

April 25.—The president in the chair. Prof. A. M. Edwards read a paper "On the presence of living insects in the human body," showing that several such cases were on record. In one case a fly had been reared from a larva ejected from the human intestines. As such larva are found mostly in decayed fruit, the plan to be followed for preventing the unpleasant results sometimes, although not always, arising from the introduction of such insects by the mouth, is to avoid eating such fruit or vegetables in a raw condition as are at all decayed.

May 2.—The president in the chair. Prof. A. M. Edwards read a "Report upon a specimen of *Anemone nemorosa* infested by a fungus." This fungus is a species quite common both in this country and Europe, upon the true leaves of the Anemone in early spring, and has been named *Puccinia anemones*. In Ray's "Synopsis" (Third Edition, 1724) it is described in company with true ferns, and it was for a long time supposed that the deeply cleft leaf of the Anemone, with the brown spots upon its under side, was a fern with sori. As Ray says, "this capillary was gathered by the Conjurer of Chalgrave," hence it has come to be known as the Conjurer of Chalgrave's fern. This fungus, like the other microscopic parasitic ones, grows beneath the surface of the plant, throwing out its threads of mycelium among the cells, until it develops the brownish coloured bodies, known as spores (perhaps incorrectly), and it is by the peculiar characters of these that species have been distinguished, although there seem two good reasons for supposing that these plants are not only dimorphous, as has been stated, but polymorphous, assuming different forms according to the habitat in which they are found. In reply to the question as to whether it was true, as was stated by farmers, that barberry bushes infested with fungus or mildew, conveyed that mildew to fields of wheat adjoining, which then showed the presence of "brand," Prof. Edwards remarked that such might very likely be the case, as very little certain is known respecting the life history of these minute plants, and he was now carrying on some experiments, by infesting different plants with fungi taken from others, so as to see if the host which they inhabited modified their characters materially. He described and illustrated, by means of diagrams, the characteristics of the wheat brand, *Puccinia graminis*, and other fungi, and expressed a hope that the botanical members would contribute specimens of such plants as they found to be infested by mildews, brands, and smuts, for the Society's collection.—The President made some remarks on the existence of human remains in caves in this country, in continuation of his communication at a recent meeting. He alluded to the well-known cave at Carlisle, Penn., which has been very carefully searched by Prof. Baird, of the Smithsonian Institution, whose investigations would be, it was hoped, shortly published. Besides the human remains there were found many of various mammals identical specifically with those now or lately living in the vicinity. But one remarkable fact had been developed—viz., that in every case they were at least one quarter larger in dimensions, so that these particular animals at least would seem to have degenerated in size during the lapse of time. Thus, for instance, numerous remains of foxes were found, having characters identical with those now living with the exception of the size. Prof. Shaler's explorations at Big Bone Lick recently, had also brought to light facts of great interest, which showed that the deer and buffalo were comparatively new comers upon this portion of the continent. He (Dr. Newberry) had found the bones of a buffalo on the west side of the Rocky Mountains, although they were not to be seen living there at the present time. The Indians of that district had traditions of the buffalo existing there at a recent period, all of which illustrated the change of fauna which had been for a long time and still was taking place upon this continent.—Prof. O. W. Morris read an "Abstract of the comparative meteorology of the month of March, for the years 1869 and 1870, and of the month of April, 1870," showing that in 1869 the lowest daily mean for March was 13·76°, and for 1870 it was 24·80°, or 11·04° higher. The mean temperature for March 1869 was 34·10°, and for 1870 it was 35·55°, or 1·45° warmer. The mean of the barometer for March 1869 was 29·834 in., and for 1870 it was 29·772 in. The mean humidity for March 1869 was 49·50°, and for 1870 it was 54·85°. The month of March 1870 was thus shown to be warmer than in 1869, the barometric pressure was a little less, and the humidity greater, although there was not so much rain. March 1870 kept up its old reputation as the "windy month." He also quoted from tables, prepared to show some other important facts in meteorology. Thus, examination of the records kept for the last sixteen years (1854-69, both inclusive), shows that the temperature during that time did not vary much, as the mean for the sixteen years is 52·60°, giving eight above and eight below the mean, and a range of 7° only, 1859 having the highest mean (55·66°) and 1868 the lowest (48·67°). The year 1869 was 1·1° below the average; the maximum of 1869 was nearly that of 1855; the minimum was greater than that of any in the series, being 85° above zero, while nine of the years it was below, and in 1866 it was 13° below, and in that year also the thermometer rose to 98·8°, the highest in the series. He also read from abstracts of the temperature, &c., kept by C. Bogert, in New York City, from 1816 to 1853.

*THE MEDICAL SCHOOLS OF ENGLAND AND GERMANY**

II.

THE German University System, described in our last article, has been recently extended to other parts of the Continent. In Holland, for example, the progress made in this direction of late years has been immense, considering the small extent of the country. Again, in France, at the time that Duruy was Minister of Public Instruction, a measure was adopted which was prompted by the same tendency. One of the most distinguished *savants* of that country (Prof. Wurtz) was sent into Germany to collect information as to the great institutions which exist in that country for the promotion of natural science. The results of this inquiry are embodied in a voluminous report, illustrated with plans of the most important buildings. The favourable impression made on the mind of M. Wurtz by all that he saw in this journey may be judged of by the terms employed in the final paragraphs, in which he sums up his conclusions, and enforces the necessity of introducing German organisation into France.

If we pass from the consideration of the resources of English schools to the functions they perform and the ends they have in view, the contrast between Germany and England becomes still more striking. All German professors are State officials, and hold their posts, with rare exceptions, for life. Consequently, the special work which they have to perform in virtue of their calling is the purpose to which they have voluntarily devoted their existence. In Germany a young man who makes up his mind to a scientific career, dedicates himself from the first to the particular branch of science which he intends to follow, and remains true to it to the end. In this way he acquires a mastery over his speciality which could not be attained in any other way; and if he is a man of mark, he becomes the centre of what in Germany is called a "School," that is to say, he acquires a following of younger men to whom he communicates the precious fruits of his own work; partly orally; partly by demonstration, in such a way that the pupils learn from him in a short time, and in the most advantageous manner, what it would take years to acquire by self-instruction. In England, on the other hand, with the exception of the few scientific men who have studied in Germany, all are what we call "Autodidacten"—*i.e.* self-taught men, who have acquired their knowledge in spite of the want of opportunities. For there are very few investigators by profession, and, in the sense above referred to, no "Schools." The number of those who hold University Professorships is extremely small, and among these even there are few who, in the absence of independent means, are willing to devote themselves exclusively to a pursuit which brings in nothing.

Those who belong to that section of the community which is most fruitful in workers—those, namely, who are without the advantages either of birth or means—cannot, for want of substance, devote their lives to physiological research with that completeness which is necessary if great results are to be obtained. The most that they can do is to give their early years to investigation, with the understood intention of eventually abandoning natural science for those practical duties which are to be the occupation of their mature life, as well as the substantial reward of their previous labours. For the development of science great part of their work is lost, partly because there are no laboratories for instruction, but still more because their time becomes absorbed in other occupations at the very period at which it could be most advantageously devoted to this purpose.

It must, however, be borne in mind that, in Austria at all events, it was not zeal for science that induced the Government to take charge of its interests. The motive is rather to be looked for in the tendency which then existed to keep everything under the management of the central authority, and to maintain its control over all social relations. It is, however, of little consequence how the system originated; for a tree that bears good fruit is none the worse for the foulness which lies about its roots. Some may be inclined to doubt wh ther it is after all advantageous that the sciences should be represented in the Government. It will not be difficult to answer the question. The man who is occupied exclusively in research (and it is only such workers that science really cares for) is very slow in reaping the fruits of his labours. The results which are to be attained in the laboratory, however valuable they may be as materials for the future enrichment and development of the people, are not marketable. A single truth may afford work for a decennium, and often only begins to be productive after the death of its originator. The position of the philosopher is special. No one is more helpless and more completely dependent on the support of the public. With the artist, who stands in a closer relation to the man of science than any one else, it is far otherwise; for the wealthy patrons, whose houses he ornaments with his works, even if they are not always capable of appreciating them, are willing to pay him for them liberally. But in the case of the philosopher, it often happens that the work of many years may be compressed into a few pages.

A nation so well-to-do as the English might perhaps be expected to afford the means for the support of science independently of the Government, especially now that the value of scientific culture is better understood than formerly. But even if the means were forthcoming, there would be no guarantee for their efficient distribution, unless that distribution were placed under the control of competent and responsible persons capable of justly estimating the future worth of a scientific worker from the earliest products of his mind. For this forecasting, endowments are necessary which are not to be met with everywhere and at all times. It is a great gain to any country to possess men fit to be entrusted with this responsibility; but, in order that they may be really useful, it is absolutely necessary for them to be in immediate relation with the central Government.

I have so far entered only into the general features of higher scientific education, without making any very special reference to medical studies. For the purpose of taking a more detailed view of the subject, we must examine more particularly the mutual relations of hospital and school. This will form the subject of a subsequent paper.

S. STRICKER

* Continued from p. 350.

ON AN UNPUBLISHED ITALIAN MS. OF THE SEVENTEENTH CENTURY

NOT long ago I acquired an MS., entitled *Estratto del Libro, segniato A; di Prete Antonio Neri*, which I think is of sufficient interest to merit a short notice in these pages. In the first place, let us make ourselves familiar with the life and writings of the priest Antonio Neri. The greater number of biographical dictionaries do not even mention him, but the "Biographie Universelle," and Hoëfer's "Nouvelle Biographie Générale" are exceptions, both giving a short account of him. As to the time of his birth, I can nowhere find a more definite date than *vers le milieu du seizième siècle*, while Poggendorff alone mentions the year of his death, which occurred in 1614. Antonio Neri was born in Florence, and was educated for a priest; but he appears never to have undertaken priestly duties, preferring to devote his time to chemical and physical studies. For the purpose of extending his knowledge in this direction, he travelled all over Europe, collecting scientific *secrets*, as they were then called, and he succeeded in amassing a large number of these. He visited the principal laboratories of Europe, and resided for some length of time in Antwerp, where he wrote his treatise on the art of colouring glass. He did not hesitate to work as a common assistant, performing the most menial operations of the laboratory, when he found it impossible to gain access to the secrets he sought by other means.

The period in which Antonio Neri lived coincides most nearly with that of his countryman Baptista Porta (born 1537, died 1615). Paracelsus died about the time of the birth of Neri; Jerome Cardan died when he was a boy; Van Helmont was thirty-five years old when Neri wrote his "L'Arte Vetraria;" Galileo and Francis Bacon had not reached the summit of their fame; Robert Fludd was busy with his "Historia Macrocosmi;" Glauber was a boy, Kunckel an infant, Becher was unborn. The Paracelsian iatro-chemistry was making way, Crollius was supporting it, while Libavius was the leader of the opposition; the famous "Tyrocinium Chymicum," of Beguinus, was about to appear; the "Academia Secretorum Naturæ," founded by Baptista Porta, had just been dissolved by Pope Paul V., on the ground that magical and unlawful arts were practised by its members; but the proceedings of this first of the scientific societies remained in the treatise "Magiæ Naturalis," which was the most popular scientific book of the period. Such was the state of the scientific world when Neri laboured and wrote.

The only work ever published by Neri was the treatise on glass-making, to which I have referred. This is a small quarto of 114 pages, and is entitled: "L'Arte Vetraria distinta, in libri sette del R. P. Antonio Neri Fiorentino. In Firenze, 1612. Con licenza di Superiori.'

The order of the ecclesiastical authorities for printing this work is conveyed in no less than seven forms, which are signed, countersigned, attested, and endorsed, and bear dates ranging between March 30 and April 7, 1612. This excessive scrutiny may appear strange at first sight, but let us glance for a moment at collateral facts. The "Index Expurgatorius" had been established by Paul IV. in 1559, and in the very first issue no less than sixty-one printers had been condemned, and the reading of works which issued from their presses forbidden. Now, there was still greater need for caution on the part of the Church; for had not a certain fellow-countryman of Neri, named Gordano Bruno, recently propagated all sorts of heresies in his "Cena de li Ceneri," and had he not suffered death for his temerity? And was there not a contemporary and countryman of Neri, whilom professor of mathematics in the university of Padua, who had shown particular relish for the doctrines of Copernicus, and a particular disrelish for those of Ptolemy and Aristotle, and altogether an insufficiency of respect for the Church? Thus it was that the utterly inoffensive "L'Arte Vetraria" came to undergo so much scrutiny, and after having been certified to contain nothing *contra fidem aut bonos mores*, to be printed with *Con licenza di Superiori* on the title-page.

At the same time, I do not at all mean to assert that scrutiny was unnecessary in regard to the scientific works of this period; for although they did not often contain anything *contra fidem*, they very frequently did contain a good deal *contra bonos mores*, in the form of invocations wherewith to raise a familiar demon, recipes for love philtres, and for ingenious draughts for ridding wives of jealous husbands, while the more philosophical "Elixir Vitæ" sometimes required the blood of a new-born babe. I recently met with an alchemical MS., evidently of some rarity, for it was written on vellum, and the binding showed that it had once been in the library of a Doge of Venice: *Recipe Sanguinis Humani* were the first words that presented themselves to the eye. Again, Beguinus says: "*Recipe quantitatem satis magnam sanguinis virorum sanorum, in flore ætatis constitutorum, pone in vase circulatorio, justæ capacitatis, in B. M. continue bulliens, donec draco propriam caudam devoraverit.*" So that, after all, Alexandre Dumas has not given us such a very exaggerated character in the person of the Alchemist Althotas in his "Mémoires d'un Médecin." As to the matter of remedies, I find the following in an MS. in the Sloane Collection (probably so late as the first half of the 17th century): "Rock-crystal, mixed with sublimed arsenic, is an excellent medecine; in fact, you need not any other medecine . . . . it being taught a witch by a demon, named Rachiel, who was of ye order of Cherubins." The quaintness and *naïveté* of this assertion are quite refreshing; now, whether "you need not any other medecine" because the remedy had the sanction of both a witch and a demon, or because powdered rock-crystal and sublimed arsenic had been found by the asserter to be peculiarly adapted for internal administration, we will not pretend to decide; but, surely, so-called scientific books sometimes required examination in the age of the priest Antonio Neri.

Let us, now that we know something of its author, turn our attention to the MS., *Estratto del Libro, segniato A; di Prete Antonio Neri.* There is good reason to believe that the matter of this MS. was extracted by some seventeenth-century chemist from a larger MS. of Neri, of which he speaks in the preface to "L'Arte Vetraria," and which he had intended to publish had his life only been spared.

The text is Italian, but the work cannot be said to be "writ in choice Italian;" it is rugged, and, of necessity, full of technical terms, and it sometimes passes into a curious kind of Latinized Italian. As to the contents, we have extracts from five of Neri's books: from the book *segniato* A, 155 pages; from B, 78 pages; from D, 5 pages; from E, 13 pages; and from F, 6 pages. Between E and F are inserted 26 pages of "Operationi Copiate da un libro antico qui in Pisa;" also 8 pages about the *Green Lion*, and 10 pages of extremely mystical and unintelligible matter, replete with symbols and Arabic words concerning a certain *Donum Dei.*

An account of the subject-matter of the extracts from the book designated A will, I think, give a fair idea of that of the whole MS. In the first place, we have an account of mercury, to which metal is assigned no less than thirty-five different names, and twenty-two symbols. The Eastern element, then very apparent in chemistry, is noticeable in such names as Chaibach, Azoch, and Baruchet. Various *fisationi* of mercury are described, and the formation of some of its compounds. Gold and silver are next discussed; the latter has fifteen names and ten symbols. The fixation and calcination of gold, the calcination of silver, the solution and tincture of silver, and the conversion of silver into gold are then described. Venus (copper) follows, among the fifteen names of which are Tubalchain, Marchaal, and Cobon, but not Cuprum, or Orichalcum, or Æs Cyprium, which is surprising. Then come iron, lead, and tin; then vitriol, which has seven symbols; sal-ammoniac, which has fourteen symbols; sulphur, which has sixteen; arsenic, antimony, sal-alchali, sal-alembrot, sal-tartaro, sal-anticar, and cinnabar. The extracts from book A are concluded by accounts of the calcination of various metals, of the philosopher's stone, and of the work of transmutation. The short extracts from the other books contain matter of a similar nature; various well-known salts are described, together with new and varied modes of making them; and different solutions of the metals, compounds, and operations.

The ideas suggested by this MS. are manifold. We can but be struck by the excessive complexity of chemistry at this period. When a substance possesses more than thirty distinct names, and more than twenty symbols, and when these are used indiscriminately in one sentence, some idea may be formed of a chemical treatise of two centuries and a half ago. Symbols were used lavishly, not alone to express substances both simple and compound, but for operations and instruments. But the alchemists and old chemists had a special object in preserving the mysticism out of which their science had sprung, and which still, as a thick vapour, shrouded it in obscurity. Their precious *secrets* would otherwise have been at the command of the vulgar, and the result of their years of toil would have been sown broadcast over the world. The true science was but just beginning to loom through the darksome mists which surrounded it. At this time the science was made up of alchemy and iatro-chemistry, with a strong flavour of Kabbalism. As to the matter itself, we find in the works of the period scarcely anything more than had been enunciated by Geber some eight centuries earlier; in fact, there was too much beating about the bush to allow of any real progress. Antonio Neri was a somewhat sensible chemist for the period. His leanings towards alchemy were not excessive; he was not a violent Paracelsian; indeed, he was rather a metallurgical chemist than an iatro-chemist.

Such is a brief sketch of an MS., the matter of which, in a completer form, the priest Antonio Neri had intended to publish had his life been longer spared. Whether the original MS. exists we know not. Perchance it may be hidden in some old monastic library among volumes of Canon Law and countless folios of Middle Age Casuistry; perchance in some dusty nook *in Ædibus Vaticanis*, among the thunderbolts of a past Hierarchy. Who can tell? Oh! if some Sovereign Pontiff would issue a mandate apud S. Petrum sub annulo Piscatoris," to command the cataloguing of the library of the Vatican, how would not Literature, and Science, and Art be benefited by the means! and how would not Italy receive yet greater honour as the focus from which emanated the glorious light of Western civilization!

GEORGE FARRER RODWELL

CATLIN'S AMERICAN GEOLOGY

The Lifted and Subsided Rocks of America, with their Influences on the Oceanic, Atmospheric, and Land Currents, and the Distribution of Races. By George Catlin. (London: Trübner, 1870.)

IN this free-speaking record of what Mr. Catlin has seen of American geology, and of his interpretation thereof, we have the results of strong observational powers and of limited scientific knowledge, stated earnestly and ruggedly, with a faithful adherence to what was first mastered in books, and to the views of nature that early teaching gave. Such works are not rare, but they are not often noticed at large, unless, as in this instance, the author's individuality, sincerity, and earnestness are true and striking. We find in this book on the "Rocks of America" that the author believes, first, in the hypothetical granite of a primæval world; secondly, in a "schistoze zone, quite around the globe, and undoubtedly more or less an open and defined fissure between the two systems" of granite below and "sedimentary formations" above (p. 81); thirdly, "that these vast sedimentary beds, underlying secondary rocks on almost every portion of the globe, have been laid by the agency of water, with the disintegrated particles of granite, and by some (as yet mysterious) process become solidified and crystallised much in the same form, and certainly with the same ingredients, as the granite from which they came" (p. 80). It appears, also, that these low-seated sediments comprise the "azoic and palæozoic rocks" of books; "that the remains of rhizopod and algæ life [*sic*] may be found below gneiss" (p. 140), but not in the limestone in the gneiss; that the acceptation of the Laurentian system of rocks, as worked out and explained by the Geological Surveyors of Canada, is to be deprecated; that the Laurentian limestones have been deposited in "the caverns formed underneath submarine mountains, which are free from all currents of the ocean, by the infiltration of water from the overlying calcareous rocks;" "that in these caverns the first movements of organic life (which could not have existed exposed to the currents of the ocean) began;" and that these limestones were thus "imbedded, and in horizontal strata, beneath azoic rocks, and containing the '*Eozone Canadensis*' [*sic*], and other rhizopod remains which have excited so much attention of late, and been ingeniously used to undermine the established system of geological formations" (p. 141). Fourthly, "that the granite crust, though cracked at various points, from contraction on cooling, has a limit to which those rents descend, below which, from intense heat, and the hasty and unindurated state that the external border of the molten mass must be in, the contraction has not taken place; and being in an arched shape, and resting on a liquid far more buoyant than water, that no fracture of the crust to the surface of the igneous mass has ever taken place, and that no amount of matter could be concentrated on the surface of the earth to produce that effect" (p. 82). Fifthly, that what any geologist would recognise as the *débris* of broken granite decomposed in place, Mr. Catlin refers to eruption from his subterranean granite crust, thus:—"In the Rocky Mountains and the Andes granite is very rarely seen, and when met (at the mountain's base, as it most often is, or on its summit), it is uniformly seen in amorphous masses of various sizes, with shapes plainly telling its history, that it has been shattered and torn from its bed by subterranean explosions or other disturbance, and lifted by (or has followed) the rising mass to the summits of the highest mountains, and flowing out from these, is found at the mountain's base, where it has rolled, while the mountain's top is gneiss" (p. 86). Sixthly, that water, getting to the molten mass below the author's granite, has expanded, and not only erupted the granitic boulders, but blown out great cavities, into which vast areas of surface (as the Mexican Gulf and Caribbean Sea) have fallen, making catastrophes, and leaving "subsided rocks"; whilst elsewhere the cavern-roofs have been held up as "lifted rocks." Seventhly. That the mountain floods rush into and along these cavities, leaving but little to reach the plains (p. 11); that such "submontagne currents" as these, "heated by the volcanic furnaces they have passed" (p. 4), rush out into the Caribbean Sea, and make the Gulf Stream. Eighthly. The Caribbean subsidence deluged the whole Antilles and many Aztec cities, dispersed some of the aborigines among the heights of Mexico and the Rocky Mountains, and sent some Caribs to Guiana, Venezuela, and Honduras, whilst others were transported to Florida, Newfoundland, and Scandinavia, in frail craft on the broad back of the new-made Gulf Stream, that still favours us with such of nature's blessings as it has to give.

Though not always urging his own suppositions without some doubt, Mr. Catlin is dogmatic enough in condemning the present views of ethnologists and geologists when not coincident with his own, as must be too often the case, judging from the foregoing exposition of the main points of his baseless and inconsistent hypothesis.

"I was born in the midst of the Apalachian Ranges, and amongst them spent my hunting and fishing days; and neither there nor in twice crossing both the Rocky Mountains and Andes chains, have I seen anything but the sedimentary and volcanic rocks, excepting here and there beds of shoved-up boulders of granite, raised in the manner already described." Thus the author writes at p. 92; and the mountain-life in youth and hard travelling in middle age, here indicated, are as plainly shown forth in the curious book before us, as a very imperfect geological knowledge is shown by the latter part of the sentence and its explanations as found at other pages.

Mr. Catlin's love of wild scenery, his recognition of the wonderful and mysterious in nature, his limited range in modern geology, his adherence to some old theories, his disapproval of later geological discoveries, and his assumption of hypothetical notions that have sprung up in his own active, wondering, and impressible mind, clearly witness that, "as a reader of geological works, and a spectator of many stupendous orographic structures" (p. 200), he has been self-taught on a very limited basis of natural science. Nevertheless, he conscientiously believes that he offers something towards the explanation of the geographico-geological structure of America, and of the history of the human millions who have inhabited those broad lands, with strange lives and languages, and have either disappeared for ever or have left degraded remnants, still decreasing under the deadly influences of the European. The world knows how warmly and persistently Mr. Catlin has laboured for the benefit of the Indians; not merely preserving their traditions and scraps of history, their languages, religions, customs, and features, but in damming back, if possible, the evils that befall them from their Christian neighbours. He has, indeed, spent the greater part of a long and toilsome life in helping them directly or indirectly; and the remembrance of their unfailing hospitality and kindness is with him in striking contrast with the treachery and cruelty they have suffered, and with the indifferent treatment he has himself received from his own people in the matter of Indian research, as detailed at pages 190 *et seq.* and in the Appendix.

T. RUPERT JONES

THE MODERN BUDDHIST

The Modern Buddhist: being the views of a Siamese Minister of State on his own and other Religions. Translated, with remarks, by Henry Alabaster, Interpreter of H.B.M. Consulate-General in Siam. (London: Trübner and Co., 1870.)

THIS is an extremely interesting little book. The minister whose views it records—Chao Phya Thipakon—conducted the foreign affairs of his country from 1856 till two years ago, when he was stricken with blindness and was obliged to retire into private life. It was then that he published the work—"a book explaining many things"—the more important parts of which are here translated. We need scarcely say that, looked at from our point of view, some of his beliefs are sufficiently strange, and that he sometimes expresses opinions on subjects which are altogether beyond the range of science. At the same time he has in many respects advanced far beyond the great mass of his co-religionists. He will accept nothing merely because it has been handed down by tradition, but demands proofs which will stand the test of rigid examination. In endeavouring to explain such phenomena as rain, epidemic diseases, the tides, &c., he will have nothing to do with spirits, good or bad; he takes his stand on observed facts, and although his explanations may sometimes be inadequate, they are generally quite in the spirit of modern Western investigation. So far as he understands them, he heartily accepts the European doctrines of astronomy. All this strikes a European reader as very incompatible with certain aspects of the

Buddhist religion; but Chao Phya Thipakon is convinced that Buddha knew quite well the truth about the real order of the world, and that he accommodated his language to the prevailing conceptions of his time, only that he might be the more free to proclaim his doctrines on higher subjects. Hence it is proclaimed lawful for a modern Buddhist to open his mind readily to all the results of modern research. Some of the semi-religious customs of his countrymen the ex-minister rationalises in a most amusing way. For instance, the beating of gongs and firing of guns which take place on the occasion of an eclipse, are by no means what they are generally represented—an effort to frighten the dragon who holds the sun in his jaws, so as to make him drop it; they are the expressions of the popular pride and pleasure that the mathematicians of the country are able to predict the time when the eclipse shall occur! With the strictly theological portions of this book, we have, of course, nothing to do here; but we may state that in comparing the different religions of the world with his own, Chao Phya Thipakon is as far removed as possible from a fanatical spirit. He expounds his views calmly, and appears always ready to accept new light from whatever quarter it may come. The objections he raises to the Christian theory of the world betoken a thoughtful and inquiring mind, although, unfortunately, those from whom he derived his ideas of Christianity seem to have been exceptionally poor representatives of their cause. The ethical conceptions of the book are generally of a very noble character. In one point—the proper treatment of the lower animals—the writer, of course, carries his doctrine too far, and he certainly bases it on grounds with which Westerns can have no sympathy; but there can be no doubt that he is practically far nearer the truth than the great mass of Europeans of our own day. On the whole, this book may be accepted as a good omen for the future of the East. It proves that amongst the best minds a genuine spirit of inquiry has been aroused, and that the old cosmogonies and superstitions are already beginning to give way before more scientific conceptions of man and the world.

OUR BOOK SHELF

How Crops Feed: a Treatise on the Atmosphere and the Soil as related to the Nutrition of Agricultural Plants. By Samuel W. Johnson. (New York: O. Judd and Co.)

MR. JOHNSON'S earlier treatise, "How Crops Grow," has been rendered familiar to the English public through Messrs. Church and Dyer's admirable edition, and forms a complete manual of the structure and physiology of the plant, treated in a manner specially adapted for agricultural students. The present work is intended as a companion treatise on everything connected with the nutrition of plants. The subject divides itself naturally into two sections, the first relating to the atmosphere, and the second to the soil, as sources of the food of plants. The question whether plants derive their nitrogen direct from the free element in the atmosphere was long a vexed one among physiologists. Mr. Johnson details the experiments which were thought to favour the argument on both sides, giving the preference, and we think rightly, to the later researches of Boussingault, and those of Lawes, Gilbert, and Pugh, which appear to demonstrate that the enormous quantity of free nitrogen in the air is not available for the food of plants; but that they draw their supply of it from the extremely minute quantities of ammonia and other nitrogenous compounds that form an essential ingredient of the atmosphere. Under the head of water as an element in plant-food, we miss any reference to the recent important researches of Dehérain, which show that the evaporation of water from leaves is determined entirely by light, and by those rays only which are efficacious in the decomposition of carbonic acid, and that it may proceed in a perfectly saturated atmosphere. This omission will probably be supplied should an English edition be published. The second portion of the work relates to the soil as a source of food for plants, and is the one which will be of special interest and value to practical agriculturists. Here we find treated in an exhaustive manner the origin and formation of soils, the kinds of soil, their definition and classification, their physical characters, and the soil as a source of food to crops, including those ingredients whose elements are of atmospheric origin, and those whose elements are derived from rocks. We can do no more than recommend to the notice of those interested in agriculture a work which we believe will be found a reliable handbook to that scientific knowledge in which the bulk of English agriculturists are at present so lamentably deficient. The most scientific of all manual occupations is actually conducted on a system which is a mixture of complete empiricism and unscientific theory.

Reflections, Historical and Critical, on the Revival of Philosophy at Cambridge. By C. M. Ingleby, M.A., LL.D. (Cambridge: Hall and Son, 1870.)

IN this *brochure* of some eighty pages, after tracing the origin and fortunes hitherto of the Moral Science Tripos at Cambridge, Dr. Ingleby seeks to gauge the efficiency of its present constitution by a threefold test; reviewing the selection that has been made of examiners, the prescription that is made of books, and the composition of some examination-papers lately set. It is shown how, more than thirty years ago, when philosophy was all but extinct in Cambridge, Sir William Hamilton, of Edinburgh, in vehemently (as his manner was) attacking Dr. Whewell's views of the prerogative character of mathematics in a liberal education, threw out the idea of a Moral Science Tripos, which sixteen years later it was reserved for his contemptuous opponent himself to carry into effect. So established, how coldly the new Tripos was, and has continued to be, looked upon by the dispensers of College favours, is next brought out with much evidence. In the choice of examiners, the remarkable fact is the preference shown for men not distinguished in the Tripos itself; two only, out of forty-six first-class Moral Science men within the ten years from 1851, having later been entrusted with the examining function! But it is in the list of books prescribed and in the examination-paper that Dr. Ingleby finds most scope for criticism. As regards books he is angry, not without reason, at the omission of certain works, and angrier, for reasons sometimes oddly expressed, at the inclusion of certain others; in the end, he would appear not greatly to mind if, among moderns before Kant, for the sake too of Kant, Hume only were retained. The questions set on modern philosophical systems seem to him "mere *aperçus* of outsiders," seldom showing true intellectual mastery and grasp.

Dr. Ingleby is always lively in his narrative, often forcible in his criticism, and more than once, when he becomes personal, a little violent. To English thinkers all round he administers raps on the knuckles with much impartiality, but the full weight of his cudgel is for the backs of Mr. Mill and Prof. Bain. He may be said to write as a disciple of Kant (with more or less of outlook towards Hegel); and every true student of mental science will be with him in his wish to see the great father of German philosophy really and at first hand acknowledged in Cambridge. When, however, his enthusiasm carries him to say that no philosophy that does not derive from Kant is able to explain the apodeictic judgments of mathematics, and that to Cambridge men other (all other?) thinkers waste their breath, the saying seems strong. Not to say that Cambridge mathematicians do not always seem to Dr. Ingleby an unexceptionable court of appeal in matters of philosophy, one does not see how they should be above listening to other philosophical doctrine any more than their German brethren. The illustrious mathematicians of this century in the country of Kant have not been noted for their readiness to accept his view of the philosophy of their science. G. C. R.

Die Zonula Ciliaris. Habilitations-schrift von Dr. Fr. Merkel. (Leipzig: Engelmann. London: Williams and Norgate.)

IN this little pamphlet the author attempts to disprove the existence of the "Canal of Petit." He describes the Zonula itself as a band, triangular in section, which passing over from the summits of the ciliary processes to the lens capsule embraces the edge of the lens, and becomes attached to both its anterior and posterior surfaces. The fine fibres of which the band itself is composed are in the anterior portion somewhat stouter, and joined together by an imbedding substance so as to form a membrane which offers abundant resistance to post-mortem changes. In the posterior portion the fibres are tender, free from any connecting substance, and very speedily break up after death; they thus readily give way before insufflation or injection, and the cavity or canal thus artificially produced in the posterior portion of the zonula is that which is known to anatomists as the canal of Petit. M. F.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Gulf Stream

NOTWITHSTANDING the mistakes in the botanic names in Mr. Groom's letter, forwarded to you by Mr. Gray, there is no difficulty in identifying the leguminous seeds alluded to. There are several different kinds which are certainly brought by the Gulf Stream from the West Indian Islands, and the countries round the Gulf of Mexico, as the plants producing them are common in Jamaica, Honduras, Guiana, &c. They comprise the horse-eye bean (*Mucuna urens*), the sword-bean (*Entada gigalobium*), the *Mimosa scandens*, Linn., *E. Pursætha* (*M. scandens*, Roxb.), and the antidote cacoon (*Feuillea scandens*). They are sometimes drifted on shore in the seed-pod, but usually the seed alone.

In an article "On some Economic Uses of Nuts and Seeds," in my *Technologist* (vol. iv., p. 339), I alluded to several of the applications of these seeds, but the superstitious one referred to by Mr. Groom is new to me, although the setting the horse-eye beans in silver is very common for bracelets, &c.

P. L. SIMMONDS

The Intended Engineering College

YOU were good enough to publish in NATURE for the 18th of last month, a letter in which I stated what appear to me to be serious objections to the foundation by the Government of a special college for the education of engineers for the Indian Service. Last week's NATURE contains a letter on the same subject from Mr. W. Mattieu Williams, to which I certainly should not think it needful to reply if my personal opinions only were the subject of discussion; but, as the matter on which I ventured to address you is one of public importance, and was treated by me as such, I must ask you to insert a few additional remarks.

The objections to the Government scheme which I have urged in my previous letters were two: first, that the creation of a Government College, which would compete on unequal terms with the principal scientific schools of the country, would be an injury to science; and, secondly, that, leaving the interests of science out of the question, it would be an improper way of spending public money.

Mr. W. Mattieu Williams's way of disposing of these objections is simple, if not very conclusive. It is, to take no notice whatever of the second (which is, perhaps, not surprising, seeing that it is only Indian and not English public money which it is proposed to throw away), and to meet the second with what is, at best, a *petitio principii.* Beginning with the assertion that I complain "on most narrow and unreasonable grounds" of "a supposed intention of the Government to aid the teaching of science"—whereas what I do complain of is the supposed intention of Government to do what I believe will have the exactly opposite effect—he devotes the greater part of his letter, not to showing that my view of the probable effects of the Government scheme is wrong, but to a "protest against the principle upon which Mr. Foster's complaint is based." According to Mr. Williams, this principle is, "that Government must initiate no scientific effort, give no special aid or patronage to any college or scientific institution, lest it should assail the vested interests of 'institutions like University College and King's College in London, and Owens College in Manchester.'"

I will not follow Mr. Williams through his vigorous commentary upon this text, and will only remark, in the first place, that my "complaint" was limited to the particular case of the Government entering into competition with private institutions, to do exactly what they are doing, without reasonable expectation of being able to do it better; and, in the second place, that the ground upon which my complaint of such competition was based was, that it would tend to hinder the spread of scientific education. The fact that my own interests and those of my college may be more or less affected if the Government scheme is carried out, might be a ground of private regret, but it certainly would not have been a reason for asking public attention to the scheme through your columns. On the other hand, I do not consider it as a reason for being silent in regard to a matter which, as I believe, concerns the interests of science and of the public.

One word more. The procedure of the Government in this matter, without previously taking the advice of visible and responsible scientific advisers, is a sample of a mode of conducting public affairs which, it appears to me, is the most serious disadvantage of a public kind under which science in this country has to labour. What we want, even far more than the expenditure of more money upon scientific objects, is some system which should assure us that what is spent in the name of science is spent for the greatest advancement of science, according to the best judgment of the most competent authorities.

University College, London, Sept. 5

Hollyberries and Birds

IN reply to Mr. Reeks's question, where his opinion as to the relations between birds and berries seems to differ from Mr. Darwin's, I think it best to allow the latter to speak for himself. At page 240 of "The Origin of Species" (fourth edition), after alluding to the part that insects play in the fertilisation of flowers, by their "unconscious selection" rendering them conspicuous and beautiful, he continues: "A similar line of argument holds good with many kinds of beautiful fruits. That a ripe strawberry or cherry is pleasing to the eye as to the palate, that the gaily-coloured fruit of the spindle-wood tree and the scarlet berries of the holly are beautiful objects, will be admitted by everyone. But this beauty serves merely as a guide to birds and beasts, that the fruit may be devoured and the seeds thus disseminated. I infer that this is the case from having as yet found in every instance that seeds which are imbedded within a fruit of any kind, that is within a fleshy or pulpy envelope, if it be coloured by any brilliant tint, or merely rendered conspicuous by being coloured white or black, are always disseminated by being first devoured." And again ("Variation under Domestication," vol. ii., p. 230): "The white Tartarian cherry, owing either to its colour being so much like that of the leaves, or to the fruit always appearing from a distance unripe, is not so readily attacked by birds as other sorts. The yellow-fruited raspberry, which generally comes nearly true by seed, is little molested by birds, who are evidently not fond of it; so that nets may be dispensed with in places where nothing else will protect the red fruit ('Bull. de la Soc. d'Acclimat.,' tom. vii., 1860, p. 359). This immunity, though a benefit to the gardener, would be a disadvantage in a state of nature both to the cherry and raspberry, as their dissemination depends on birds. I noticed during several winters that some trees of the yellow-berried holly, which were raised from seed from a wild tree found by my father, remained covered with fruit, whilst not scarlet berry could be seen on the adjoining trees of the common kind. A friend informs me that a mountain ash (*Pyrus aucuparia*) growing in his garden bears berries which, though not differently coloured, are always devoured by birds before those on the other trees. This variety of the mountain-ash would thus be more freely disseminated, and the yellow-berried variety of the holly less freely, than the common varieties of these two trees." It appears to me that a hollyberry falling by its own weight from the bush would be borne vertically downwards; and though nourished by a soil impregnated with the decayed leaves of the parent tree, the young plant would be almost entirely deprived of light, and would soon succumb to its more vigorous rivals in "the struggle for existence." Perhaps in a country where but little land is left uncultivated, "the great majority" of seeds transported by birds "would be deposited on arable or pasture land," and thus succeed no better than the others; but so far as my limited experience extends, the most usual positions in which seedlings of the holly naturally spring up, seem to be at the bases of steep rocks or of trees whose branches are not sufficiently low and spreading to exert an unfavourable influence. If Mr. Reeks's speculations be correct, they appear to me to point to the ultimate extinction of the species in a state of nature rather than to its gradual modification.

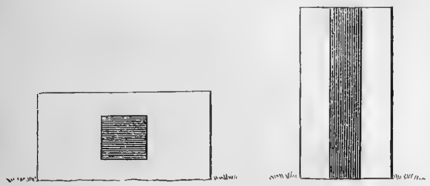
Mirages

THE reading of the two letters of your correspondents in the last number of NATURE has called to my mind the fact, which may not be generally known to your readers, that mirages are of frequent occurrence (and I need not add annoyance) to riflemen, especially "small-bore shots."

The most remarkable case of which I have heard was seen at Wimbledon, during the meeting of the National Rifle Association, in July last. The target at the 1,000 yards range is of an oblong form, 12 ft. wide by 6 ft. high, and with a bull's-eye three feet square. On lying down to shoot on the level ground, the target appeared in a reverse position, with the bull's-eye running through the entire height, from top to bottom, thus—



TARGET 12 ft × 6 ft — THE SAME DURING MIRAGE.

the quasi-phantom target continually moving from right to left, backwards and forwards. But this was only visible when lying on the level ground; for in shooting from a mound about four feet high the target appeared quite natural; and what seems stranger still, the lateral motion did not follow the direction of the wind; for it sometimes moved with the wind and sometimes against it. Friends of mine have seen exactly the same phenomenon both at York and at Altcar.

I have several times, on the range here, seen the bull's eye appear to slide up to the top of the target, or down into the ground; and this latter seems the most common and universal form of mirage.

I need not add, that in all these cases the sun-light was intense.

Halifax, Aug. 29

Kant's Transcendental Distinction

HAD I cherished the wish to involve Mr. Mahaffy in a war of words (λογοθηρία), so often degenerating into a war *about* words (λογομαχία), his straightforward and sensible letter, *wreathed* with courtesy and generosity, would have extinguished it. But, with some desire to justify my own censure, I had no such wish; and now that I know exactly what he had in mind, in the examination question, as in the note on page 57 of his work, I will say my say as briefly as possible on his view of Kant's "distinctions."

I thought, and still think (and here the learned translator of Fischer, has misapprehended me), that Kant intended to contrast *general* Sense (not particular sense, as colours, odours, &c.) with Understanding. Otherwise, the repeated reference to "Herr von Leibnitz" would be unintelligible. (See Hartenstein's Ed. of the K. r. V., p. 241 *et seq.*) To suppose, as Mr. Mahaffy suggests, that something more recondite, something quite radical was meant by Kant, seems to me a gratuitous refinement; for *a priori* elements of sense, as those of understanding, are *transcendental*; and the distinction would have only a *logical* difference; or, in Kant's language, it would be a distinction of logical, not of transcendental, reflection. No one, I am sure, knows better than Mr. Mahaffy, that all transcendental *distinction* is the result of transcendental *reflection*; and to this the doctrine of Time and Space is a necessary preliminary; that doctrine, therefore, is not based on the transcendental distinction. I cannot doubt that Kant called the generic distinction between the two faculties (Affection and Function) *transcendental*, not because he was contrasting transcendental elements, but because the distinction was drawn by *transcendental reflection*; *i.e.* reflection which, by the vantage of a transcendental ποῦ στῶ, refers a conception to this or that faculty.

Accordingly, we are not called upon to give a more recondite meaning to the distinction in question in order to explain the use of *transcendental* as applied to it. Rather let us bear in mind what Dr. J. H. Stirling pointed out to me some months ago, that Kant somewhat loosely applies that adjective to other matters besides the *a priori* elements of experience. In fact, he applies it to the said *distinction* and *reflection*, and also to the thing in itself, an object exercising an unknown function, feigned to account for a known state. The unknown function indeed might be called transcendental, but the object is in itself a mere nullity. If Sensation be referred to the *kick* (as Dr. Stirling calls it) received by us from the feigned object, that *kick* is transcendental; but "das Object bleibt uns unbekannt *und transscendente.*" We say, then, that the two forms of sense and the four forms of thought (in apperception) are *transcendental and constitutive of experience*; but the object in itself is *transcendent* and *regulative of thought*. If Kant departs from his own nomenclature in the case of the noumenon, we need not be surprised if he does so in the case of the distinction between sense and understanding.

The bearing of this question on "Kant's View of Space" (which was the topic of controversy between Mr. G. H. Lewes and Dr. J. J. Sylvester in the columns of NATURE) is noteworthy here. The sensibility, according to Kant, is not spontaneous or active, like the understanding. The forms, then (*i.e.* the institutions of Time and Space), are not, cannot be, products of the *activity* of any faculty, and therefore time and space cannot be forms of *Thought* in any legitimate sense of the word. Let it be used in the widest sense possible; let it stand for *the active faculty of mind in general*; and then it can be proved that Kant would have refused to refer to it the forms of general Sense, because he denied to general Sense any activity whatever.

Valentines, Ilford, E., Sept. 6

Volcanic Agency *v.* Denudation

MR. DAVID FORBES holds that, in instituting "a comparison between the relative magnitude of the operations of internal and external forces in determining the main external features of our globe, we must grant the first rank to the internal, volcanic, or cataclysmic agencies, since, had it not been for their operations, our globe would have remained without any visible land for the rivers to traverse, or the rain and ice to disintegrate and wear away."

The latter part of the statement cannot, of course, be called in question. But does the conclusion necessarily follow? Suppose I say that a father who died before his son was born, ought, as far as that son's education was concerned, to rank before the schoolmaster who taught him, because but for the father there would have been no boy to teach; or that the quarryman who extracted a block of marble from the quarry ought to rank before the sculptor who shaped it into a statue, because but for the quarryman the sculptor would have had nothing to work upon. In truth, in a case like this, it is hard to attach any definite meaning to the idea of rank. If Mr. Forbes had said that in the task of bringing the earth's surface into its present shape, internal forces have done more work than external

I should have known exactly what he meant, and made bold to differ from him.

I feel sure, however, that those geologists who have endeavoured to revise the almost forgotten teaching of Hutton as to the important part played by subaerial denuding forces in forming the present surface of the ground, are by no means forgetful of the obligations they are under to upheaval for furnishing them with materials to be shaped; and in cases of great mountain chains they have always admitted that the superior elevation of the ground is mainly due to internal action, though they hold that all the sculpturing of the upheaved mass into gorge and peak is due to atmospheric agency. A. H. GREEN

79, Dodworth Road, Barnsley, Sept. 3

Geology of Devonshire

A RAILWAY of eight or ten miles is now in course of construction between Totnes and Ashburton in Devonshire. To a geologist the cuttings near the latter town are most interesting. I am not a geologist, although the science is deeply interesting to me. I returned from Ashburton ten days ago. The rocks there at one part of the line were evidently volcanic. They appear exactly as if they had been melted, and in boiling up a scum or froth had risen on the surface, and in cooling had left air-bubbles, now nearly filled with sometimes yellowish crystals. The rock is very hard, and has a stratum of what was once slate, ten or twelve feet thick, and as the workmen work it out it bears the colour which great fire would give it. As blocks of the other rock are torn out by powder, they are found to contain or enclose fragments several inches square of the superincumbent slate rock, too hard to be melted. This rock is not stratified, but breaks into any form. A few hundred yards off they are working through ironstone as hard as iron itself. The heavy sledge hammer rings on the blocks as on an anvil. At the east end of the town are two pits worked for umber, indeed there are several fields of which the soil a few inches below the surface consists wholly of umber. I do not expect there is any one in the neighbourhood who feels an interest in geology. I saw a letter in NATURE on a geological subject from Mr. Pengelly, of Torquay and I wrote him on the above subject. I have no doubt the line is very interesting in the other parts, as the rocks greatly vary thereabouts.

A learned geologist would have made what I have attempted to describe more interesting. He would find much to employ him in that neighbourhood. W. LUSCOMBE

Hereditary Deformities

IN the lessons in Ethnology in "Cassell's Popular Educator," it is stated, on the authority of Dr. Theodor Waitz, and the Secretary of the Anthropological Society, that "an officer, whose little finger had accidentally been cut across, and had, in consequence, become crooked, transmitted the same defect to his offspring. Another officer wounded at the battle of Eylau, had his scar reproduced on the foreheads of his children." And again, "In Carolina, a dog which had accidentally lost its tail transmitted the defect to its descendants for three or four generations." Do these stories rest on a good foundation? We know that congenital peculiarities of form and disposition are transmitted from parent to offspring, but that an accidental *deformity* should be so transmitted is a very different affair, and if substantiated would introduce *Accidental Distortion* as a co-worker with natural selection in the modification of species.

Faversham, Kent, Aug. 27 WM. FIELD

Poisoning by Œnanthe crocata

PERMIT me to send you the following notes with regard to the case of poisoning by *Œnanthe crocata* which appeared in your issues of 18th August and 1st September.

I. As to the poisonous properties of *Œnanthe*, Prof. Christison found that plants gathered in certain localities were harmless, while others from different places were highly poisonous.

II. As to the mode of death. This seems materially to differ from that observed and recorded with regard to poisoning with hemlock (*Conium maculatum*). In the case of poisoning with hemlock which took place in Edinburgh in 1845 (recorded in the *Edin. Med. and Surg. Journal*, No. 164, and also Prof. Bennett's "Principles and Practices of Medicine") the mind remained clear till the end, and death resulted from asphyxia produced by slow paralysis of the muscles of respiration. The muscular paralysis commenced in the feet.

In the recent case of poisoning by *Œnanthe* there seems to have been coma and convulsion for half an hour previous to death; no paralysis seems to have occurred over the body. From the account of the hemlock case to which I have referred, that plant also seems not to have any particularly acrid taste. The part that seems strange to me is the difference in the mode of death with plants so nearly allied to each other as the *Œnanthe* and the *Conium*. J. W. E., EDIN.

NOTE ON SOME INSTANCES OF PROTECTIVE ADAPTATION IN MARINE ANIMALS

THE various phenomena of mimicry and protective adaptation have recently received much attention, notably from Messrs. Darwin, Bates, and Wallace, and some very interesting facts and reasonings on the subject are contained in the recently published "Contributions to the Theory of Natural Selection" by the last-named author. It can scarcely be needful to explain at much length the nature of the phenomena in question. Well-marked instances of mimicry are not very common; some of the most surprising are those of the leaf and stick insects of the Tropics, which it is almost absolutely impossible, when at rest, to distinguish from dead leaves and twigs. The importance of these resemblances, in conferring protection from attack, will be at once evident. Commoner instances of adaptation, which may indeed be noticed wherever we turn our eyes upon the animal creation, are those of more or less complete resemblance of colour between the animal and its surroundings. The most remarkable instance of this kind which has come under my own observation is perhaps that of the caterpillar of the Emperor moth (*Saturnia pavonia minor*), which, with its green ground and brilliant pink spots, is almost undistinguishable from the heather upon which it frequently feeds.

Numerous instances of this kind amongst terrestrial animals might be brought forward, but less attention has been paid to similar points in the less highly-organised of marine animals. They are, for the most part, much less easily observed in their natural haunts, and their habits and the dangers to which they are exposed are of necessity imperfectly understood. We may note, however, that fishes very commonly assume the colours of surrounding objects; the flounder is almost exactly of the colour of the sand on which it lies, and fishes which bask amongst groves of seaweeds are often of brilliant and variegated colours corresponding very much with the vegetation around them.

The two instances which form the subject of this notice came under my observation while dredging in June last in the Frith of Clyde. In one spot the dredges brought up many plants of *Laminariæ*, with their roots, which consist of a conical mass of contorted and intertwined fibres about a line or two in diameter; amongst these were imbedded quantities of nullipores—a calcareous seaweed of the genus Melobesia—(*M. calcarea*). The larger weed had, in fact, grown in a bed of the nullipore, which came up abundantly in the dredge, and indeed now forms on a closely adjacent part of the coast a raised beach of several feet in thickness. Amongst the nullipore which matted together the laminaria roots were living numerous small starfishes (*Ophiocoma bellis*), which, except when their writhing movements betrayed them, were quite undistinguishable from the calcareous branches of the Alga; their rigid, angularly-twisted rays had all the appearance of the coralline, and exactly assimilated to its deep purple colour, so that though I held in my hand a root in which were half a dozen of the starfishes, I was really unable to detect them until revealed by their movements.

The second instance is that of a shellfish, *Lima hians*. This beautiful mollusc is well known frequently to construct for itself a nest—a long tube lined with byssal fibres and covered externally, after the manner of a caddis-worm, with nullipores, stones, old shells, or probably any material which lies conveniently at hand. We may perhaps account for a habit so different from that of other mollusca by the following considerations:—

The animal is an exceedingly showy one, more so than almost any other British mollusc, having two valves of snowy white, from between which are protruded long tentacular fringes of a brilliant orange or vermilion hue; when alarmed, it darts, or almost, as one might say, flies, in a fitful manner through the water, showing its gorgeous colours very conspicuously—so that indeed in the Channel Islands it has acquired the name of "Angel's Wings." Other mollusca, such as some of the Pectens, are brilliantly coloured, and live without the protection of any nest, but their shells are very strong and close firmly, so that they could not easily be masticated by ordinary fishes. The shell of the Lima, on the contrary, is very fragile, and would easily be dealt with by fishes which are accustomed to devour wholesale crabs and other hard-bodied creatures. It is, therefore, easy to believe that the two characters of tenderness and brilliant colouring would speedily ensure the extinction of the species were it not protected in some extraordinary manner such as that of the concealment afforded by a nest. Mr. Wallace has shown, in a very interesting manner, how birds of brilliant plumage build nests of a character adapted for concealment during incubation, and it seems to me that the similar habit of the Lima may probably be referred to the same cause.

GEORGE S. BRADY

SWALLOWS' NESTS*

A FEW months ago M. Pouchet published an article on the subject of swallows' nests, which seemed destined to modify all our previous ideas of reason and instinct. According to this naturalist, the common swallow had modified his habits, and had made certain progress in the art of nest-building.

Had this theory been correct, we must have renounced our preconceived notions which place an insuperable barrier between reason and instinct. If we assume instinct to be a faculty incapable of development, and not progressive in the animal, it is clear that if any modification or progress were once scientifically proved to have taken place in the arts of which each animal is capable, it would be necessary henceforward to classify such arts as appertaining to the domain of reason.

The communication, therefore, made by M. Pouchet to the Académie des Sciences would have had great weight had the facts which it related been confirmed by subsequent observation.

Such, however, does not seem to be the case, for M. J. B. Noulet has recently pointed out the error contained in M. Pouchet's statement.

According to M. Noulet, there are two distinct varieties of swallows, the window swallow (*Hirundo urbica*, of Linnæus), and the chimney swallow (*Hirundo rustica*).

These two types do not intermingle, and have somewhat different habits; for instance, the chimney swallow is always the first to arrive and the first to leave these countries. Their nests are also different, and the difference is so well marked that there need be no difficulty in deciding as to the builders who have constructed them.

The city swallows (*H. urbica*) always choose the lofty situation, and group their nests in continuous lines, sometimes double and even triple. The *H. rustica*, on the other hand, establishes itself lower down, and constructs its nest apart from its fellows. The nests, too, of the first-named variety are chiefly distinguishable by a greater depth, and by a circular aperture just large enough to allow the bird to go in and out without difficulty.

M. Pouchet, paying no attention to the difference existing between the two varieties to which we have alluded, takes the nests of the city swallow for those of this rustic sister brought to a higher degree of perfection.

This, at least, is M. Noulet's opinion. It remains to be seen if M. Pouchet will accept the explanation, or whether he will be prepared to defend his own theory. In either case the readers of this journal shall be informed.

ALFRED NAQUET

* "Nos deux hirondelles et leurs nids." Par J. B. Noulet.

FACULTY OF SCIENCE IN UNIVERSITY COLLEGE

SOME months ago it was announced in our columns that a Faculty of Science had been formed in University College. In the prospectus now issued for the forthcoming session there appears the following general statement:—

"The Faculty of Science has been instituted to bring into full light the actual extent of the scientific teaching in University College, and to meet, consistently with sound educational principles, the growing demand for instruction in science.

"The Faculty of Arts in University College, instituted to give a general training in literature and science, such as is required for a degree in arts in the University of London, not only has from the first contained chairs in which the scientific instruction has been developed far beyond the needs of arts-students, but by a steady process of growth has come to include others bearing no relation to an arts-curriculum. So considerable is the scientific staff now actively at work in the college, that the authorities believe the time has arrived when the science-teaching carried on within its walls may assume all the character of independence and dignity associated with the academic title of Faculty.

"The demand for instruction in science and the recognition of science in education are facts beyond question. In University College itself the number of students seeking a broad scientific training or pursuing special scientific studies has gone on steadily increasing; while in the University of London and elsewhere, degrees in science, both general and special, have been conferred for some years past. The importance, also, of science as a preparation for industrial pursuits is now generally acknowledged, as appears in the efforts that have been made of late years to supply scientific instruction in so-called technical schools.

"The main principle represented by the new Faculty is, that science should first of all be cultivated for its own sake, and that even where there is a practical object in view, a broad foundation should be laid of general scientific training. It is believed that the habits of thought thus engendered are the first conditions of all true advance, either in scientific discovery or in practical invention. A second principle is, that the pursuit of science should not be divorced from literary culture; and this the Faculty, from its position in University College, is specially enabled to uphold. As regards the interpretation of the word Science, it only remains to add that this is taken in no narrow sense. Certain subjects are included which lie out of the sphere of Natural Science, as commonly understood, but none that do not admit of a strictly scientific treatment."

As at present constituted, the Faculty includes chairs of pure mathematics, applied mathematics and mechanics, physics, chemistry, and practical chemistry, mineralogy and geology, engineering, architecture and construction, botany, comparative anatomy and zoology, physiology, practical physiology and histology, philosophy of mind and logic, political economy.

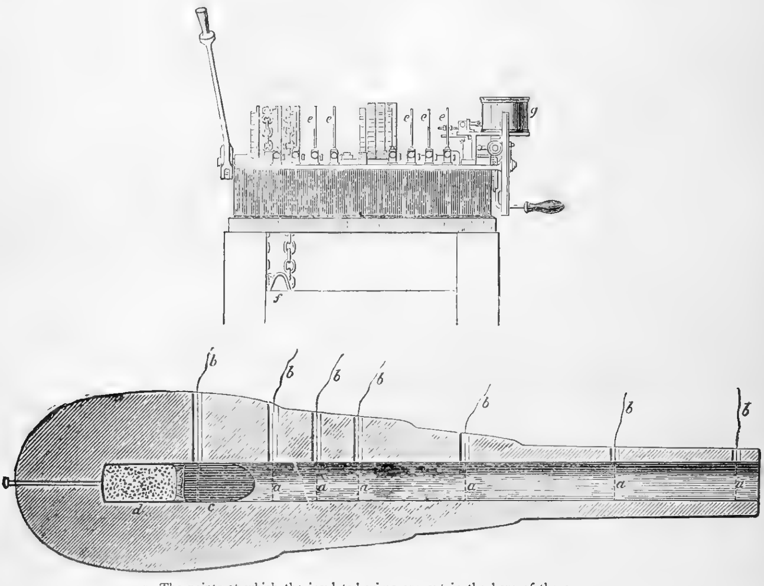
THE SCIENCE OF WAR

III.

GUNS AND GUNPOWDER

WITHIN the past twelve months an invention of considerable ingenuity has been matured which promises to enlarge to a marked degree our knowledge of the science of gunnery. We are all aware of the great perfection to which the cannon in use now-a-days have been brought, and how they represent the results of progress which has been steadily going on during three or four centuries, until at last we have succeeded in producing guns rifled to such a degree of precision that any object visible at a couple of miles may be hit with certainty, while in some cases a distance of ten or even eleven thousand yards is actually reached by the shot. These are improvements at once patent and appreciable, and such indeed as might be anticipated from constant practical and theoretical study of the subject; but while congratulating ourselves upon the advance made in this branch of gunnery science, we cannot, at the same time, but marvel at the slight progress effected towards improving the source of our motive power, and at the fact that no explosive agent has yet been brought forward to supersede the gunpowder now used.

Explosive mixtures have, it is true, been proposed from time to time, whose advent has been heralded with such high-flown praise and promises that one could not but suppose that the days of gunpowder were numbered; in



a The points at which the insulated wires are cut in the bore of the gun.
b The insulated wires leading to the induction coils and disc apparatus.
c The shot.
d The cartridge.
e Revolving discs.
f Weight for setting machinery in motion.
g Stop clock to record the number of revolutions.

one respect or another, however, the new-comer always failed to satisfy its severe military censors, and was thus thrown on one side and forgotten. Even nitro-glycerine and dynamite, of which chemists were at one time so very sanguine, have been entirely rejected for military purposes, and gun-cotton is indeed the only explosive material, besides gunpowder, to which our war authorities are inclined to give ear. The very important qualities which pyroxilin exhibits under various phases of combustion, its immense power, its portable and convenient character, and furthermore its comparative safety when in store and in course of manufacture, render it in some respects equal and even superior to gunpowder for engineering operations.

Nevertheless, at the present moment our knowledge even of gun-cotton is not sufficiently advanced to allow of its being universally employed in the same manner as gunpowder, and it is to the latter, therefore, that we must still look for the principal source of explosive power.

It appears strange that, being as it were continually thrown back upon our elementary explosive, no radical improvements should have been effected in its manufacture; we still employ the proportions of sulphur, charcoal, and saltpetre as they were laid down in the first instance by Bacon and Schwartz, and in fact so stationary has been our position in regard to the matter that it would appear almost as if perfection had long since been attained.

While, however, the chemical composition of powder has remained unchanged, some very important modifications in its rate of burning have been of late years brought about by merely altering its mechanical form and density. Indeed by thus varying its outward character, and without in any way tampering with its chemical composition, an exceedingly rapid, or on the other hand a leisurely, burning product may be secured from precisely the same materials. This means of controlling the explosive character of powder is of especial value in connection with heavy rifled guns, in which an evenly burning product is an absolute necessity; and indeed the most important condition to be fulfilled in gunnery science is always to employ in a gun that powder which is best adapted to the arm. Now it is a well-known fact that the larger the grains of powder are made, the slower does a charge of it burn, supposing always the particles to be uniform in size, and not of a thin chip-like character, or irregular in shape. In rifled guns a slow, regular-burning powder is a *sine quâ non*, for, unlike the case of smooth-bore howitzers and mortars, a steady and increasing push, and not a violent jerk, is necessary to force the projectile through the grooves. For mortars, therefore, a comparatively fine-grain powder is employed, while for big rifled cannon a material of the coarsest description, with grains approaching in size that of a hazel nut, is invariably preferred.

The best charge for a gun, especially if rifled, is moreover that which increases in power as the shot passes through the bore, and which exerts its greatest force as the projectile leaves the muzzle, *but not earlier*; so that, on the one hand, the maximum explosive power is not put forth until the instant the mouth of the gun is reached and the last impetus given, while on the other hand no loss of power is suffered by the charge still burning after the bore is empty. If the charge burns quickly the shot is brought into action too rapidly, and the gun consequently subjected to excessive strain; whereas, if the combustion of the powder is too slow, the shot does not receive the full benefit of the charge, and a large portion of it is lost. Thus, as may easily be imagined, the difficulty has hitherto been to fix upon the precise description of charge necessary to the gun, and it is just this difficulty that has recently been solved by the elaboration of an instrument which accurately informs us of the velocity of any shot during its passage through the gun.

The possibility of discovering what takes place in the bore of a cannon at the time of its discharge, and of ascertaining how fast the shot travels, is a subject that has long attracted the attention of artillerymen, and among others that of a talented officer, Captain Andrew Noble, of the Elswick Ordnance Works. This gentleman's labours have recently been crowned with success; and an apparatus has been devised of which one hardly knows whether to admire more its exceeding delicacy or its wonderful results. With its aid the examination of gunpowder is now being conducted with comparative ease, and what is still more important, with unerring certainty.

A detailed description of the instrument, which has received the name of Chronoscope, would necessitate more space than we have here at our disposal, but its main features, and the principle upon which it is based, are easily explained. The tube or bore of a gun is fitted inside at certain intervals with metal rings (to the number of six or eight) the outside margins of which are sharpened into so many knife-edges. On a shot passing along the bore and through these rings, the edges of the latter are jammed down upon and made to cut through the ends of various insulated wires, one of which is placed under each ring. If we now suppose each of these wires to be in connection with an electric battery, it follows as a matter of course that as one wire after another is cut through, and the insulation consequently removed, an electric current passes; so that if there are six rings and wires fitted at intervals in the tube of the gun, the passage of a shot along it would be instrumental in producing six electric sparks following rapidly one upon the other.

We now understand how the shot is made to tell the tale of its flight; but there remains yet to be explained how the story is written down. This recording of the signals is accomplished by a very simple arrangement. A series of metal discs, one in connection with each wire, is made, by means of a clock-work arrangement, to revolve at a certain rapid velocity, say at the rate of 1,000 inches in a second; the surface of the discs is of polished silver, coated with lamp-black, and as soon as the desired speed has been attained, the gun, which is in electrical communication with the instrument, is fired. As the shot traverses the first ring, No. 1 wire is cut through, and a spark thereupon hops over to the recording disc, removing a little of the lamp-black covering, and thus marking the place by laying bare a minute spot of bright metal. No. 2 wire, when cut by the second ring, leaves a similar record upon another disc precisely in the same manner; and so on with Nos. 3, 4, 5, and 6, the relative position of the six spots on the six discs indicating exactly the velocity with which the shot has passed the six different rings or stations.

A very simple calculation is now necessary to get at the results; if there is a distance of one inch between each point, we know that one-thousandth part of a second has sufficed for the shot to travel from one ring to the other, for we remember that the discs were revolving at the rate of a thousand inches per second. This, however, only by way of example, for as a matter of fact we may mention that a shot usually takes from $\frac{1}{200}$th to $\frac{1}{300}$th of a second to traverse the whole length of the bore, its speed being somewhat slow when passing the first rings, and increasing as it approaches the muzzle of the gun.

A certain amount of correction is of course necessary when reading off the results, but the accuracy of these may at any time be verified. Thus, in order to ascertain whether the electric and mechanical arrangements of the discs are in good order, it would be necessary merely to place the whole number of wires together under a single ring, so as to be cut through at one and the same moment, when the points on the discs should, of course, all coincide.

The great importance of this beautiful invention need not be dilated upon by us, as the value of its aid in experiment is at once apparent to the veriest tyro in gunnery. As a measurer of time and speed of the most perfect character, its delicacy is certainly unsurpassed; for, by merely dividing every inch of the discs into a thousand divisions or degrees, we are at once enabled to calculate with precision to the millionth part of a second.

NOTES

A WEEK or two ago we announced a rumour to the effect that the Government had refused to allow a ship to convey the eclipse observers to Spain and Sicily next December. The rumour was too well founded; the Government has actually refused to tell off a ship for this purpose. This decision in the teeth of the plainest precedents requires no comment on our part; in fact, it is beyond all comment, it is astounding. We are enabled to announce, however, that the American Government, more enlightened than our own, are making extensive preparations; and upon the results of their labours and those of the Continental Governments Englishmen must therefore fall back, in a research which is eminently English. The Americans will send three corps of observation, to be stationed respectively at Malaga, Sicily, and some place in Turkey most available for making the best scientific records and views. One of these corps will be sent from the Naval Observatory, and the other two will be composed of the most scientific men in the country, including the professors from Harvard University. Before the war broke out it was arranged that Rear-Admiral Glisson should extend to the corps at Sicily all the aid and cooperation in his power. But the original plan has been spoiled for the present by the troubles in Europe, Admiral Glisson being obliged to move his squadron to the Baltic for the protection of American commerce in that vicinity.

WE regret to learn that the health of Gen. Sir E. Sabine, the distinguished and venerable president of the Royal Society, is at the present moment such that he is likely soon to demand relief from the pressure of those duties which he has hitherto performed with so much credit.

BEFORE our next number is printed, the annual meeting of English *savants* will have commenced at Liverpool under the presidency of Professor Huxley, whose inaugural address we hope to give in our next issue. The meeting is likely to be one of great interest, and various circumstances will combine to bring together an unusual number of the representatives of every branch of science, including not a few of our foreign *confrères*, who we trust will enjoy the peaceful retreat from the turmoil on the Continent. Atomists and Non-atomists, Cataclysmists and Uniformitarians, Darwinians and Anti-Darwinians, will, for the moment, take the place of Gauls and Teutons—would that *their* differences could be as peacefully discussed! Some useless talk there doubtless will be, but we trust much earnest search after truth for truth's sake, and much evidence of real scientific work accomplished during the past year. We shall endeavour to give a report of the proceedings in the various sections, and to this end we must ask, and confidently expect to receive, the hearty co-operation of the Association itself, not only of the officers of sections, but of every individual member who takes part in the meeting.

THE result of the experiments at Woolwich in reference to war balloons is that it has been found that a height of 100 fathoms at horizontal distance of 600 fathoms from the enemy would enable observers to secure the widest expanse of view. It is ascertained that captive balloons attain stability. The balloon having taken a stationary position, eight cameras and lenses spread round the country at equal distances enable the country to be photographed. The inclination and length of the cord to keep the balloon in the same stratum of air was found to be easily calculable. By the new system of military telegraphy for field service telegraph wires can be carried through the air from *terra firma* to a balloon, and the wire can be paid out as fast as the balloon sails; and two or more balloons can be kept in communication with each other, so that telegraphic operations can be made from the balloon to head-quarters and thence to the base of operations. It is believed that war balloons will be manufactured at the Royal Arsenal, and that officers of Royal Engineers will be trained in their use.

THE *New York Technologist* for September describes a pocket rifle invented by Mr. Stevens. It is said to be capable of doing very accurate work, and the price is moderate. The method of loading is so simple that the weapon can be fired five times in a minute. By simply touching a spring the muzzle of the barrel drops down, leaving the breech exposed; a cartridge is then inserted, the barrel returned to its place, and the weapon is ready for use. For all light game they cannot be surpassed, and their penetration is considerable, driving the ball through three one-inch boards.

MR. W. G. SMITH has recently called attention to the great amount of heat generated by fungi, confirming Dutrochet's observation that it is greater in the case of *Boletus æneus* than of any other plant except the Arum. Mr. Smith believes that it is common to all *Boleti*, especially after decomposition has set in. Three large and beautiful specimens of *Boletus colopus* packed in a box were found by Mr. Smith to raise the temperature of the air from 70° to 75° Fahr., the heat evolved being apparent to the hand.

WE gain some notion, says the *Gardener's Chronicle*, of what a siege means when we learn from Paris that the veteran director of the Jardin des Plantes, the well-known chemist, Chevreul—aptly called, from his researches into the nature of fatty substances, "the king of the fatty acids,"—has placed himself at the head of a brigade composed of *employés* of the Museum, and betaken himself to the fortifications. M. Delaunay, the Director of the Observatory, and M. Milne-Edwards, have marched to the scene of action at the head of nearly the whole of the officers and servants of the Academy of Sciences and the Museum. What should we think here in London if the chief librarian of the British Museum, with Professor Owen and Mr. J. J. Bennett as his *aides*, took the field with their subordinates and occupied Shooter's Hill, or if the director at Kew, with his staff, took upon themselves the defence of Richmond Hill? And yet this is what it has come to in Paris.

A SANITARY council for Bohemia has been formed, consisting of Professors Jaksch, Halla, Kaulich, Town-District Surgeon Dr. Grosse of Prague, and District-Surgeon Dr. Hosier of Karolinenthal.

MR. G. FARRER RODWELL has succeeded Dr. Debus as Lecturer on Natural Science at Clifton College.

THE *Yale College Courant* states that Prof. Silliman has resigned his position as instructor of chemistry in that institution.

WE are authorised to state that there is no foundation for the statement which appeared recently in one of the daily papers, that the London Institution in Finsbury Circus is likely to be removed in order to make room for a railway station.

THE preparations for the Argentine National Exhibition at the city of Cordova are in active progress. The building is approaching completion, and the tramway to connect it with the railway station has been commenced. The tramways in the city have experienced great success, and caused an amount of building speculation in the suburbs beyond the available supply of labour. Several important railway proposals, involving prospective loans of magnitude, are under discussion in Congress.

CORNELL UNIVERSITY (for a notice of which see NATURE, August 11) has recently acquired a fine and valuable collection of fossils from one of its many admirers in England. The educational value of such a collection in America, as illustrating the English geological works, is very great, and Cornell University may well be proud that it has so speedily received such a valuable gift.

IT is proposed to found a Museum of History, Antiquities, and Arts, in the Central Park, New York. This movement is under the auspices of the New York Historical Society, and a grant of land has been given by the Government for that purpose. The plan embraces the erection of suitable buildings where historical relics and treasures of local and national interest may be deposited for preservation and exhibition.

SIG. LARANJA E OLIVEIRA forwarded to a recent meeting of the French Academy of Sciences an account of a very remarkable electric shock experienced at Porto-Alegre, Brazil, on the 9th of June. A thunderstorm was progressing at the time, and large drops of rain falling, with a light south breeze. At 100 metres from his own house, as a flash of lightning without thunder appeared over his head, one of Sig. Oliveira's servants felt a remarkable tingling through the whole of his body, ascending upwards from the soles of his feet, succeeded by a violent trembling; his hair stood on end, so as almost to throw off his hat. At the same time, at the distance of about two metres, white smoke ascended from the ground, accompanied by small consecutive flashes of lightning, but the whole lasting only an instant. A door key, which he had in his pocket, attracted for two days afterwards a needle suspended by a thread.

MM. RABUTEAU and Peyre have been experimenting with the root of a plant in use at the Gaboon as an ordeal poison, and locally known as m'boundou or icaja. It will be remembered that it was from this source that the highly valuable Calabar bean was obtained and utilised in medicine. The authors state that, even in very dilute decoctions, it is very bitter, and appears to contain one or more alkaloids, since the aqueous decoction is largely precipitated by iodide of potassium, and also by phospho-molybdic acid. The poisonous effects of this substance bear some similarity to the effects of brucia; but the authors state that, under certain conditions this poison does not hurt men. Some of the lower animals are readily killed by it; a dose of three milligrammes of the alcoholic extract placed under the skin of a frog kills it; and rabbits and dogs are killed by doses of from 15 to 25 centigrammes of the same extract introduced into the stomach.

M. ROUSILLE, Professor of Chemistry in the Agricultural School of Saulsaie, describes a remarkable phenomenon witnessed by him on Mons Pilatus, at sunrise on July 19th. The air was foggy, the temperature 10·5° C., the barometer 647 mm., the altitude above the sea being 1288 metres. Whitish clouds appeared to form a crest to the mountain, the wind was light from the east, the sun at first very pale, obscured by a light cloud; but suddenly the sky appeared as if on fire, and at the same time the shadow of the mountain was projected on the horizon, at the same time that the image of the sun was reflected in the clouds to the west, surmounted by two rainbows, one above the other, and separated by a grayish band. The image of the sun was orange; the two rainbows which surmounted it consisted of two colours only, red and orange mingled together, and placed symmetrically in each of the rainbows with respect to the separating gray band. The upper bow was paler than the lower one. In proportion as the clouds approached the spectators, the image of the sun increased. At the same time that the rainbows became larger, some black lines became more and more clear, and were soon easily recognised as the shadows of the spectators. As the clouds advanced, the phenomenon disappeared three or four seconds before the spectators were enveloped in them; but the clouds again disappearing, the phenomenon was repeated three times successively in the space of eighteen minutes. The phenomenon appears to have been of the same nature as the well-known Spectre of the Brocken in the Hartz Mountains.

THE second part of Vol. I. of the Natural History Transactions of Northumberland and Durham has just been issued. The following are the most important papers contained in it:—A list of Freshwater Algæ collected in Northumberland and Durham (excluding Diatomaceæ and Desmidiæ) by Mr. G. S. Brady. On a new Labyrinthodont Amphibian from the Northumberland coal field; and on the occurrence in the same locality of *Anthracosaurus Russelli*, by Albany Hancock. The new Labyrinthodont, obtained from the Low Main seam of the Newsham colliery is a small species of Huxley's genus *Urocordylus*, and the name proposed is *U. reticulatus*, expressive of the reticulated structure of the surface of the cranial bones. On some curious fossil fungi from the Black Shale of the Northumberland coal field, by A. Hancock and T. Atthey (illustrated). The same authors contribute two papers (also illustrated) on the genera of fossil fishes *Climaxodus* and *Janassa*. Notes on the Entomostraca of Northumberland and Durham, by Mr. G. S. Brady (illustrated). The Meteorological and Climatological Reports for 1869, by the Rev. R. F. Wheeler, occupy a considerable portion of the volume, and are illustrated by tables and some very curious and interesting drawings of the solid residue left on evaporating rain-water, which fell in London, on the Clyde, at Manchester, and at Newcastle. The volume closes with the annual address to the members of the Tyneside Naturalists' Field Club, by the President, Rev. R. F. Wheeler.

DR. W. F. R. SURINGAR has contributed to the Annals of the Botanical Museum of Leyden a monograph of the Algæ of Japan, chiefly those collected by Von Siebold. The illustrations, both of the Diatomaceæ and the Sea-weeds, are of extreme beauty.

PROFESSOR HALFORD, of the University of Melbourne, in a paper read before the Medical Society of Victoria, has reviewed at length the history of twenty cases of snake-bite treated by his method of injecting liquor ammoniæ into the veins during the last eighteen months. These cases were all in the hands of different practitioners in the colony, who have each reported on them. Recovery followed in seventeen cases. In thirteen of these the practitioners in attendance expressly report that the patients were in a dying condition, and, in their belief, would soon have died, but for the employment of this remedy in the manner prescribed. The method employed was that introduced by Dr. Halford, and first brought to the knowledge of the profession here by him, in the pages of the *British Medical Journal*, through Mr. Paget; viz. by injecting dilute ammonia—say, at the least, thirty minims of the liquor ammoniæ B. P., specific gravity 959—into a superficial vein; the vein being first exposed, and its coats pierced with the nozzle of a hypodermic syringe. Dr. Dempster, Dr. Rae, Dr. Langford, Mr. Dallimore, and Dr. Meyler, each in his own words, and from the observation of separate cases, describe the curative effect as being immediate, and the recovery from collapse to be so rapid and startling as to be "almost magical." This method of treatment, of which such remarkable effects are detailed, has been sharply criticised; but Prof. Halford successfully vindicates the claim of the snakes to be considered highly venomous—almost as much so, he intimates, as some of his London critics. They included the tiger-snake, the brown and black snake of Australia, which are affirmed to be as deadly as the cobra and rattle-snake of India. Strong testimony to the efficacy of the treatment in saving life was borne by Australian practitioners who took part in the discussion, and vindicated Prof. Halford's claim to be considered as the discoverer of a means of rescuing many from an otherwise inevitable death.

A VALUABLE addition to scientific literature has been lately published in Boston, viz.: "Alaska and its Resources," by Mr. W. H. Dall, the director of the Scientific Corps of the late Western Union Telegraph Expedition. This work throws much light upon the flora and fauna of this little visited and comparatively unknown portion of America, lately acquired by the United States Government.

F. MULHAUSEN, civil engineer of Brunswick, has invented, according to the *British Medical Journal*, a new freezing and ventilating machine of remarkable ingenuity. The cold is produced by the mechanical expansion of atmospheric air. It produces, when in operation, any desired degree of cold, freezes water without the use of any chemical agents, and will effectually cool and ventilate any apartment or building, on whatever scale, large or small. In hospitals, especially in tropical climates, where the production of ice and the cooling of the air are often matters of great urgency, and always of great value, in theatres and workshops, and in our new Indian barracks, such a machine will be of infinite value. The London theatres can hardly afford to be without it. The labour of one man, with a small 5-horse motor power machine, will produce 100lb. of ice an hour, and cool 15,000 cubic feet of air from 30° to 50° below Reaumur (*sic* in *B. M. J.*) The production of pure ice, for the purpose of cooling our drinking-water and furnishing a cheap mode of replenishing our domestic refrigerating safes during the hot season, will be a great addition to the sum of comfort in London life. Cheap ice will be especially a great boon to the hospital and sick-room; nothing is so refreshing for the parched lips of the sick man. If it were not so costly as it now is, ice would be very largely used in all hospitals, and would be an infinite boon to the sick.

SCIENTIFIC INSTRUCTION AT THE IOWA STATE UNIVERSITY

THE *American Scientific Monthly* states that the faculty of the State University of Iowa have, with marked unanimity, resolved to recommend to the Board of Regents a new course of study for the first three years, in order to adapt the internal organisation of the institution to the spirit of the new organic law passed by the late General Assembly.

According to this plan, the students have four regular hours of work, lecture, or recitation each school day. This time is equally divided between the *letters* (language, history, &c.), and the *sciences* (mathematics, physical and natural science). The direction of these two classes of studies is to be respectively under the Faculty of Letters and the Faculty of Science, each to have complete control over one-half of the students' time.

Of the two hours spent in the different sciences, one hour is devoted to mathematics, the other, in the two first years to physical, in the third year to natural science. This order might, perhaps, with advantage to the student, be changed so as to have the second year in physical science succeed instead of precede the year in natural science; the student would thereby profit from his greater proficiency in mathematics.

After having completed this three-years' course—which is the same for all students in the sciences, but permits the student, under certain wholesome restrictions, to substitute the different languages one for the other—the student can intelligently decide whether he desires to graduate in the sciences, the letters, or in pedagogics. In the last case, he needs not to have studied any foreign language, but will have spent a great amount of time in the study of his vernacular and its literature; he may then enter the Normal Department, and, at the close of one year, receive the degree of B.D. (Bachelor of Didactics). If, however, he has studied foreign languages, especially Latin and German, he can, after two years of studies, selected according to his own pleasure from among the higher branches taught at the University, obtain either the degree of B.Ph. (Bachelor of Philosophy) or B.A. (Bachelor of Arts). To obtain the former, at least two-thirds of the studies selected by him must have been in the department of Science, while to obtain the latter degree the same fraction should have been studied in the department of Letters.

Facilities for part-graduate courses are also offered, and have, indeed, already been improved by several gentlemen in the past year. We abstain from giving forth details concerning this plan until the Board of Regents shall have taken action thereon. We believe, however, that this plan, in a judicious manner, combines the best features of the American College system with the German University system. It will equally prevent one-sidedness and class-drudgery; while securing familiarity with the *elements* of the principal branches of human culture, it will, at the same time, not only permit each mind to follow its own bend, but also give every individual a fair chance to ascertain correctly in what direction his mind leads him.

This new organisation is especially important to those interested in science. Hitherto, most students commenced the study of science after having spent several years in book studies, especially the dead languages. It seemed they had been imbued with the absurd notion that such studies form a proper preparation for the study of physical and natural science. Experience has, however, abundantly confirmed the common-sense view, that the exclusive pursuit of such literary branches, by permitting the faculties of observation and logical reasoning to slumber, does unfit students for the successful study of nature. For the sake of the student, we are glad that this system, at last, has been thoroughly abandoned. The students will hereafter commence the study of physical science immediately upon entering the University, and, in regular succession, become familiar with the elements and principles of the same. They will take up the natural sciences only after they have become familiar with the elements of physical science. Hereby the professors of physical and natural sciences will, at last, have an opportunity given to teach science in such a manner and at such a time as they deem necessary. We are glad to state that this great reform has the cordial support of each member of the faculty.

NEW CLASSIFICATION OF CLOUDS*

NO one is ignorant that the study of clouds is, from the point of view of our practical needs, one of the most important questions meteorology can present us. Indeed, there is no other meteorological manifestation can so fix the attention of the yeoman in the city, of the agriculturist in the country, of the tourist on the mountain's summit, of the soldier in war, of the sailor in continual strife with the disturbances of atmosphere and sea, and, in fine, of the savant in general.

We everywhere see these different social elements continually watching the diverse appearances which the clouds offer us, and casting upon them a look of interrogation, of disquietude, of desire, of a wish constantly renewed to grasp their forms, in order to predict good or bad weather, according to our social needs.

It is especially when the atmosphere threatens some perturbation, rain, storm, tempest, that the common people examine the character of the clouds. But how often, at every moment of the day, do they ask each other about the temperature, hot, cold, or wet, which sensibly exists, while just as often do they pass by unheedingly the clouds, which exert a no less direct or indirect action upon atmospheric variations, as well in the abnormal state as in the normal.

Moreover each country, according to its geographical position, topography, &c., has its own type of clouds. Here the *Cirrus* predominates, there the *Cumulus*, elsewhere such and such form of clouds which do not exist in other places. All these different appearances of clouds are everywhere intimately connected with some particular condition of climate, and these climatological conditions powerfully influence, in their turn, the health, agriculture, navigation, and the thousand other social concerns of humanity. We may say that the clouds are a great book of nature, constantly open for the perusal of all classes of society. Like a compass, the clouds show us at every instant the direction, the velocity, and the altitude of the superior currents which afterward determine the inferior winds at the surface of the earth. There is, therefore, a permanent weathercock as long as the sky contains a single cloud, however small it may be.

There is necessity, therefore, for undertaking a profound study of clouds in their diverse scientific and social applications; for making researches upon the *nature, form, quantity, direction, velocity*, and *azimuthal rotation* of clouds, corresponding to each stratum perfectly characterised by the origin, intimate constitution, and meteoric products of the vesicular vapours and congealed particles which constitute them. For, in the intimate nature of clouds there is a fundamental condition to be established, which results from the physical force acting immediately after gravitation, upon their constitution. This is the element of *heat*.

Despite this scientific interest, despite this practical need which each feels, and which is so universally acknowledged, despite all this, the study of clouds is yet unhappily in its infancy. It is rarely one sees "clouds" inscribed in the meteorological registers of observatories, and when they are, the registrar has wholly neglected to note their form, their quantity, their direction, their velocity, and their azimuthal rotation. Some say simply, "clouds;" others mention the form or the quantity, may be the direction, or exceptionally these three elements, but assuredly they neglect the velocity, and especially the azimuthal rotation which I have first signalised in clouds, and which is not yet understood. In fine, not a single register gives these five elements for one stratum of cloud, much less for each distinct stratum of those which very often appear superposed in the atmosphere.

* Contributed by Prof. Poey, of Havana, to the Semi-Annual Session of the National Academy of Sciences, held at Washington.

We now proceed to present the basis of a new classification, more in harmony with the actual data of the science, and which is the fruit of twenty years' assiduous study upon the clouds, in the Antilles, as well as in Mexico, the United States, and Europe. From the beginning (at that date) of my meteorological studies at Havana, a city situated in the tropics where the *ensemble* of atmospheric phenomena affects an extreme simplicity in consequence of their surprising regularity, which is effaced as we approach the higher latitudes, ever since, I say, I have more and more felt the necessity of reforming Howard's nomenclature. For a long time I was unable to understand the four cloud formations, which I had come to reject, namely: Stratus, Nimbus, Cumulo-Stratus (different forms of Cumulus), and Strato-Cumulus. It was only later that, having been able to consult Howard's original work, I perceived the errors into which Kaemtz and all the meteorologists had fallen. I have, then, to introduce into Howard's classification the essential modifications which the continued progress of meteorology now requires, in order that the nomenclature may be more in harmony with our new conquests. I acknowledge with pleasure that Howard's classification of clouds, which has ruled without a rival for more than half a century (A.D. 1802), was originally based upon a profound study, directed by great acuteness in the observation of facts. But unhappily this is too plainly stamped with the locality where Howard's studies were alone prosecuted. I am speaking of the gray and cloudy sky of Great Britain, whence are his *Strato-mist*, his imperfect distinction of the two strata *Cirrus* and *Cumulus*, or his *Nimbus* (the rain cloud), the difference which he has established between *Cumulus* and *Cumulo-stratus*, without counting many other details of description, which are faulty, in relation to Cirrus, Cirro-stratus, and Cirro-cumulus.

Here is now the vindication of my three new clouds. When certain clouds are spread out uniformly, cover the whole face of the heavens, take a gray or ash-colour, under which state rain may occur for hours and whole days, what name do we give to these clouds? They are not Howard's *Nimbus*, as we conceive them and as they are generally described. These clouds are neither stormy, nor have they electrical manifestations, there is only a fine and continuous rain. Under this stratum—for it is a true stratum—we see constantly other clouds more or less considerable, but always isolated, come to be lost in it and to increase its thickness. On the contrary, before this stratum begins to break up, and during this operation, we see these same formless fragments detach themselves and fly to other regions. This inferior stratum is not alone, for when its disruption has taken place we see through it another stratum of clouds, whiter and less dense, which is broken up in its turn, and ends by disappearing in an inverse order to that of the first inferior stratum. Have we a name for this variety of cloud, so common in time of rain from the inter-tropical regions to high latitudes, especially in winter, during falls of snow? Does Howard's term Nimbus and his description of it account for this sort of cloud? Certainly not. We name indifferently a *Nimbus*, the single storm cloud, as well as this inferior stratum, or yet the two united strata, and all this without electrical manifestations. This is what I call *Pallium*; that is to say, those strata of which the superior is formed of *Cirrus*, constitute the *Pallio-cirrus* and the inferior of *Cumulus* constitute the *Pallio-cumulus*. The fragments of clouds which differ entirely from the *Cumulus* or *Cumulo-stratus* are the *Fracto-cumulus*.

Hence we see the necessity of distinguishing these two strata by different names; Howard's unique name of Nimbus did not do this, while granting him the greatest descriptive exactitude, which he is far from possessing. This necessity results moreover from the fact that the stratum of *Cirrus* is formed many hours, and even many days, before that of *Cumulus*, especially in the equatorial regions, and in fine that the latter disappears first. Without this distinction we are obliged to call the first stratum *Cirrus* and the second *Cumulus*; but as under this state of strata the form and physical properties of Cirrus and Cumulus change completely, there results the confusion and errors daily committed.

As regards Howard's classification as a whole, while retaining the two types of *Cirrus* and *Cumulus*, with his two derivative clouds, *Cirro-stratus* and *Cirro-cumulus*, I reject entirely his *Stratus*, his *Nimbus*, and his *Cumulo-stratus*, together with the *Strato-cumulus* of Kaemtz, for the following reasons: *Stratus*, because it is not (according to Howard) a cloud properly so-called, but a *mist* or *hoar frost*, or yet by the effect of an optical illusion, a *Cirrus*, a *Cirro-stratus*, or a *Cirro-cumulus*, as seen in perspective at the horizon; *Nimbus*, for the reason that it is an inexact denomination which is moreover applied to an idea as vague as incorrect, from the moment that *Cumulus* is not truly rainy as far as it is found displayed, forming a stratum as dense in appearance and below a second superior stratum of *Cirrus*, equally rainy; *Cumulo-stratus*, because it differs in nothing from Cumulus, according to Howard's own definitions, the three fundamental characters of cloud type and of its derivations being common to these two forms, namely: their horizontal bases, their superior hemispherical basins, and the ascending aggregation of their aqueous particles; in fine, *Strato-cumulus* (Kaemtz's cloud of night), because this modification answers in no manner, no more than Howard's *Stratus* to *clouds of night*, and because, on the contrary, its other characteristics correspond to *Cumulo-stratus*.

On the other hand, I substitute for *Nimbus* the *Pallium*, which I sub-divide into *Pallio-cirrus* and *Pallio-cumulus*, according as its stratum is composed of *Cirrus* or *Cumulus*. This term has the triple advantage of embracing the character, the form, and the effect—that is to say, the *Cirrus* or *Cumulus* forming a rainy stratum. I introduce, in fine, the determination of a second transitorial form, which seems to me can be rigorously distinguished from the preceding in the double relation of cause and effect. This is the *Fracto-cumulus* fragments of clouds which are wandering about without determined form, before their transformation into *Cumulus* (or *Cumulo-stratus*), which are precipitated or detached from the inferior surface of the stratum of *Sallio-cumulus*, and which, in fine, are spread out in horizontal bands at the summit of the *Cumulus* on the approach of gusts of wind. These *Fracto-cumulus* differ from the Cumulus in this: they have neither the horizontal base nor the superior hemispherical basins while they are not very extended; but as soon as they become a little more increased we see at once forming at the centre of the fragment a space more dense and blackish than the rest, which gradually settles until it constitutes the horizontal base of the *Cumulus* (*Cumulo-stratus*), the upper part also becoming rounded by degrees. Thus the *Fracto-cumulus* is the infancy of the *Cumulus*, otherwise called *Cumulo-stratus*, the terms being synonymous.

This new classification is wholly based upon the *nature*, the *form*, the *quantity*, the *direction*, the *velocity*, and the *azimuthal rotation* of the clouds corresponding to each stratum fully characterised by the origin, intimate constitution and meteoric products of the vesicular vapours and congealed particles which constitute them. For, in the intimate nature of clouds there is one fundamental condition to be established depending upon the physical force which first acts upon their constitution; it is the element of *heat*. Clouds are therefore distinguished into *snow clouds* and *ice clouds*, of which the constituent particles are more or less congealed; then into *clouds of aqueous vapour*, of which the vesicles, empty or full, float in a medium above the freezing point.

Under this fundamental aspect there are but two types of clouds properly so called, the *Cirrus* and the *Cumulus*. To the *Cirrus* are attached three transitional forms: the *Cirro-stratus*, *Cirro-cumulus* and *Pallio-cirrus*; and to the *Cumulus*, two other transitional forms; the *Pallio-cumulus* and the *Fracto-cumulus*.

Here is a table of my new classification of clouds compared with that of Howard:

NEW NOMENCLATURE OF POEY

First type.	*Cirrus*	Ice clouds.
Derivative	Cirro-stratus	Ice clouds.
	Cirro-Cumulus...	Snow clouds.
	Pallio-cirrus......	Snow clouds.
Second type.	*Cumulus*............	Vesicular clouds of aqueous vapour.
Derivatives	Pallio-cumulus....	
	Fracto-cumulus...	

OLD NOMENCLATURE OF HOWARD.

First type.	*Cirrus*
Derivatives	Cirro-stratus.
	Cirro-cumulus.
Second type	*Cumulus.*
Derivatives—Cumulo-stratus.	
Third type	*Stratus,*
Derived from the three types—*Nimbus.*	

My nomenclature appears probably more in accordance with the nature of the clouds in this sense than the two types, *Cirrus* and *Cumulus*, are rigorously based upon the constitution of ice and snow-clouds of aqueous vapour. Where there is no proof of the existence of Howard's third type, being that, according to this savant, it is a mist which overspreads the earth at sunset, but which is raised in the morning at the first appearance of that luminary. As to number, my nomenclature offers the same determination of cloud forms, that is to say, seven—the two types and five derivatives.

The order in which the clouds are placed in my table correspond, at the same time, to the order of their appearance, from the highest region of the *Cirrus* down to those nearest the earth, where the *Fracto-cumulus* are produced, according as the vapour of water passes from the state of frozen particles to that of aqueous vesicles, or *vice versa*. However, the *Pallio-cumulus*, which serves as a transition between the two types and their derivatives, is found a little more elevated than the *Cumulus*.

I have thought it suitable to modify Forster's vulgar nomenclature by substituting other names more in harmony with the form and nature of the clouds. I give in continuation the old and new classification :

	Forster's Nomenclature	Poey's Nomenclature
Cirrus	Curl-cloud	Curl-cloud
Cirro-stratus	Wane-Cloud	Thread-cloud
Cirro-cumulus	Sonder-cloud	Curdled-cloud
Pallio-cirrus		Sheet-cloud
Cumulus	Stacken-cloud	Mount-cloud
Pallio-cumulus		Rain-cloud
Fracto-cumulus		Wind-cloud

With the exception of Cirrus, whose name, "Curl-cloud," approaches nearest the form of this species of cloud, all the determinations have been changed. The Pallio-cumulus replaces the Nimbus, also named "Rain-cloud."

I.—CIRRUS (HOWARD).

Cirrus, so named by Howard ("the cat's tail," of sailors), are composed of filaments, whose *ensemble* resembles sometimes a curled hair, a twisted tuft, plumage, the flowing tail of a horse, at other times they are disposed in long, straight bands parallel to each other, or divergent palmated, or like a fish bone or vertebral column, their greater axis being oriented according to the sailing of the cloud and the direction of the wind existing at that altitude, which is not slow in making itself felt on the earth. When they form two or more systems of straight parallel bands, by an effect of perspective, they appear to diverge from their point of departure at the horizon and to converge toward the point of the horizon diametrically opposite, as do the rays of the rising or setting sun.

The *Cirrus* have always a whiteness, sometimes brilliant, sometimes pearly dull. The earliest and the latest reflections of the solar rays upon the clouds colour them with a charming rose tint, more or less intense, according to their density. Their propagation is excessively slow, and their altitude is not less than 10,000 metres (more than six and a quarter miles). These clouds are the highest, slowest, most rarified, most variable in their forms, and the most extended. The appearance and disappearance of *Cirrus* proclaim simultaneously the end and the commencement of good weather. The barometer sinks and then rises, the *ensemble* of meteorological accompanying phenomena pursuing the same course. We quote from Howard :

"They are first indicated by a few threads pencilled, as it were, on the sky. These increase in length, and new ones are in the meantime added to them. Often the first formed threads serve as stems to support numerous branches, which in their turn give rise to others.

"The increase is sometimes perfectly indeterminate ; at others it has a very decided direction. Thus the first few threads being once formed, the remainder shall be propagated in one or more directions laterally, or obliquely upward or downward, the direction being often the same in a great number of clouds, visible at the same time ; for the oblique descending tufts appear to converge toward a point in the horizon, and the long straight streaks to meet in opposite points therein, which is the optical effect of parallel extension. The upward direction of the fibres or tufts of this cloud is found to be a decided indication of the decomposition of vapour preceding *rain* ; the downward as decidedly indicates *evaporation* and fair weather. In each case they point toward the place of the electricity which is evolved at the time.

"Their duration is uncertain, varying from a few minutes after the first appearance to an extent of many hours and even days. It is long when they appear alone and at great heights, and shorter when they are formed lower and in the vicinity of other clouds.

"This modification, although in appearance almost motionless, is intimately connected with the variable motions of the atmosphere. Considering that clouds of this kind have long been deemed a prognostic of wind, it is extraordinary that the nature of this connection should not have been more studied, as the knowledge of it might have been productive of useful results.

"In fair weather, with light, variable breezes, the sky is seldom quite clear of small groups of the oblique *Cirrus*, which frequently come on from the leeward, and the direction of their increase is to windward. Continued wet weather is attended with horizontal sheets of this cloud, which subside quickly and pass into the *Cirro-stratus*.

"Before *storms* they appear lower and darker, and usually in the quarter opposite to that from which the storm arises. Steady high winds are also preceded and attended by streaks running across the sky in the direction they blow in."

II.—CIRRO-STRATUS.

Thread-cloud.—Howard's *Cirro-stratus* is distinguished from the pure *Cirrus* by its filaments being smaller, more compact, more ramified, and, so to say, completely stratified. They are lower, more dense, for often the sun's rays pierce them with difficulty. Their whitish tint is clearer, and it also becomes rose colour in similar circumstances. Their motion is a little more rapid. When at the horizon, we only seeing the vertical projection, they take the appearance of a long and very narrow band. Howard says :

"This cloud appears to result from subsidence of the fibres of the *Cirrus* to a horizontal position, at the same time that they approach each other laterally. The form and relative position, when seen in the distance, frequently give the idea of shoals of fish. Yet in this, as in other instances, the *structure* must be attended to rather than the *form*, which varies much, presenting at times the appearance of parallel bars, or interwoven streaks like the grain of polished wood. It is thick in the middle, and extenuated towards the edge. The distinct appearance of a *Cirrus*, however, does not always precede the production of this and the last modification.

"The *Cirro-stratus* precedes *wind* and *rain*, the near or distant approach of which may sometimes be estimated from its greater or less abundance and permanence. It is almost always to be seen in the intervals of storms. Sometimes this and the *Cirro-cumulus* appear together in the sky, and even alternate with each other in the same cloud, when the different evolutions which ensue are a curious spectacle ; and a judgment may be formed of the weather likely to ensue by observing which modification prevails at last. The *Cirro-stratus* is the modification which most frequently exhibits the phenomena of the Solar and Lunar halo, and (as supposed from a few observations, the Parhelion and Paraselene also. Hence, the reason of the prognostic of foul weather—commonly drawn from the appearance of Halo. The frequent appearance of Halo in this cloud may be attributed to its possessing great extent, at such times, with little perpendicular depth, and the requisite continuity of substance.

"This modification is, on this account, more peculiarly worthy of investigation."

III.—CIRRO-CUMULUS.

Curdled Cloud.—It is sufficient that the *Cirro-stratus* sink a little, or that the temperature of the region they occupy be slightly elevated, in order that the frozen aiglets may be reduced to snow, and give birth in consequence to Howard's *Cirro-cumulus*. In the first place the axes of the *striæ* grow round ; then, by degrees, the entire stratification becomes so, until it forms little balls or corded cotton which we call "frizzled" clouds of "curled" sky (in French, *montonnes* or *pommele*,) when it is completely covered ; in Spanish, *cielo empedrado*. On the contrary, if the *Cirro-cumulus* are elevated a little, or if the temperature is lowered, they return to the superior type of *Cirro-stratus*. The little balls of snow are congealed and crystallised anew into aiglets.

The *Cirro-cumulus* are more dense and lower than the *Cirro-stratus*, from which they are derived, although generally the edges of the small agglomerations or of the entire mass of cloud is transformed into *Cirro-stratus*, whenever, by a greater elevation or a lower temperature, the congelation is more vigorous. Their motion is also more rapid, their colour slightly greyish, and they may, moreover, be tinged rose-colour, or, rather, become reddish.

The *Cirro-stratus*, but more especially the *Cirro-cumulus*, are remarkable by reason of a characteristic of the highest importance, from the point of view of the distribution of congealed aqueous vapour, and one which has escaped the sagacity of Howard and his successors. It consists in the most fantastical combinations, reproducing all the formations, hydrological, and physical, of our Continent and seas. Here a deep bay with promontories, capes, peninsulas, isthmuses, &c.; there, a river, brooks, lakes, &c.! further on, vast continents and open seas. The entire mass and the outlines of each of these accidents are besprinkled with *Cirro-cumulus*, sometimes edged with *Cirro-stratus*, of which the volumes of little balls are seen diminishing and vanishing from centre to circumference, while at the side, in the empty spaces, we perceive the purest azure of the heavens. Should it be a lake, the water will be represented by the blue sky, and *terra firma* by the *Cirro-cumulus* which surrounds it. By carefully studying all these transformations we remark in them the greatest analogy with the phenomena of the precipitation and congelation of dew upon solid bodies. There is, therefore, at this altitude, in the same stratum, and one after the other, so to say, some portions of the atmosphere enjoying different degrees of density and of temperature, in order that the congelation of aqueous vapour may take place in so variable a manner.

The influence of *Cirro-cumulus* upon the lowering of the temperature at the surface of the earth is so considerable that the human body feels it at once. A curdled sky at the new moon of a calm night in the tropics is a sky relatively glacial for these latitudes.

This effect may be due to their greater proximity and to the considerable quantity of balls of snow which constitute this type of cloud. The *Cirrus* being found much elevated and the *Cirro-stratus* much less abundant, although both are formed of glacial aiglets, have not the same influence upon the terrestrial temperature. Howard says:

"The *Cirro-cumulus* is formed from a *Cirrus*, or from a number of small separate *Cirrus*, by the fibres collapsing, as it were, and passing into small, roundish masses, in which the texture of the *Cirrus* is no longer discernible; although they still retain somewhat of their relative arrangement. This change takes place throughout the whole mass at once, or progressively from one extremity to the other. In either case the same effect is produced on a number of adjacent *Cirrus* at the same time and in the same order. It appears in some instances to be accelerated by the approach of other clouds.

"This modification forms a very beautiful sky, sometimes exhibiting numerous distinct beds of these small connected clouds, floating at different altitudes.

"The *Cirro-cumulus* is frequently seen in summer, and is attendant on warm and dry weather. It is also occasionally and more sparingly seen in the intervals of showers and in winter. It may either evaporate or pass to the *Cirrus* or *Cirro-stratus*."

Under the generic name of *Pallium*, I have classed two forms of clouds, which present the appearance of a mantle or veil of considerable extent, of very compact texture, well defined at the edges, of an excessively slow march, and embracing, moreover, the visible vault of the sky. According as the *Pallium* is formed of *Cirrus* or of *Cumulus* it is distinguished into *Pallio-cirrus* and *Pallio-cumulus*. The appearance of these clouds signalises bad weather, and their disappearance good weather.

The stratum of *Pallio-cirrus* is first formed, and some hours or some days afterwards that of *Pallio-cumulus* is formed under it. These two strata remain in view at a certain distance from each other, and by their reciprocal action and reaction produce storms and the heavier rains, accompanied with considerable electric discharges. They are electrified, but with contrary signs; the superior stratum of *Cirrus* is negative, and the inferior one of *Cumulus* is positive, the same as the rain which it disengages; while the electricity of the air, at the surface of the earth, is negative. But when these two strata attract each other a discharge is produced; and the inferior stratum continues to pour out the surplus water it contained without giving any sign of electricity, no more than the air in contact with the earth. This state continues until the inferior stratum opens up, the superior afterward, they then disappear, the one after the other. Fine weather then returns. The *Pallium* chiefly predominate during the rainy season, in inter-tropical regions, and in the higher latitudes during winter, at the time of falls of snow. A part of the *Pallio-cumulus*, which has not been reduced, or which has not been scattered to other regions, gathers at the horizon and is transferred into the *Cumulus*. As to the *Pallio-cirrus*, they disappear entirely if fine weather is maintained.

THE ANCIENT LAKES OF WESTERN AMERICA, THEIR DEPOSITS AND DRAINAGE *

THE wonderful collections of fossil plants and animals, brought by Dr. Hayden from the country bordering the Upper Missouri, are from deposits made in extensive fresh-water lakes which at one time occupied much of the region lying immediately east of the Rocky Mountains. The water of these lakes was first salt or brackish, as the remains of oysters and similar estuary forms show. By continental elevation the whole country west of the Mississippi was raised out of the cretaceous sea, and these estuaries became lakes inclosed by raised dry land. The knowledge of this country from the Mississippi to the Pacific Ocean has been accumulated by various explorers besides the writer, as Dr. Hayden, Mr. George Gibbs, Professors W. P. Blake and Thomas Antisell, and Prof. J. D. Whitney and the State Geological Survey of California, and Baron Richtofen, the lamented Rémond, Drs. Shiel, Wislizenus, and others. Besides Mr. Clarence King has explored a large tract of this country, but his very important contributions have not, as yet, been made public. The general character of the topography of the region west of the Mississippi has been given by these great lines of elevation traversing the country from north to south. There are the Rocky Mountains, the Sierra Nevada, and the Coast Ranges. The last is the most modern, and is composed, for the most part, of Miocene Tertiary rocks. Parallel with this lies a narrow trough, in California traversed by the Sacramento and San Joachin Rivers, encroached on by the mountains at places, but still in Oregon and Washington, traversed by the Willamette and Cowletz Rivers. These two sections are drained through the Golden Gate and Columbia. The mountain barriers formerly caused the valleys to consist of great inland lakes, which are now only represented by the chain of small pieces of water still to be seen in that region of country. East of the Sierra Nevada and between it and the Rocky Mountains is another still larger basin. For a thousand miles it has no openings to the westward, which are less than five thousand feet above the sea, but at three points there are gateways, which may be passed, but little above the sea level. These are the *canons* of the Sacramento (Pit River), the Klamath, and the Columbia. These have been cut through by the drainage of the interior of the continent. The former beds of the lakes have thus been left dry and waste—the only real desert on the North American continent. The Sierra Nevada is older than the Coast Ranges, and projected above the ocean, though not to its present altitude, previous to the Tertiary and even Cretaceous ages. This we learn from the fact that strata belonging to these formations cover its base. The mass of the Sierra Nevada is granitic rocks and metamorphic slates, proved by the California Survey to be triassic and jurassic. These slates are traversed by the gold-bearing quartz. East of the Sierra Nevada is a high and broad plateau five hundred miles wide, and from four to eight hundred feet in altitude, and reaches south into Mexico. This mountain belt was once the margin of the Pacific Ocean. Its crest is crowned by volcanic cones like gigantic towers of a fortification. The central portion of this plateau was called by Fremont "the great basin," as it forms a hydrographic basin drained by the Columbia and Colorado. The former makes its way to the ocean through a gorge in the Cascade Mountains, whilst the latter escapes to the south through a series of *canons*, of which the most important is nearly a thousand miles in length, and from three to six thousand feet deep. In vol. vi. of the Pacific Railroad Reports the country of the Columbia is described and the reasons for concluding that it had cut its way through the Cascade Mountains, and similar facts were observed in the district drained by the Klamath and Pit Rivers. Certain peculiarities are to be seen in the country between the Sierra Nevada and Rocky Mountains. In the northern and middle portions of the great table lands the surface is somewhat thickly set by short and isolated mountain ranges, sometimes called "the lost mountains." These rise like islands above the level of the plain, and are generally com-

* Contributed by Professor J. S. Newberry to the Proceedings of the New York Lyceum of Natural History.

posed of volcanic or metamorphic rocks. The spaces between them are level desert surfaces. Towards the north and west, on the tributaries of the Columbia, Klamath, or Pit Rivers, the plateau is cut by these streams, and the deposit can be examined. The rocks are nearly horizontal, some are coarse volcanic ash, with fragments of pumice and scoriæ. Others denominated "concrete" resemble the old Roman cement. Many are quite white, and are generally known as "chalk-beds," though they contain no lime. The late Prof. J. W. Bailey determined these to consist of the remains of fresh-water species of Diatomaceæ. The stratification and horizontality of these beds show them to have been thrown down from great bodies of water which once covered the greater part of these level plains. From south-western Idaho and eastern Oregon have lately been brought large collections of animal and vegetable fossils, of great variety and interest. The plants were mostly collected by the Rev. Thomas Congdon, of the Dalles, Oregon, at great risk of life and while exposed to great hardships, on the flanks of the Blue Mountains. They are apparently Miocene, forming twenty or thirty species, nearly all new, and which represent a forest growth as varied and luxurious as can be found on any portion of the continent. The animal remains came mostly from the banks of Castle Creek in the Owyhee district, Idaho. These were sent by Mr. J. W. Adams of Ruby City. They consist of bones of the mastodon, rhinoceros, horse, elk, and other large mammals of which the species are probably in some cases new, in others identical with those obtained from the deposits examined by Dr. Hayden. There are also bones of birds and great numbers of the bones and teeth of fish. These last are cyprinoids applied to *Mylopharodon*, *Milocheilus*, &c., some three feet and more in length. Also many fresh-water shells, as *Unio*, *Corbicula*, *Melania*, and *Planorbis*. These illustrate the inhabitants of the extinct lakes, which were of a much larger size and greater depth than the great fresh-water lakes which now lie upon our northern frontier. Between these were areas covered with a luxuriant and beautiful vegetation and inhabited by herds of elephants and other great mammals. In the streams were numbers of fish and mollusks of species now extinct. Gradually these lakes evaporated and at last became dry. In the Klamath lakes and Suisun Bay we have their remanents, whilst on the Columbia the drainage-streams have cut *canons* two thousand feet deep. At times the peace and quiet of this country were disturbed by violent volcanic eruptions from the peaks of the Sierra Nevada, which ejected showers of ashes covering the land and filling the lakes, as is seen in the strata now existing, some ten and twenty feet thick. Sometimes lava was thrown out and covered hundreds of miles of surface, and is now seen as solid basalt. Then quiet reigned, and new fresh-water deposits were formed, only to be succeeded by other volcanic disturbances. Some parts of this plateau have not been drained, and the remains of the ancient lakes now exist as Salt Lake, Pyramid Lake, and others. These are gradually diminishing, as is to be seen by indications all around their borders, where we can trace ancient shore lines. The alkali plains and salt flats mark the places of dried-up lakes; all of these still existing being excessively salt. This is the state of things at the north. In the south, the great Colorado plateau is without mountain barriers or local basins, and there are few traces of extinct lakes. This arid district was once a beautiful and fertile plain, drained by the Colorado, which, on the western margin poured over a precipice five thousand feet or more high, into the Gulf of California, which then reached several thousand miles farther north than it does now. In time the river cut its way farther back through the subjacent rocks, and at last formed that remarkable gorge, nearly a thousand miles long and three to six thousand feet deep. As the channel deepened, the country around became dryer, until it was the arid plain we find it now. Almost no rain falls on this plain, therefore the walls of the *canon* remain sharp-cut precipices unaffected by moisture. On the east of the Rocky Mountains is the great plateau country of the plains, which differs from the country to the west, by not being bordered on its east by a mountain chain, but sloping gradually to the Mississippi. Its surface was also covered by great fresh water lakes, larger, if not more numerous, than those now existing on our northern boundary. From the northern portion of this plateau Dr. Hayden has brought his specimens, and he has there obtained a harvest of scientific truth which will form for him an enduring and enviable monument. He has studied the deposits which accumulated in these lakes, and they are very rich in specimens of both animal and vegetable life. The vertebrate remains have been studied by Dr. Leidy, who has published his investigations in the splendid monograph so well known, and which forms a contribution to palæontology, not second in value or interest to that made by Cuvier, by his illustrations of the fossils from the Paris basin, nor to that of Falconer and Courtly, descriptive of the Sewalik hills of India. The first instalment of the plants have been described by Dr. Newberry, in the report of Colonel W. F. Reynolds, U.S.A., not yet published. The descriptions are published in the Annals of the Lyceum of Natural History of New York, vol. 9, 1868. The general conclusions from these examinations have greatly enlarged the flora of the Tertiary and Cretaceous periods. Since then largely additional material has been collected by Dr. Hayden, Mr. Congdon and Dr. Le Comte, and Dr. Newberry; and in Alaska by Mr. W. H. Dall and Captain Howard, and by others in Greenland. The flora and fauna of the lake deposits on both sides of the Rocky Mountains apparently belong to one and the same geological age, and tell the same story as to topography, climatic conditions, and development of animal and vegetable life. There is a striking difference in one particular between the deposits east and west. In Oregon, Idaho, and Nevada, volcanic material has accumulated in the lake basins to a much greater extent than on the east of the mountains. The deposits of the Upper Missouri regions are shales, marls, and earthy limestones, with immense quantities of lignite and almost no traces of volcanic material. The animals and vegetables of the Tertiary here were in much greater number than now. This existed long enough for thousands of feet to accumulate in the lake basins, and sometimes these deposits are found turned up on edge on the flanks of the mountains, showing that this chain, although existing in embryo from the earliest palæozoic ages, has been subjected to great modifications. The collections made by Dr. Hayden at various points differ among themselves. In every bed are new species, and between some deposits there are no connecting links. In the beginning of the cretaceous the land surface and climate of this continent were similar to the present period, the trees for the most part belonged to the same genera. Then most of the region west of the Mississippi sunk beneath the ocean, and the cretaceous deposits were made containing more tropical species. There were islands in the western sea, and the Gulf Stream had a course north and west from the Gulf of Mexico to the Arctic Sea. In the earlier Tertiary ages the continent here emerged from the ocean and approached the previous and present conditions indicated by the flora. In this category are to be placed the Green River Tertiary beds, those of Mississippi studied by Lesquereux, and those of Brandon, Vermont. In the Miocene the continental surface was broader, the western lakes were fresh, and the vegetation very much like that of the present day. A few palms then grew as far north as the Yellow Stone River, and a flora flourished in Alaska and Greenland as varied and as luxuriant as now grows along the fortieth parallel. At this time land connected Europe, this continent, and China, as the flora in this region was essentially the same, a large number of plants being common to the three continents. The mammals were peculiar; over our western plains rolled herds of great quadrupeds rivalling in number and variety those of southern Africa at the present time. This state of things continued during the Pliocene age and up to the ice period. In the middle Tertiary the climates of Alaska and Greenland were those of New York and St. Louis at present. Then came the Glacial epoch, and the climate of Greenland of the present time is brought down to New York, and all the northern portion of the continent is wrapped in ice. This change of climate was gradual, but the animals and vegetables were driven southward until the glaciers reached the thirty-eighth or fortieth parallel, when a temperate climate prevailed in Mexico, and only on the southern border would the temperature be what it had previously been on our northern border. Thus nearly all the animals were exterminated or forced into very narrow limits in southern Mexico. Plants bore their expatriation better, and as a consequence we find the present flora of our continent much more like that of the Miocene than is our fauna, though most of the forest-trees have become extinct. Of these the Glyptostrobus is an example, which grew all over our continent and northern Europe. In the glacial period it was exterminated except in China, where it now grows. So when we compare the present flora of China and Japan with that of the eastern half of our continent, we find the strongest proofs of their relationship; many species are identical, while others are but slightly changed. Some of the great mammals of the pre-glacial period bade defiance to these changes, as the mastodon and elephant, both of which could endure great changes of climate, and the mammoth, we know, was defended from cold by a thick coat of hair and wool. We find its remains embedded in peat-bogs and marshes, where they were mired and suffocated, and it is even claimed that here, as in Europe, it was contemporaneous with man.

SCIENTIFIC SERIALS

Annales de Chimie et de Physique, July, 1870.—This number contains a paper, by M. A. Müntz, on the Composition of Skin, the modifications it undergoes during the process of tanning, and on the decomposition of tannin in the tan-pits. The experiments detailed in this paper were undertaken by the author to determine, from a theoretical point of view, the changes taking place in the conversion of hides into leather. A piece of ox-hide which was being converted into leather for the soles of boots was selected as the most appropriate for the investigation, and the operations were commenced after cleansing and depilation. In these processes no chemical change would take place, except perhaps in cases in which lime is employed in the depilation, a small quantity of which is deposited in the skin, but afterwards removed by a solution of glucose. The following process of *swelling* consists in steeping the hides in an acid liquid for a time varying from three weeks to two or three months. This acid liquid contains acetic and lactic acids and a small quantity of tannin: its effect is to distend the pores of the epidermis and thus facilitate the subsequent process of tanning. During the swelling so much water and other substances are absorbed that the hide increases in weight to such an extent that it is now as heavy as it was before the cleaning and depilation, the addition of dry matter amounting to nearly 19 per cent.; a small quantity of mineral matter is lost, the augmentation being due to the addition of carbon, hydrogen, and oxygen. After eleven months in the tan-pit an increase of nearly 83 per cent. was observed; a small diminution in the quantity of nitrogen took place, while the mineral constituents and carbon, hydrogen, and oxygen were augmented. The organic materials added had exactly the same composition as those absorbed by the hide during swelling, but they differ much from the composition of tannin. The author believes that the loss of nitrogen during the tanning process is due to a decomposition of part of the leather, for ammonium salts were found in the liquor from the tan-pits. The structure of leather is also very different from that of skin; while the latter is fibrous the former is spongy; skin will absorb three or four times its weight of water, swelling considerably, but leather scarcely absorbs one and a half times its weight, and without increase of volume; 100 parts of skin by treatment with boiling water leave 3·35 of insoluble matter, the rest being converted into gelatine; the residue from leather under the same circumstances is about 48 per cent. The compound obtained by the action of tannic acid on gelatine differs very much in composition and properties from leather. A description is given of a process for the estimation of tannic acid; and M. Müntz announces the observation that the residue, after boiling skins with water, contains a substance dissolved by Schweitzer's cupro-ammoniacal reagent, and thus resembling cellulose, but containing about 15 per cent. of nitrogen. The author next gives an account of the composition of the mineral substances present in skin and in leather, and points out the changes produced during the tanning. He concludes that the tannic acid is partially converted into more oxidised compounds, as gallic acid, glucose, lactic, acetic, formic, carbonic acids, and most probably propionic acid, the remaining less oxidised residue converting the skins into leather. The experiments detailed in this paper were carried out in the laboratory of M. Bossingauult.—M. L. Henry contributes a paper on glyceric tribromhydrine, the object of which is to show that the compound obtained by Berthelot by the action of phosphoric bromide on dibromhydrine or epibromhydrine, and described by him as tribromhydrine, must have been some other compound. The author points out that the saturated compounds of the triatomic radical $(C_3H_5)'''$ obtained either from the allylic group or from glycerine, are always identical, with the single exception of Berthelot's tribromhydrine, which boils at 180°, while the tribromide of allyl obtained by Wurtz by the action of bromine on allylic iodide, boils at 217—218°. He also shows that the analysis given by Berthelot is not as concordant with the theoretical numbers as might be expected, and that the physical properties described by him do not correspond with those that might be looked for in a compound of the composition $C_3H_5Br_3$. Finally, he announces that by the action of phosphoric bromide on pure dibromhydrine, he has obtained the true tribromhydrine, which, in all its physical and chemical properties, is identical with the tribromide of allyl of Wurtz.—The next paper is by M. P. Schützenberger, on a new acid of sulphur. Schönbein observed that when a solution of sulphurous acid is placed in contact with zinc the liquid becomes yellow, and acquires the property of decolorising indigo and litmus, but after a short time sulphur is deposited and the reducing action of the liquid disappears. M. Schützenberger has employed a concentrated solution of sodic bisulphite in the place of the sulphurous acid, and has succeeded in preparing the salt of a new acid. A flask of about half a litre capacity was filled with zinc shavings and a strong solution of sodic bisulphite poured in. The vessel was then closed and placed in cold water; after half an hour the odour of sulphurous acid had disappeared, when the liquid was poured into a flask containing $1\frac{1}{2}$ litres of alcohol and the mixture agitated. A crystalline deposit of the double sulphite of sodium and sodium was produced, and from this the clear liquid was rapidly decanted into bottles, which were filled entirely, closed, and allowed to cool. After a short time a mass of fine colourless needles was deposited, consisting of *sodic hydrosulphite* $\left.\begin{matrix}(SO\,H)'\\ Na\end{matrix}\right\}O + H_2O$. It is rapidly oxidised by exposure to the air into sodic bisulphite, and the solution when placed on filter paper is so rapidly oxidised that sufficient heat is evolved to cause steam to be given off. On adding sulphuric or oxalic acid to the solution an orange red colour is produced, but the liquid is rapidly decolorised with deposition of sulphur. Sodic hydrosulphite may also be obtained by nascent hydrogen evolved by electrolysis. The production of this compound is represented as follows:—

$$\underset{\text{Sodic bisulphite}}{\left.\begin{matrix}(SO)''\\ Na\,H\end{matrix}\right\}O_2} + H_2 = \underset{\text{Sodic hydrosulphite}}{\left.\begin{matrix}(SO\,H)'\\ Na\end{matrix}\right\}O} + H_2O.$$

The oxidation of the hydrosulphite thus:—

$$\left.\begin{matrix}(SO\,H)'\\ Na\end{matrix}\right\}O + O = \left.\begin{matrix}(SO)''\\ Na\,H\end{matrix}\right\}O_2.$$

The decomposition of the acid:—

$$2\left.\begin{matrix}(SO\,H)'\\ H\end{matrix}\right\}O = 2\,H_2O + S + SO_2.$$

The solution of the sodium salt is gradually transformed, out of contact with air, into sodic hyposulphite and water:—

$$2\underset{\text{Sodic hydrosulphite}}{\left.\begin{matrix}(SO\,H)'\\ Na\end{matrix}\right\}O} = H_2O + \underset{\text{Sodic hyposulphite}}{S_2O_3Na_2}.$$

By means of an alkaline solution of sodic hydrosulphite indigo is rapidly converted into white indigo; acetone produces isopropylic alcohol; and oil of bitter almonds is partially transformed into benzylic alcohol. This substance promises to be a useful reducing agent for many operations.

In the *Revue des Cours Scientifiques* for Aug. 27 is a translation of Prof. Hofmann's address in honour of the late Prof. Graham, delivered before the German Chemical Society, which occupies the greater part of the paper. Then follows a report of the sittings of the Anthropological Society of Paris on April 21 and May 5, containing a report on the Ethnology of Lower Brittany, which led to an animated discussion on the origin of species and the theories of transformation and natural selection. A translation is also given of Prof. Sterry Hunt's paper, read before our Royal Society, on the probable seat of volcanic action. In the number for September 3 is a report from M. Giraud-Teulon on the causes of myopy, its relative frequency, and its influence in military efficiency. M. Marey continues his interesting and valuable paper on the flight of birds, which is here discussed from a mechanical point of view. We have the reports of the sittings of the Anthropological Society on May 19, June 2 and 16, and July 7 and 21; the subjects of discussion being the brain of man and of the primates, pathological osteology of the newly-born, acclimatisation of Europeans in Africa, and the conclusion of the discussion on transformation. The *variétés* comprises a paper by Prof. Nélaton, of the Faculty of Medicine of Paris, on wounds produced by fire-arms.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, Aug. 29.—A single paper only was read at this meeting by M. J. Boussinesq, a theoretical essay on the laws, found by experiment by M. Bazin, for the uniform flow of water in open channels. The formulæ deduced by the writer from theoretical considerations he found to agree with those indicated by M. Bazin from experiment, and also not to differ materially from those which M. Darcy has given to represent the rapidity in circular pipes full of liquid, for the axis of the pipe or at one-third or two-thirds of the radius.

NEW YORK

Lyceum of Natural History, May 9.—The President in the chair. Professor Charles A. Seely "On the Constitution of Ammonium-amalgam."—Dr. Isidor Walz's "Notes on the Extinction and Reducing Power of Mercury." "At the last meeting of the Chemical Section of the Lyceum, I drew attention to the conversion of liquid zinc-amalgam to a gray powder, when shaken with a solution of potassium bichromate. Subsequently I became convinced that this phenomenon was solely due to the extinction of the mercury, and have made a number of experiments regarding the phenomenon of which I present the following results. It is hardly necessary to state that the mercury used was absolutely pure. It is very difficult, but essential, to use chemically pure mercury, as even a very small trace of a foreign metal is often sufficient to influence the results materially. The experiments were made in ordinary test-tubes, in which the materials were shaken a length of time varying from a few seconds to ten minutes. I believe that we ought to distinguish between two methods or kinds of extinction, namely the mechanical and the chemical. The former is effected by a very large number of solutions of neutral salts, which exert no chemical action on mercury, and even by pure water, if shaken long enough. The extinction of the mercury in this case is produced simply by the interposition of fine films of the liquid between the globules, into which the mercury is separated by the mechanical agitation, and which are thus prevented from running together again. By mechanical extinction mercury is converted into what appears to be a fine powder, which, however, never loses its white colour and metallic appearance, and under the lens its globular structure is clearly seen. Quite interesting in many cases are the reactions which accompany the chemical extinction of mercury, which takes place when the metal is shaken with a solution of a salt, by which it is chemically affected. In these cases the newly-formed mercury compounds act in the same way as the films of liquid in the former instance, preventing the separate globules from reuniting. A finer division of the metal is obtained in less time than by the mechanical method, and the resulting metallic powder is generally of a dull gray leaden colour. When a solution of potassium bichromate is poured upon mercury, the convexity of the surface is at once destroyed; presently the surface is tarnished and begins to look wrinkled, while at the same time a greenish-black powder commences to deposit itself. This greenish-black powder is a mixture of chromic and mercurous oxide; it is formed abundantly when the two liquids are agitated more or less strongly; the mercury is at the same time completely extinguished, and at the end of the reaction neutral potassium chromate alone remains in solution, which is not acted upon by mercury. Ferric chloride extinguishes mercury; ferrous and mercurous chlorides are formed. Potassium permanganate also acts upon the metal; manganic and mercurous oxides are deposited, while potassic hydrate remains in solution. Mercury shaken with Fehling's solution is simply extinguished mechanically, when all the reagents used are pure; but when a very small quantity of zinc-amalgam is added, Cu_4O is reduced from the solution. A solution of potassium ferricyanide does not affect the fluidity of mercury; but when the two are shaken together a green powder is formed in large quantities, which, if allowed to stand, changes to a dark, and later still to a light blue colour. Potassium ferrocyanide appears to be formed at the same time. I am still engaged in studying this interesting reaction, and will endeavour to determine if this blue powder is Prussian blue or not. Sodium hyposulphite, also, does not affect the mercury physically; on agitation, however, a heavy black powder, mercuric sulphide, is formed. Its amount increases with the lapse of time, and in one of my test-tubes, which has hardly been disturbed for weeks, the original black sulphide has assumed a yellowish red colour. I conclude from these observations that the reducing power of pure mercury is greater than is generally supposed, and I expect to be enabled to obtain some interesting results from an extension of these experiments. I have repeated some of Lowe's experiments, which he described at our last meeting, and can state that similar results are obtained by substituting palladium bichloride for the platinum salt. I cannot, however, yet coincide with him in considering his final product as hydrogenium-amalgam, as by every method by which it has yet been made it contains another metal besides mercury and hydrogen, namely, either platinum, palladium, gold, or silver, in no inconsiderable proportion."

May 16.—The president in the chair. Mr. Frederick Prime, jun., read a paper on the Metallurgy of Argentiferous Galenas, giving details of the several processes at present in use, with their various advantages and disadvantages. He entered into a detailed account of the methods put into practice in Freiberg, and showed how these could, and would, be used in the United States.

THURSDAY, SEPTEMBER 15, 1870

THE MUSEUMS AND SCIENTIFIC INSTITUTIONS OF LIVERPOOL

FOR the third time since the founding of the British Association for the Advancement of Science, its annual meeting is being held in Liverpool. Those who, from former visits, are conversant with the town and its multitudinous attractions, will have every inducement to attract them thither once more; but as there are many who are paying Liverpool a visit for the first time, it may not be superfluous to direct special attention to those points which come more especially under the notice of all who are interested in scientific objects and pursuits, the more especially as during the meeting of the Association time is limited, or fully occupied during the chief portion of the day.

In Liverpool, then, first and foremost stands the Derby Free Public Museum, which is for once to belie its name by being closed to the general public during the meeting of the British Association, being only open to the members. As the reception-room occupies the central hall of this building, it will be of necessity much visited, and we have not the slightest doubt that its fine collections will be duly appreciated and admired. Visited yearly by upwards of half a million people of all classes it may be said without prejudice to other and much older country museums, to be the finest museum out of London. It took its rise in the zoological collection presented to the town by the late Earl of Derby some twenty years ago. The munificence and philanthropy of the late Sir William Brown induced him to erect the handsome building in which the Museum and Free Library are now placed, entirely at his own cost (about 35,000*l.*), on land given by the Corporation for that purpose. Since that time the museum has acquired by special gifts some extremely valuable and large collections, to be hereafter noticed more particularly, and is in daily receipt of specimens and contributions from its many admirers. Owing to the great maritime trade of Liverpool, the Museum is being constantly supplied with valuable specimens, collected by ships' officers and seamen all over the world; and as these gifts are acknowledged in the local papers each week, every inducement is held out for others to follow such good examples. The Museum, which is under the able curatorship of Mr. T. J. Moore, aims at being a Zoological Museum, and, moreover, essentially a practical and working one. For this purpose the specimens are arranged as far as possible in open table-cases, and proceed in order from the lowest animal forms, the Protozoa, through all the Invertebrata, to the Reptilia, Aves, and Mammalia.

Beginning in the room labelled Bird-room No. 1, the table-cases are filled with fine specimens of Protozoa, Corals, &c., and as the general arrangement in the cases throughout the Museum is pretty much the same, its completeness and perfection will be gathered if we describe one case more particularly in detail. We will take the large class of Spongida. In the centre of the case is placed a card about the size of a page of an octavo book, on which are legibly printed the chief characteristics, and an accurate description of the class of animals which are represented in the case. In the Spongida and many others, these descriptions are taken from Professor Huxley's work on the Classification of Animals. Around this card are arranged the mounted specimens, each accurately named and its locality given. British species are marked by distinctive labels, and the case is completed by the introduction of fossil specimens. Thus at a glance there is given an accurate description which can be soon copied out, and around it are placed the recent and fossil specimens of the class of object described. In short, upright, cases above these are arranged any more conspicuous and showy objects of the same class. The simplicity and thorough usefulness of the Museum may be easily imagined when it is understood that this system is pursued throughout, and that, in the large classes of Insecta and Crustacea, all the subclasses and distinctive genera are similarly treated.

Before leaving this room we cannot but notice a magnificent specimen of the rare coral *Isis Hippuris*, from Port Elizabeth (?), and the fine collection of the elegant Venus' flower-baskets (*Euplectella*), in reality a sponge, from the Philippine Islands. In Bird-room No. 2 we proceed, through the classes of Polyzoa and Molluscoida and Ascidia, to the Mollusca proper. There is a fine case of *Terebratulæ*, which deserves notice, as the recent specimens are very numerous, and are contrasted with good fossil specimens. A hasty glance showed us recent specimens from New Zealand, the Moluccas, China, Philippine Islands, South Australia, America, Sandwich Islands, Japan, Sicily, North Britain, Peru, Norway, Panama, Singapore, California, the Mediterranean, &c. &c., —surely not so bad for one case of rare shells in a local museum.

In the next rooms, Bird-rooms Nos. 3 and 4, the Bivalve shells are followed by the Gasteropoda and Cephalopoda, proceeding onward to the Crustacea and Insecta, of which there are—especially in the latter class—very fine and well-arranged collections. In the collection of Mollusca and Gasteropoda is incorporated a valuable typical collection presented to the Museum in December 1869 by Mr. S. Smith. All around the three rooms we have described are arranged large upright wall-cases filled with stuffed specimens, chiefly birds, whilst in Room 5 are arranged the collection of fish and reptilian remains. There is a fine skeleton of the Dodo, from Mauritius, which was presented by Mr. Higginson, and is only excelled by the slightly more perfect ones in the British Museum and the Cambridge Anatomical Museum.

The collection of stuffed animal remains is arranged in the basement of the building, and is chiefly remarkable for the fine specimens of the Gorilla which are there exhibited. It is under process of re-arrangement, and so does not show to much advantage. The British collection is excessively poor, especially in birds, and there is every opportunity to any one who has a collection of British birds to present them to the Museum, where they will be much appreciated, and certainly properly utilised.

In a room below the basement is a small but almost unique collection, which we cannot but think will be largely visited this week. We allude to the collection of aquaria, where many of the rarest and most interesting marine and freshwater animals may be seen to great advantage. It is no slight advantage for the naturalist to study from living specimens the appearance and habits of such rare animals as the Axolotl from Mexico, and the Proteus from the caves of Adelsberg. In other aquaria are specimens of salamanders from Central Europe, the gigantic bull-frog of America, and many curious and rare American fish. There are also examples of the English lump fish, grey mullet, soles, flounders, shanny, and the rare blenny. The beautiful appearance of these fish, and their varied and in some cases gorgeous hues, cannot be imagined by those who have only seen the same fish when dead. There are also several fine tanks full of sea-anemones in very thriving condition.

We have now nearly exhausted the scientific portion of the Museum; it only remains for us to notice the poor collection of geological specimens, which looks particularly bad just at present, as it is under process of arrangement. Still it is not much at the most, and is decidedly inferior in every way to the rest of the contents of the Museum. There is, however, a small case full of fine specimens of ferns and other carboniferous plants, collected by one of the local secretaries, the Rev. H. H. Higgins, from a railway cutting about eight miles from Liverpool. We hope to direct special attention to this new bed in another column, as it is within such easy distance of Liverpool, and the remains there found are so valuable and plentiful that all geologists attending the Association should pay it a visit.

Besides the above, there is still much to be seen in the Derby Museum, for in 1867 Mr. Joseph Mayer, a wealthy Liverpool citizen, presented to the town his exceedingly valuable collection of antiquities, coins, and gems. Its value is shown by the following extract from the report of the Library and Museum Committee :—"This collection, it is no exaggeration to say, is the finest of the kind ever presented to the public. In some of its departments, those of Wedgewood ware and ivory carvings, it is unique. It contains the best collection extant of illustrations of the Liverpool pottery ware, a manufacture for which the town was once celebrated, but which has long been extinct In Egyptian and Assyrian antiquities it is very rich, particularly in gems. The Fausset collection of Anglo-Saxon remains, the finest extant, forms a portion of it, together with a large number of ancient manuscripts and illuminations."

In recognition of this valuable gift a statue has been erected to Mr. Mayer in St. George's Hall. The collection is arranged in three tiers of galleries, round a wide open space in the centre of the Museum, and communicating with each other and the rest of the Museum. We cannot afford space to give any full description of this Museum, but its varied collections of antiquities, ancient armour, ancient weapons, musical instruments, coins, gems, watches, carvings, intaglios, Wedgewood and Majolica ware, rare MSS. and Mexican hieroglyphics, will all command crowds of visitors. In the upper gallery is placed *the Collection of the Lancashire and Cheshire Historic Society*, which holds its meetings in Liverpool, and a collection of valuable antiquities from the sea-coast between Leasowe and Hoylake in Cheshire, which belong to Mr. Ecroyd Smith and others, and concerning which Mr. A. Hume, of Liverpool, recently wrote a long and illustrated description in his "Ancient Meols"—the name of an old Anglo-Saxon and English settlement supposed to have been submerged by the sea.

The next place which will claim the most attention in Liverpool, after the Derby Museum, is the *Bidston Observatory*. This is reached by taking the ferry boat to Seacombe, and thence either omnibus or cab to the Observatory, about two miles distant. It stands in a fine situation, commanding most extensive views, and is about 200 feet above the level of the sea. Its great attraction, beside the fine equatorial telescope it contains, are its ingenious self-registering meteorological instruments. Of these the first to see is King's self-registering barometer, where, by means of an ingenious arrangement, the hourly movements of the barometer are self-recorded. There are only three such instruments in England—this one, one in Birmingham, and one in Mr. Crossley's private observatory in Yorkshire; and they are stated to be superior to the ordinary photographic method employed elsewhere. In an upper part of the building is an instrument whereby, on the same sheet of paper, four different set of observations are self-registered. These are, the velocity of the wind, its pressure and its direction, and the amount of rain-fall. The instrument only requires to be attended to once a day, and then acts twenty-four hours without intermission. When we visited it on Saturday the pressure of the wind had reached as much as 65 lbs. per square foot, and its velocity at that time was about seventy-one miles per hour. The Observatory is open to all members of the Association on production of their tickets, and Mr. Hartnup, its director, will have great pleasure in showing and explaining all the instruments. We must not omit to notice a very ingenious and beautiful chronograph for recording transits by means of a most delicate piece of mechanism acting by electricity, and literally writing its own observations.

Returning to Liverpool, there are one or two more museums which deserve attention. The first of these is the *Museum of the Royal Institution*, in Colquitt-street. Before the opening of the Derby Museum, this was the principal museum in Liverpool, but it is now left comparatively in the shade. It is essentially a natural history museum, but the specimens are not well stuffed, and, together with the rooms, which are badly lighted up, have a very dingy and dirty appearance. There is, however, a fine collection of birds ranged round the walls of the two best rooms, the centre of which is occupied by a large collection of shells, neatly arranged and displayed, and well named, of which the chief specimens came from the collection presented to the museum by Mr. George Green, of Liverpool. The mineralogical collection, which wants re-arranging and classifying, has lately received large additions from the collection of the late Dr. James Stewart Trail, of Edinburgh, lately presented to it. There is a geological collection arranged round an upper gallery, but of which nothing commendable can be said. The materials are there for a good typical collection, and there are a few good American collections which are interesting; but they all sadly want naming and properly arranging, localities given, &c.

Next to this is an Economic Museum, which is worth visiting, arranged somewhat on the system employed at South Kensington. Besides these, there is a herbarium, a fair collection of butterflies and beetles and a collection of fungi from the Liverpool district, and a good collection of zoophytes from Bootle, near Liverpool. There is also a small collection of ethnographical objects, weapons, Indian remains, flint axes, &c., and the usual miscellaneous objects of a local museum. There is a large stuffed specimen of the sea-elephant from the South Shetland Islands, which is valuable, as the species is yearly becoming much rarer. It seems a pity that some arrangement could not be made between the two museums, so that this one could be lightened of some of its heterogeneous contents, and more room given for a better display of some special collections. Besides this, those who are interested in mineralogy should not fail to visit the *Medical Institution*, in Hope-street, where Phillips's mineral collection is well exhibited. There is also the *Museum of the Royal Infirmary School of Medicine*, which is more likely to please those interested in medical pursuits than the general public.

To those botanically inclined, the extensive *Botanical Gardens in Edge Lane* will be very attractive. They cover an extent of about eleven or twelve acres, and are very tastefully laid out, and the large conservatories contain many fine and choice exotics.

Those who are interested in the practical application of science to the requirements of the present day, should not fail to visit *the Liverpool Sewage Utilisation Works at Sandhills*. These are open to all members of the Association, and will be found to afford much practical knowledge on a subject that is yearly attracting more attention.

The Liverpool scientific societies, though they have existed many years, have failed to attract very much attention, or to become prominently known. The most important of these is *the Lancashireand Cheshire Historic Society*, which was started about 1847, as a purely antiquarian society in all matters relating to the two counties. It has published a set of transactions containing much valuable information; but of later years it has enlarged its scope and taken in other branches of scientific knowledge, with a result, we fear, not commensurate with the wishes of its promoters. *The Liverpool Philosophical Society*, and *the Liverpool Geological Society*, unlike the similar societies in Manchester and Leeds, are but little known outside the city in which they hold their meetings.

Soon after Owens College was founded in Manchester, a somewhat similar college, called *Queen's College*, was started in Liverpool; but whether owing to lack of energy or good management on the part of its directors, or from the overpowering influence of the old-established Collegiate Institution, it has certainly failed in approximating in any direction to the national importance and value that the former college has obtained.

In some degree compensating for these failures, Liverpool possesses a very extensive and much-patronised *Field Naturalists' Club*, which does a great deal by weekly excursions to infuse into its members a taste for natural science and out-of-door scientific work, and there is little doubt but that from all its members the British Association will receive a hearty welcome; and let us hope that from this year's meeting may date an increased impetus to Science in the neighbourhood.

J. P. E.

NOTES ON THE GEOLOGY OF THE COUNTRY AROUND LIVERPOOL

THE following brief notes on some of the points of geological interest may perhaps be of use to geologists from the South of England visiting the British Association's Meeting at Liverpool.

The tract of country lying between the rivers Dee and Mersey, known as the peninsula of Wirral, is composed of Triassic rocks, forming a series of undulating ridges and valleys, running parallel with the strike of the rocks. The average elevation of the crest of the hills is about 150 feet, and they, as well as the valleys, are more or less covered with glacial drifts. The northward prolongation of the hills and valleys is abruptly terminated by a broad plain, but little raised above the sea-level, which forms the seaward portion of the Hundred of Wirral. This plain, which is composed of peat partly covered with alluvium, is drained by the River Birket, which flows eastward along its whole length, from a little south of Hoylake, until it falls into Wallasey Pool, an arm of the River Mersey, which separates the tract of comparatively high land known as Wallasey (anciently an island) from the Triassic hills south of the Pool.

Crossing the Mersey, the town of Liverpool is found to rest on a continuation of the Triassic hills south of the river, but more deeply covered with drift, which has in most cases so entirely filled up the valleys that the whole of the Coal-measure and Triassic districts of south-west Lancashire are one vast plain, surrounding a central nucleus formed by the spurs of the Pennine Chain, composed of the Millstone Grit.

The latter formation, on the borders of the Lancashire coal-field, reaches an average thickness of 5,000 feet, and is composed of four great beds of grit, divided from each other by thick beds of shale. These beds are known as the *Rough Rock*, or first grit; the *Haslingden Flags*, or second grit; the third grit; and the *Kinder Scout*, or fourth grit. The first and fourth grits are generally coarse, conglomerative, and massive; the third, as a rule, finer and not conglomeratic—both it and the fourth grit are often divided into two, three, and even more beds of thick seams of shale, which thin, wedge out, and thicken in the most irregular and local manner. In fact, though the Millstone Grit, as a whole, maintains a general average thickness in any special area, its members in *detail* appear to be ever changing places in relative consequence with each other, proving the shallowness of the sea, the proximity of land, and the existence of currents laden with different materials, sand and pebbles washed from those deep-seated quartzites which raised their heads above the sea at the time of the deposition of the grit in the area now occupied by the Pennine Chain.* Workable coal-seams occur in the first and third grits, and thin seams in the fourth; associated with them are shales in which a flora and fauna of about 30 species occur, the same species recurring in the different seams of shale: 18 species occur in the shales of the "Feather-edge" coal† (in the Rough Rock); amongst them are *Calamites Suckowii*, and *Pecopteris arborescens*. The former species I recently found in some shales of the second grit, exposed

* Prof. E. Hull, F.R.S., Quart. Journ. Geol. Soc., August, 1868.
† This coal is described by Mr. E. W. Binney, F.R.S., in the Trans. Geol. Soc. Man. vol. i.; by Prof. E. Hull, F.R.S., in Geol. Surv. Mem. "On the Geology of Oldham," and in the "Geology of Bolton-le-Moors."

in the new excavations for the Liverpool Waterworks' upper reservoir, above Alance Bridge, north of Rivington. A little further west another bed of black shale occurs, apparently on the same horizon as that from which the Geological Survey Map (six-inch map, Lancashire, sheet 78) records the presence of *Goniatites*. These and other fossils also found in the shales forming the roof of two coal-seams, occurring between the second and third grits. The shales dividing the latter grit are also fossiliferous in two instances in Lancashire, and *Goniatites* may be found in the shales between the third and fourth grits, at Old Kates Dingle and Shore Brook, below Noon Hill, east of Rivington (reached from Adlington Station). They reach, I should say, a thickness of 600 feet, and contain two thin coal-seams. The Kinderscout grit, though nearly 1,000 feet thick, appears to be almost devoid of organic remains; but the occasional fragments of *Stigmaria* testify to the existence of land during the period of its deposit, as do also the thin seams of coal.

The Coal Measures.—These are so well known through the various survey memoirs of Professor Hull,* and papers of Mr. E. W. Binney, F.R.S., that it is needless for me to describe them. They are divided into three divisions: the upper is devoid of coal, and is absent in South-west Lancashire; the middle coal-measures contain all the valuable coals, the best being that at the base, known as the Arley Mine, which is perhaps equal to any coal in England. The sixth seam, above the Arley, is the celebrated Wigan "cannel coal:" it is three feet thick at that town, thinning out in every direction, with Wigan as a centre, as shown by Mr. Hull.

The Lower Coal Measures, or Gannister beds, from their containing siliceous concretions, locally called "Gannisters," have five or six workable coals which are known as Mountain Mines. Coal-measures occur at Neston on the west coast of Cheshire, and again at Croxteth Park, near Liverpool, and it is probable that they underlie the whole of the Triassic rocks of Wirral, and of part of Liverpool itself.

Permian.—No geologist should leave Liverpool without visiting the two Permian outliers, discovered by Professor Hull, at Skillaw Clough and in Bentley Brook, Bispham (north-east of Ormskirk); they consist of sandstones, marls, and magnesian limestone.†

Trias, or New Red Sandstone.—This is divided into the following subdivisions:—

Keuper Series	Grey and Red Marls . .	1,000 feet
	Lower Keuper Sandstone .	400 "
Bunter Series	Upper Mottled Sandstone.	500 "
	Pebble Beds	800 "
	Lower Mottled.	100 "

The *Lower Mottled Sandstone* is best seen in the Liverpool district, at Eastham, on the Cheshire side of the Mersey, where it forms a cliff capped by the *Pebble Beds*. The latter are well seen in the quarries at Everton, above Liverpool; they are generally stained a deep brick-red with peroxide of iron, and contain seams of quartz-pebbles running along the lines of current-bedding seams of grey and red marl, which also occurs in small pockets in the rock. The *Upper Mottled Sandstone* is, as a rule, pebbleless, much false-bedded, streaked and mottled in its middle portion, yellow above, and deep bright red below. The latter beds are well seen at the mouth of Bromborough Pool, near Birkenhead; the middle beds at Ormskirk, where the celebrated section, first described by Mr. Hull,* occurs, where nearly level beds of conglomeratic Lower Keuper Sandstone rest on the denuded upturned edges of the variegated beds of the Upper Mottled Sandstone: it is exposed in the railway cutting leading towards St. Helen's, a little east of the town.

Lower Keuper Sandstone.—The base of this sandstone in this as in other districts, is extremely pebbly, and consists of hard grit, not unlike some of the beds of the millstone grits, and like them, and the sands and gravels of the Middle Drift Period, is much false-bedded. The middle portion consists of fine-grained freestones, separated by thin seams of grey marl, supporting water: these are well seen in the railway cutting at Orrel (east of Waterloo),† first described by the writer in the Survey Memoir on the district. The Labyrinthodon bed (3 to 4 feet thick) occurs near the base of this part of the Keuper Sandstone: it is best seen at Storeton, near the windmill (on the Cheshire side of the river): many fine footprints may be seen in the Liverpool museums. In the Orrel Railway cutting, magnesia is found to occur in the shale, as well as pseudomorphous crystals of salt, which also occur in the shales at the top of the sandstone, or at the base of the marls, whichever way they may be taken; for the sandstones, shales and marls, are in reality only one series gradually passing from the one into the other, as the sea grew shallower and shallower, and became supersaturated with salt, until at length the sea became a salt lake. From this sequence there is, however, one exception in this district, which I have not noticed elsewhere. A conglomeratic bed occurs near the very top of the Keuper Sandstone, immediately below the horizon of the shales; the pebbles consist of quartz, and are apparently derived from the same source as those occurring in some of the millstone-grit beds. The existence of round pebbles in a deposit proves either the proximity of a coast line or the shallowness of the water at the period of deposition; for unless the water is shallow, currents, I know by experience, have not the power to move pebbles. The Trias, as a whole, appears to have been formed during a period in which subsidence hardly kept pace with the deposition of sands and clays brought down by rivers from continental lands. This upper pebble bed would appear to have been thrown down at a moment when the movement of subsidence was greater than usual, causing islands of quartzites, or possibly of millstone grit, containing quartz-pebbles.

Keuper Marls.—This division attains an immense thickness in the country between Liverpool and Southport; but is so deeply covered with drift, glacial and post-glacial, that sections are very rare. Much of it, like the northern end of Cheshire, is scarcely above high-water mark, forming a low-level plain covered with peat-moss; between it and the sea intervenes a tract of blown sand, forming dunes or "hoes" as they are locally called, which is traversed by the railway from Liverpool to Southport.

* Mem. Geol. Surv. "Geology of Wigan." By E. Hull, F.R.S.
† Mem. Geol. Surv., "Description of 90 S.E.," and "Geology of the country between Liverpool and Southport." By C. E. De Rance, F.G.S.

Looking seaward from the train, the eye can descry nothing but range behind range of dunes, the only variety being produced by the irregularity of their heights; the only change from the ceaseless monotony of their yellow slope, the dark green stripes of dwarf willows that serve still more strongly to bring out the sterility o the scene. Leaving the train at Ainsdale, or Hightown, and examining the Lancashire Sahara more closely, it is found to consist of three portions:—a range or series of ranges of sand hills, from one to two miles in breadth. sloping down to the peat-moss,—a central plain,—and a range of sand-hills between the plain and the sea, protecting the former from the latter. Their incoherent masses would, however, be of little avail, were it not for the matted roots of the Sand-reed (*Ammophila arundinacea*), locally called "starr-grass," and woven by the people into mats and other articles, and which grass they were unable, until lately, by an old Act of Parliament, to cut or destroy, under the most severe penalties. In the plain, or rather in the series of small oval plains divided from each other by little ridges, running from the sea to the land, there is, in the summer, a dense carpet of spongy moss, mixed with sedges, and sprinkled with flowers. The great quantity of lime constantly set free by the dissolving of marine shells in the sand, causes many of the plants to be of species generally found on a chalk soil. Here occur various plants belonging to the Gentian tribe, as the Perfoliate Yellow-wort (*Chlora perfoliata*), the Red Centaury (*Erythræa Centaurium, E. pulchella*, and *E. latifolia*). *Gentiana Amarella*, with its purplish-blue flowers, will be also found about this time. On the adjoining moss-land occurs the rare marsh-gentia, *Gentiana Pneumonanthe*, with its large blue bell with five green stripes, With it grows the Buckbean (*Menyanthes trifoliata*). In the "slacks" (the local name for the little oval plains in the sand-hills), the beautiful *Pyrola media* occurs in great abundance, as does also the Grass of Parnassus (*Parnassia palustris.*) Each of these slacks has a distinguishing name, as "Bull-rush," "Long," "Mayflower," "Round," and "Dale Slacks:" these in winter receive the drainage of the sand hills, which, being stopped by the carpet of vegetation, forms a series of large standing pools of water, in the midst of apparently porous sand.

To return to the Keuper Marl: it is a series of red, green, and grey marls, with occasional seams of freestone, much ripple-marked, and beds of shale, generally with pseudo-morphous crystals of salt, and often veins of fibrous gypsum. Through denudation, the top of it is never seen, and it is therefore, with the exception of the Drift, the newest formation in the Liverpool district.

Glacial Drift.— Professor E. Hull, F.R.S., proved (in a paper read at Manchester, in 1862) that the Glacial Drift in the Manchester district was capable of division into an Upper and Lower Boulder Clay, divided by a Middle Sand and Gravel, which he called the "Middle Drift." The writer, in a paper on "Glacial Phenomena of Western Lancashire and Cheshire," read at the last meeting of the Geological Society, attempted to prove that this classification holds good, not only in the whole of Western Lancashire, but from the River Dee to the flanks of the Cumberland and Westmoreland Mountains; and since writing that paper he has found that the terrace of Glacial Drift skirting the mountains of North Wales, lying between them and the sea, is capable of that division, the cliffs of boulder clay east of Llandudno (round the Little Orme's Head) being distinctly divided by a *Middle Sand*, containing the same species of shells as those occurring in the Lancashire Middle Drift.

The *Lower Boulder Clay* (the writer endeavoured to show, in the paper alluded to above) was formed by an ice-sheet, which covered nearly the whole country down to a level of about 150 feet to 200 above the present sea-level; this clay he termed the "High-level Low Boulder Clay." Below a level of 100 feet, the clay appears to have been formed by the summer melting of an "ice-foot," which surrounded the sea-margin—at that level the land, through subsidence, standing that amount lower than at present. An amelioration of climate then took place during which the sands and gravels of the *Middle Drift*, with shells of Celtic type, were deposited round the edges of higher, and still higher, successive coast-lines, as the land gradually sank, until the sand and gravel, at Macclesfield, more than 1,200 feet above the present sea-level, was deposited in water of the *same depth*, and containing the *same shells*, as that in which the middle drift of Blackpool, only fifty feet above the sea was deposited. The phenomena exhibited by the middle drift, of the invariable rise from the sea to the land, in an inclined plane—the undulating surface, now far below, now up to, but never above, that plane—can only be explained by the theory that it was formed as *sand-banks* in shallow water on a gradually subsiding tract; and the *Upper Boulder Clay* is a marine deposit, formed of the detritus brought down by glaciers in the valleys of the Cumberland Lake district, to the ice-foot, which melting carried its spoils over the sea-covered plains. All these divisions are more or less well seen in the Liverpool district, especially on the Cheshire side of the river, in the neighbourhood of Egremont and Eastham. Further south, north of Chester, the Middle Drift is particularly well developed. Most of the boulder clay in North Cheshire belongs to the upper division, the lower clay being absent, having been denuded away. Glacial striæ were discovered by Mr. Morton F.G.S., at Flaybrick Hill, the direction being N. 30° W. at an elevation of 120 feet above the sea-level; and at Toxteth Park, the direction being N. 42° W.; also by Mr. Hull, F.R.S., at Kirkdale, the direction N. 15° W., caused probably by icebergs during the Upper Boulder Clay period.

In the district between Liverpool and Southport a bed of sand occurs, forming a line of old sand hills at the inland edge of the peat-moss plain, and making a sort of step between it and the comparatively high-level (80 to 160 feet) boulder-clay plain above. One of these hillocks is called Shirdley Hill; I therefore called the sand the "Shirdley Hill sand."* It is about 30 feet thick, and underlies the later deposits of the peat plain, but rests itself on a thin deposit of what I called the "Lower Peat." Above this sand, and beneath the great bed of peat (Upper Peat), is a bed of grey clay containing freshwater shells, which I called the "Lower *Cyclus* clay." I have observed it from the Island of Walney, in North Lancashire, to the coast of North Wales, and believe it, as well as the peat above it,

* "Description of Geol. Surg. Map, 90 S.E." and "Post-Glacial Deposits of Western Lancashire and Cheshire," read at last meeting of the Geol. Soc.

occurs at the bottom of the greater part of the Irish Sea. All along the coast of Lancashire, Cheshire, and to a certain extent North Wales, the peat, with a forest at its base and the clay containing the roots of the trees, may be seen, nowhere so well as at Leasowe, in Cheshire, and at the mouth of the Alt, Hightown, Lancashire (eight or nine miles from Liverpool). In both localities the peat, the forest at the base, and the grey clay below, occupy the country inland, run *under* the sand dunes, emerge on the coast, and disappear under the sea sand at low-water mark. In North Cheshire the peat is sometimes split into two, a bed of grey clay, with *Scrobicularia piperata*, being intercalated in the mass. This I consider to have been formed when the Mersey entered the sea, through what is now the gorge of Wallesey Pool. Very near the top of the peat a thin seam of sand occurs, both in Cheshire and Lancashire, containing *Tellina Balthica* and *Cardium edule*. I called it the zone of *T. Balthica*. The grey clay of the Isle of Man, with *Cervus Megaceros*, is no doubt of the same age as the "Cyclus Clay" of Lancashire.

Those who visit Hightown will find the peat, which is there from twelve to twenty feet thick, covered on either side of the River Alt with an alluvium which, near the sea, contains *Scrobiculariæ*, and inland graduates into a fluviatile deposit, with freshwater shells. They will find the base of the sand dunes, where they rest on the upper surface of the peat, to be, as at Leasowe, in North Cheshire, a freshwater deposit, which I called the *Bythinia tentaculata* sand; it contains thin seams of peat up to a height of eight or ten feet from the base.

My notes are already so long that I abstain from saying anything of the marine fauna of the coast and other matters: those that I have written refer to districts in which the maps, &c., of the Geological Survey are already published, and I have of course written as a private geologist, stating my individual opinions.

C. E. DE RANCE

H.M. Geological Survey

THE SECOND PROVINCIAL MEETING OF THE IRON AND STEEL INSTITUTE

THE Institute bearing the above name was originated about two years ago, chiefly by the North of England ironmasters, among whom there are many gentlemen who combine in themselves great practical skill and a large amount of scientific knowledge. It was not formally launched into existence till the month of June, 1869, when the inaugural address was delivered to a meeting of the members, held in the Hall of the Society of Arts, by the president, the Duke of Devonshire, who is intimately and extensively connected with the iron and steel trades through the great works of Barrow-in-Furness, perhaps the greatest Bessemer steel works in the world. The aim of the Institute is to hold two meetings annually—one in London, in the spring, and the other in the country in the autumn. The first provincial meeting was held, about a year ago, in Middlesborough, the capital of the Cleveland district, the greatest and most scientific iron-making district either in this or any other country. In May last the second metropolitan meeting was held; and now the second provincial meeting has just been held at Merthyr Tydvil, in South Wales. At all these three meetings there have been read papers of very great interest and importance, both from a scientific and a practical point of view. Then, taking the experience of the two provincial meetings, the members not only have the benefit of hearing the papers read and of taking part in the discussions to which they give rise, but they also have the opportunity of visiting the numerous works that are thrown open for their inspection, where they can see scientific theories put to practical tests, and where they can compare notes with each other upon the subjects which deeply concern them as practical and professional men. It is well known that "iron sharpeneth iron:" and in these country meetings of the Iron and Steel Institute this wise saw has many apt illustrations. Examples to imitate are seen in abundance; many points are observed that are suggestive and that excite to further improvements in other hands; and in numerous instances things are seen which impart lessons of a totally different sort, inasmuch as they show what errors of commission are to be avoided. Both successes and failures can give instruction to thoughtful minds.

This year's provincial meeting of the Institute, as already indicated, has been held at Merthyr. It opened on the morning of Tuesday, 6th September, in the Temperance Hall of that town, the centre and most important seat of the iron trade of South Wales. After the transaction of some formal business, and the appointment of Mr. Henry Bessemer as the president-elect of the Institute, the business of reading and discussing the papers prepared for the meeting was proceeded with. Altogether there were seven papers set down for reading and discussion on the mornings of Tuesday and Wednesday, the 6th and 7th September, which was all the time that could be devoted to that work, as the afternoons were required for visiting and inspecting the works in and immediately around Merthyr, while Thursday and Friday were required for the inspection of works at a distance. One praiseworthy feature in connection with the meetings in Merthyr was the circumstance of printed copies of the papers being in the hands of the members before they were read by the authors. Owing to this arrangement members were generally enabled to come prepared to enter upon the discussion of the papers with intelligence and with some degree of satisfaction. In two instances the papers supplied to the members were accompanied by engravings of the objects described. Both of these features of the Iron and Steel Institute Meeting might be copied with advantage by other learned societies, as they are calculated to impart additional interest to the meetings.

The Iron and Steel Institute already numbers upwards of 350 members, including several peers of the realm, about a dozen members of Parliament, and almost every person in the kingdom who has of late years added to the stock of our knowledge regarding the manufacture, the manipulation, and the use of iron and steel. It has very soon acquired a national importance, and its future prosperity seems to be almost assured. In order to make the Institute more and more useful to the persons who may be connected with it as members, it is intended to publish a Quarterly Journal of the Institute instead of the Transactions. This will commence on the 1st of January, 1871, and its contents will be as follow:—

First, the proceedings of the Institute, and of the Council from time to time. Second, the papers and discussions at the general meetings of the Institute. Third, communications from members upon matters of special interest to the trade, which are approved by the Council. Fourth, a quarterly epitome of inventions, discoveries, publications, and proceedings bearing upon the British iron and steel trades. Fifth, a comprehensive report on matters connected with the iron and steel trades in foreign countries. It is very satisfactory to know that the foreign department of the journal will be under the special management of Mr. David Forbes, F.R.S., and that the general editorship will be conducted by Mr. John Jones, F.G.S., the Secretary to the Institute and to the North of England Iron Trade.

We now proceed to give a brief notice of the papers read at the recent meeting at Merthyr:—

I. "On the Geological Features of the South Wales Coal-Field." By Mr. William Adams, Cardiff. In this paper, which was of special interest to such of the members as were strangers to the district, the author traced the history of our knowledge regarding the position, nature, and extent of the coal deposits which have given such an industrial importance to South Wales. Attention was directed to this coal-field as far back as the year 1570, but the essay itself did not appear till the year 1796, when it was published in the *Cambrian Register*. Since that time many persons have devoted attention to the subject, including Edward Llwyd (1697, "Philosophical Transactions," 1712); Edward Martin (Royal Society, 22nd May, 1806); Buckland and Conybeare (1822, "Geological Transactions," vol. i.); Robert Bakewell (1833); Sir Henry J. De la Bêche (1846, "Memoirs of the Geological Survey," vol. i.); Mr. Hussey Vivian, M.P. (1860); and Mr. Hull (1861, "Coal Fields of Great Britain"). According to Mr. Adams, the South Wales coal-field extends from Blaenavon and Pont-y-pool, on the east, to St. Bride's Bay, in Pembrokeshire, on the west, a distance of about ninety miles; while its breadth varies from about sixteen miles on the east to about four miles in the extreme west. The superficial area is given as low as 906 square miles (Hull), and as high as 1,200 square miles; but Mr. Adams puts it at 937½ square miles, or 600,000 acres. Taking the average thickness at sixty feet, as given by Mr. Vivian, M.P., one of the Royal Commissioners on the Coal Supply, and deducting one-third for loss in working, for faults, waste, &c., the extent of coal is 36,000,000,000 tons. The author pointed out the qualities of the mineral in different parts of the coal-field. On the east it is bituminous, and makes a very superior coke; it continues so to Rhymney; at Dowlais it becomes free-burning; at Cyfarthfa it begins to take on the characters of anthracite; and further westward the coal becomes more and more distinctly anthracitic, until, in the west, it becomes so pure that it is worked for drying hops and malt and for distilling purposes, &c. Within the field there are obtained the well-known steam coals of Merthyr, and the Aberdare and Rhondda valleys. Argillaceous ironstones are very abundant and good. They are interstratified with the coal, and have an aggregate thickness of from sixty to seventy inches or upwards, and until about thirty years ago they yielded practically all the iron which was smelted in Wales. Since then the deficiency for the iron-works has been drawn from other British and foreign mines. The pig iron made in South Wales in 1854, according to Mr. Hunt's "Mineral Statistics," was 750,000 tons, and the coal raised in the same year was 8,500,000 tons, while the amount raised in 1868 was 13,210,000 tons. Owing to the remarkable denudation in the valleys of the district, the lowest seams of coal can be won by pits of less than 1,000 yards in depth throughout about two-thirds of the basin. A greater depth may be required west of the Vale of Neath and on to Llanelly, where the deepest part of the basin occurs. Throughout the coal-field there are faults, running north-west and south-east, which give a vertical displacement of 250 or 300 yards; and there are others running east and west which give a displacement of from 400 to 500 yards; and one is said to occur in Pembrokeshire which is equal to a displacement of upwards of 666 yards. The deepest pits are those which reach down to the nine-feet seam; their depth varies from 304 to 435 yards. In the coal-field there is found some of the best fire-clay known; there is also a remarkable siliceous stone, which is used to make the well-known refractory fire-bricks called Dinas brick. Alum shales occur, and, near Pont-y-pool, a rich oil shale is found, which yields on distillation from fifty to fifty-five gallons of crude oil, of which twelve to fifteen per cent. may be separated as mineral turpentine. Mr. Adams also referred to the extent and distribution of the mountain limestone—so useful as a flux in smelting the ironstone—and in the fossils which the coal measures of the district contain; and, in concluding his very valuable paper, he also strongly urged the desirability of a new geological survey on the six-inch scale being made.

In the course of a short discussion which followed the reading of the paper, several interesting points were raised, more especially in reference to the effects of the faults in changing the character of the coal.

II. "On Pumping and Winding Machinery." By Mr. G. C. Pearce, Cyfarthfa Iron Works. This paper embraced a short description of the pumping and winding machinery lately erected at the Castle Pit, near Merthyr, the property of Mr. R. T. Crawshay. Notwithstanding the shortness of the paper, it would be difficult to give a satisfactory description of the machinery in the form of an abstract, especially without illustrations. But a few facts may be mentioned. The pit is 333 yards in depth to the bottom of the sump, but the pumps only raise the water 279 yards, where there is an adit. It is of an oval form, 22 feet 8 inches long by 12 feet wide, with a brattice dividing the winding parts from the pumps; and it is all built with brick throughout. The total cost of the machinery and the sinking of the pit was about 30,000*l*., the winding engine alone costing above 4,000*l*.

In the afternoon of Tuesday the Castle Pit was visited by the members of the Institute, many of whom were much struck with the gigantic and ingenious character of the machinery erected by Mr. Pearce.

Mr. E. A. Cowper, C.E., F.R.S., followed with some observations in reference to the working of steam for pumping, winding, and blowing engines; but no discussion ensued.

III. "On the Condition of Carbon and Silicon in Iron and Steel." By Mr. George J. Snelus, Associate of the Royal School of Mines, chemist at Dowlais Iron Works. This paper was of considerable length and very elaborate. It contained the results of a long course of experimental inquiry, instituted with a view to determine the conditions in which the two non-metallic bodies, carbon and silicon, exist in iron and steel. Dr. Percy had said in his celebrated work, "Iron and Steel," that not a trace of graphite could be detached by the point of a penknife from the fractured surface of highly graphitic iron; but Mr. Snelus had proved the incorrectness of this statement by examining some pig iron which had cooled slowly under a mass of slag, and which had in consequence very large crystals. From the surfaces of these crystals the graphite could not only be separated with the point of a penknife, but even with the finger-nail; and when the graphite was removed the iron underneath rapidly rusted in a damp atmosphere. The same thing was afterwards observed with the fractured surface of Bessemer pig-iron, and the scales removed were found on further examination to be pure carbon. By pulverising pig-iron and then using the magnet a considerable amount of graphite was separated. Other mechanical means were employed, and the same results were obtained. In spiegeleisen the carbon was found to be almost wholly combined. The author had never found as much as five per cent. of combined carbon in pig iron, although many analyses had been published in which the carbon was put down at even six per cent. Mr. Snelus was not inclined to believe that there was any definite compound of carbon and iron but, he thought that the carbon was dissolved in the iron, the amount taken up by the molten iron varying according to several circumstances. According to Mr. Snelus there is no pig iron that is destitute of silicon, and he had never met with a case in which either steel or wrought iron was totally free from it. Good Bessemer and tool steel rarely contains more than two or three parts in 10,000. One part of silicon in 1,000 of Bessemer steel renders it hard and brittle when cold. In ordinary Bessemer pig iron it is present in quantities varying from one to four per cent. The author gave it as his opinion, from experimental inquiries, that silicon is dissolved or "occluded" in iron in the same way as carbon is, but that the solvent power of the metal is so much greater for silicon than for carbon, that it is quite a rare thing, even if it ever occurs, for silicon to separate in a free state from the iron; and he considered that the methods of mechanical separation which he had adopted for the investigation of the condition of carbon and silicon would prove effectual aids to the ultimate analysis of iron, and a valuable supplement to the ordinary methods of research.

Mr. Isaac Lowthian Bell complimented Mr. Snelus upon the great value of his paper, and criticised some of the statements made in it. On the presence of silicon in steel, Mr. Bessemer said that a very general opinion prevailed in the trade (and it was correct when they spoke of large quantities) that silicon was deleterious to the make of iron. It was the impression that they should get rid of silicon, and they would then make better iron. That was not the case, in proof of which assertion he called attention to the old steel process as carried on in Sheffield, and adduced instances to show that the presence of silicon improved the quality of the manufacture. He had not had an analysis of the best quality of Sheffield steel that did not contain silicon.

A discussion was then taken upon a paper read at the meeting held in London in May last, the subject of which was "A Method of Designing Rails," and the afternoon was spent in visiting the works of the Plymouth Iron Company, the Castle Pit winding and pumping machinery, and the Cyfarthfa Iron Works, the property of Mr. Crawshay. At the last-named works there was seen an immense stock of puddled iron, upwards of 20,000 tons, stacked in "houses," each containing 300 tons.

The proceedings were resumed on Wednesday morning. The papers read were the following:—

I. "On a New Form of Pyrometer." By Mr. C. W. Siemens, C.E. F.R.S. D.C.L. After describing briefly the Wedgewood and Gauntlett pyrometers, and one previously constructed by himself, Mr. Siemens proceeded to describe a pyrometer of more universal applicability. It is based upon the peculiar properties of the pure metals to offer an increasing resistance to the passage of an electrical current with increase of temperature. A platinum wire of known electrical resistance is wound upon a cylinder of fire-clay, upon which a helical path has previously been cut to prevent contact between the turns of the wire. The coil of wires, so prepared, is enclosed within a cylindrical casing of platinum if the temperatures to be measured exceed the welding heat; or of iron or copper, if lower temperatures only require to be measured. The two ends of the coil of wire are brought out end ways, and are attached within the protecting tube to thicker leading wires of copper, insulated for a short distance by being passed through pipe-clay tubes, and further on by india rubber or gutta percha, terminating at the measuring instrument, which may be placed at any convenient distance. The characteristic feature of this instrument is that the usual calculations necessary to determine electrical resistances by the Wheatstone or other methods are dispensed with, and a reading in degrees of a large scale is at once obtained by so placing the index lever that the electrical current, generated in a small battery and passed through the measuring instrument, including the platinum wire of the pyrometer, produces no deflection of the galvanometer needle. The temperature which these degrees represent is expressed by a table of reference, which accompanies each instrument. The correctness of this instrument depends solely on the ratio of increase of electrical resistance in the platinum wire, with increase of temperature. This rise is considerable, the resistance being increased fourfold by an increase of temperature from the freezing point to about 3,000° Fahr. The ratio of increase is, however, not uniform, but follows a parabolic law which the author embodied in a table. The pyrometer last described is the result of more careful investigation on the part of Mr. Siemens, who has been animated by a desire to fill up a blank in the means at our disposal to carry on metallurgical inquiries with a high degree of certainty, and he therefore does not seek any commercial compensation, through the Patent Office or otherwise, for using this invention.

A discussion followed, in which Mr. Snelus, Mr. I. L. Bell, and Mr. E. A. Cowper took part.

II. "On the Efficiency and Durability of Plain Cylindrical Boilers." By Mr. Jeremiah Head, Middlesborough. The author of this paper aimed at pointing out the many high qualities possessed by the plain cylindrical boiler, to investigate the cause and extent of the defects which they possess, and to point out satisfactory remedies for them. Such boilers are still in large request. Out of 17,825 boilers now on the books of the various boiler insurance companies 4,052, or 22·7 per cent., are of this type. But such boilers are very liable to fracture and break their backs, and Mr. Head gave an explanation of the causes of such occurrences, and explained the method which he had adopted to prevent the recurrence of such a mishap in a boiler that had been repaired about the beginning of March last. His plan is to suspend the boiler upon volute springs. No springs are necessary for boilers of 30 feet long upon two supports; but for lengths of 60 to 75 feet five supports are required, the end ones being furnished with double springs.

The discussion following this paper was so long that no time was left for the consideration of a paper by Mr. Kohn, C.E., on "The Production of Alloys of Iron and Manganese, and on their Application to the Manufacture of Steel." A paper on "A Contribution to the History of the Puddling Process" was also left over for consideration at the next meeting in London. On that occasion the place will be selected for the next autumn meeting.

In the afternoon of Wednesday, the world-famous works of the Dowlais Company were visited by the members of the Institute. Thursday was occupied with a visit to Swansea, where an inspection was made of the Landore Steel Works, where the Siemens-Martin process is carried on; the Hafod Copper Works, belonging to Mr. Vivian, M.P., and the Spelter Works. Friday was devoted to a visit to the Crumlin Viaduct and the Ebbw Vale Company's Iron and Steel Works. These several inspectorial visits were thoroughly enjoyed, and the hospitality with which they were attended was most profuse. Doubtless, many of the practical and professional men who were present at the inspection gained a large fund of mental insight which will, ere long, be applied to practical advantage, or, at all events, be put to a practical test.

A Mirage

As several notices of Mirage seen in Britain during the present year have recently appeared in NATURE, I venture to trouble you with the following substance of a few brief notes (made on the spot) of an instance which I witnessed on April 15, 1870.

With a companion I was walking slowly from Chesilton, in the "Isle" of Portland, along the western slope of the famous Chesil Bank, in a north-westerly direction—my friend on one of the numerous narrow terraces into which the slope is broken, I on that next below. The day was bright and warm, and the sea was calm. Having occasion to stoop down, I caught sight of what for the moment I thought a considerable pool of water on the terrace on I which stood, in the direction in which we were moving. A moment's thought reminded me that a pool in such a beach of loose pebbles was out of the question, and convinced me that for the first time in my life I saw a Mirage. The hour proved to be exactly noon, Greenwich time. My friend, on having his attention called to it, saw a similar "pool" on his terrace. On trying a series of experiments, we found that when we were quite erect the phenomenon was barely visible, and would never have commanded attention, but that as the eye was brought nearer and nearer to the surface the "pool" grew larger and larger; that in ordinary cases each observer could see it on his own terrace only, but that when he brought his eye to the outer edge of one terrace the "pools" on it and on that next below were visible at the same time, and were almost blended. As we advanced so did the Mirage. At 12.20, local time, when the sun was, of course, a very few degrees west of south, it bore N. 33° W., magnetic variation being allowed for. The apparent water, like the real water in the adjacent sea, was a dark blue. We left the beach at two o'clock, and noted that the "pools" were as distinct as ever; and, being then some distance from Portland, we observed a similar phenomenon in that, the opposite, direction.

Lamorna, Torquay, Sept. 10th, 1870 W. PENGELLY

External Configuration of the Earth

UNDER the heading of "Volcanic Action *v.* Denudation," I observe in the last number of NATURE (Sept. 8th), a letter from Mr. A. H. Green, in which that gentleman finds fault with the conclusion arrived at in the following quotation, apparently extracted from some, to me unknown, report of my lecture on volcanoes, the original of which is given in the *Geological Magazine* for July 1870; in instituting "a comparison between the relative magnitude of the operations of internal and external forces in determining the main external fractures of our globe, we must grant the first rank to the internal, volcanic, or cataclysmic agencies, since, had it not been for their operations, our globe would have remained without any visible land for the river to traverse, or the rain and ice to disintegrate and wear away;" but as immediately afterwards Mr. Green himself adds, "the latter part of this statement, cannot, of course, be called in question," these very words, alone, seem to me tantamount to a complete admission that he can have no basis whatever for disputing the deduction that the internal agencies must be placed in the first rank; be it remembered, also, that his quotation is merely a summing up of the evidence brought forward in the course of the lecture.

What I maintain—and I imagine every unbiassed person, whether scientific or not, if but endowed with a reasonable amount of common sense, will agree with me,—is, that when comparing the relative importance of the two very opposite forces which have combined to model the external surface of our globe, in all times down to the present, the precedence must be given to that agency which is admittedly, not only the primary one, but also the one which actually called the other into existence.

In answer to Mr. Green's similes, and as he says that, in a case like this "it is hard to attach any definite meaning to the idea of rank," I may assist him by simply asking, for example, whether any reasonable person, after contemplating, say St. Paul's Cathedral, one of the most prominent features of our metropolis, could possibly think of ranking the architect who originated it below the stone-mason, or sculptor who, directed by him, afterwards altered so vastly the external appearance of the rough shell of the edifice as it first rose from the ground.

Every one, whether geologist or not, admits that the most striking features in the world's physical geography are the mountain ranges which rise up and look down upon the plains below, formed from their own *débris*; and when it is remembered that these mountains are but so many grand proofs of the intensity and activity of those internal forces which not only elevated them, but, in most instances also, even supplied the larger portion of the rock substance which builds up their entire masses, does it not seem strange that any question of rank should arise, when comparing them with those external forces (denudation, &c.) which, of very necessity, can only be great in proportion as the anterior internal forces developed the conditions necessary for calling them into existence, and provided materials for them to operate upon?

11, York Place, Portman Sq., W., Sept. 12th, 1870

The Meteor of 15th August

IN NATURE, page 357, you give notices and sketches of the Meteor of 15th August, and invite further description.

The particulars stated by the Duke of Argyll, and specially the very exact location assigned to the Meteor by your Portrush correspondent, render it probable that a tolerable approximation may be made to the exact position as regards height, &c.

To this end, and in supplement of notice accompanying diagram second, NATURE, page 357, the following details are important.

The Meteor's apparent position is recovered by means of its very close proximity to summits of the Binn hill, near and to the north of this place, with assistance of the six-inch Ordnance maps.

Local Time of first appearance	8·50	8·55 P.M. 15 Aug.
Altitude, uncorrected for refraction,	7°35′25″	8°31′30″
Azimuth, west of north,	66°2′3	67°23′10″

Observer's position, exactly in line of High-water level, In Latitude 56°3′51″ North, Longitude 3°12′45″ West.

The apparent size of the Meteor partly explains these pairs of limits, within which the nucleus at least may be located.

GEO. J. P. GRIEVE

Kirkbank, Burntisland, Sept. 12th

GEOLOGICAL DISCOVERY IN LIVERPOOL

ALL geologists visiting Liverpool for the approaching Meeting of the British Association for the advancement of Science will be glad to hear of the recent discovery of some new beds in the coal measures near Liverpool, which are exceedingly prolific in fossil remains. The new line of railway between Liverpool and St. Helen's runs at one place not far from Rainhill, through Thatto Heath, where a long cutting was rendered necessary. This cutting is through beds all belonging to the carboniferous strata—a thick coal seam, and the accompanying beds of shale and fireclay being all cut through. The fireclay contains abundant remains of all the varied plants of this epoch, with a few marine shells, *Anthrocosia* in some places. There is a large collection of these fossils now on exhibition in the Derby Museum, collected by the Rev. H. H. Higgins, who has shown great energy in the matter, and who has most generously presented his collection to the museum. This collection well merits the attention of all geologists, especially those interested in fossil botany. The plants found are in the most perfect state of preservation, and they are by no means difficult to meet with. They are chiefly *Sigillaria*, *Calamites*, *Lepidodendron*, *Neuropteris Loshii*, *N. nervosa*, and *N. gigantea*: some of the species, the rarer *Asterophyllites* and *Sphenophyllum*, together with many others, being not yet accurately determined. Throughout the clay are found scattered nodules of ironstone, which, on being broken up, are found to contain fossil remains, generally ferns or *Equiseta*. There have, however, been two exceedingly valuable finds lately made, two fine specimens of the wings of Neuropterous insects having come to light. One of these is in the possession of the Rev. H. H. Higgins; and the other, measuring some 3 to 3½ in. in length, is in the possession of Mr. E. Cleminshaw, of Merton College, Oxford. Both of these will be exhibited at the approaching meeting. They were both found in the ironstone nodules, and are very interesting, as only one other specimen, we believe, is known from the English coal measures. Not far from this cutting is a small coal pit, from which many interesting fossils are to be obtained. These are chiefly fish-remains, teeth, jaws, scales and bones, and a few rare ferns. The ease with which the blocks split into thin laminæ render these fossils easily found, and they are in a good state of preservation.

This locality is easily reached by train from Lime Street Station to Rainhill, from which place it is distant some twenty minutes' walk. The navvies on the line are very obliging, and have all the finer specimens, with which they are very willing to part for a few coppers or some tobacco.

J. P. EARWAKER

NOTES

We have reason to believe that the scheme for the proposed Indian Government School of Engineering is being warmly combated by the scientific branches of the army, whose counter proposal is that the Royal Military Academy at Woolwich should be made into an equivalent of the *Ecole Polytechnique*, and that young men intended for the engineering service of the Indian Government should be educated there, or better still, officers of the Royal Engineeers should be lent to the Indian Government. On this very important topic we would ask whether the result of the first report of the Royal Commission on Military Education, which is still sitting, has not been to reduce both in quantity and quality, the scientific teaching at Woolwich, which was already so absurdly small, that, mathematics apart, more science might be learned at many commercial academies.

It will be a long time before England forgets the loss of the *Captain*, though probably when a serious naval engagement does come, the going down of the largest ships, with the loss of all men on board, will be almost a matter of course. But as we have so often heard lately, *à la guerre comme à la guerre*, perhaps a more subdued thrill will then run through us. There seems little doubt that the *Captain* was top-heavy. The fearful rapidity with which, first a roll of 10 deg., then of 22 deg., then of 25 deg., and then a terrible catastrophe were recorded, leave no doubt on this point, and the turrets, the six twenty-five-ton guns, heavy armour, and masts high above the centre of gravity, must bear the blame. Fortunately, however, Captain Moncrieff's last achievement, which we described a few weeks ago, comes to our assistance by abolishing the turrets, and puts the weight of the enormous guns precisely where it is wanted.

The balloon is becoming a war engine with a vengeance. M. Nadar has been appointed a member of the Committee under the presidency of M. Berthelot, for the scientific defence of Paris, and several captive balloons are to be employed ; while we learn from Strasburg that captive balloons are to be used for dropping nitro-glycerine bombs on the powder magazines of the town ; the operations are to be conducted by an Englishman named Walter, and Herr Mahler, of Berlin.

The annual excursion of the London and Middlesex Archæological Society took place on Tuesday last. Notwithstanding the inclemency of the weather there was a numerous attendance.

The Warwickshire Agricultural Society's annual gathering was held on Tuesday last at Leamington. The Earl of Warwick presided at the annual dinner, which was attended by the representatives of both divisions of the county. As usual at these agricultural meetings, we fail to discover anything in the proceedings calculated to convey any impression to the agricultural mind of the necessary intimate connection between agriculture and science.

A leading article in the *British Medical Journal* for Sept. 10 is very severe on the insufficiency of the education at present given to our medical students, and the consequent inferiority, comparatively speaking, of the medical profession in this country. "The miserable inferiority in scientific research ; the dearth of original work, the want of exactness, the poverty of physiological investigation, the ignorant impatience of practical detail which we all have to deplore so much in the mass of professional work at this day, are due to the inadequate preliminary cultivation of our students ; to their defective training in scientific method ; the small base on which the pyramid of medical lore is made to stand. The solemn deprecation of excessive devotion to microscopical research ; the empty sneer at chemical physic ; the idle and mischievous disregard of instruments of precision—the sphygmograph, the thermometer, the laryngoscope, the ophthalmoscope—are all the expressions of a Philistine ignorance. . . The inferiority of English to German medicine is due to this inferiority of preliminary training." Judging from the letters we have received, medical men here are very indignant at the strictures on English medical training contained in the two articles by Professor Stricker, recently printed in our columns. This is what one of their own journals says on the subject. Here is food for thought for the members of our Science Commission during the recess.

The editor of the *Gardeners' Magazine* offers a prize of twenty guineas for the best essay on irrigation as applied both to the farm and the garden. There is probably no question of greater material importance to England at the present time. A system of storage and irrigation by which the superfluous rain that falls in autumn and winter, frequently carrying devastation in its course, could be intercepted, stored, and applied to the fertilisation of the soil between May and August, would ensure to the farmer, and consequently to the country, a gain that would be simply incalculable in such summers as the one we have just experienced.

The Museum of Natural History in Madison University, New York, has had its valuable collection lately classified and arranged. Among its most valuable possessions are reckoned the collection of tropical and other rare birds collected by Prof. Bickmore ; a group of gay beautiful plumaged birds brought from the Spice Islands, are especially noticeable. There is also a good collection of North American birds.

Mr. J. J. Bennett, the Curator of the Botanical Department of the British Museum, has just issued his annual report for 1869. The principal business done in the department during the year has been :—The rearrangement of a portion of the presses of the general herbarium ; the rearrangement of certain orders of *Apetalæ* and *Endogens*, and of the lichens, both British and foreign, with numerous additions to each ; the selection of a very large number of specimens from the herbarium of the late Mr. N. B. Ward, and from the collection of Abyssinian plants send by Dr. Schimper through the Foreign Office ; the naming, arranging, and laying into the general herbarium of Berlandier's Mexican collection, of Linden's collection from New Granada, Tate's from Nicaragua, Coulter's from California, Sartwell's *Carices* of North America, Wright's collections from the Neilgherry Hills and from India generally, Jameson's from the Andes of Quito, *Orchideæ* from different countries, ferns from the islands of the South Pacific, and of a large number of miscellaneous specimens of various families and from different countries ; the examination and arrangement of the recent and fossil *Coniferæ* and *Cycadeæ*, and of Mr. Brown's collection of fossil woods ; the arrangement and incorporation in the general herbarium of a large number of European plants ; the rearrangement of various portions of the British herbarium, and of the collection of fruits and seeds ; and the rearrangement of various parts of the collection contained in the Exhibition Rooms, and especially of the cases containing *Coniferæ* and *Cacteæ*, with large additions. The most important additions to the collection during the year have been :—Upwards of 1,000 European plants from the collection of Dr. Rostan and the late Mr. N. B. Ward ; 900 plants of Ingermannland ; 300 from Sicily ; 200 European fungi ; 200 Italian cryptogams ; 3,000 plants of Abyssinia, collected by Dr. Schimper ; more than 3,000 plants of South Africa, from Mr. Ward's collection ; upwards of 500 from Madeira, collected by Lemann and others ; nearly 1,000 from the mountains of Altai ; 1,000 from India, collected by Dr. Wright ; 400 from Malacca, collected by Griffith ; 100 from the Feejee Islands, collected by Harvey ; 1,000 from North America ; 400 fungi of South Carolina ; 300 plants from Nicaragua, collected by Tate ; 700

from the Andes of Quito; a fine set of pine cones from California; numerous specimens of plants and fruits, chiefly from Africa. The number of visits paid to the herbarium during the year for purposes of scientific research was 974.

WE have already signs of the opening of the medical session on the 1st of October next. The number of the *Chemical News* for Sept. 9th is devoted to a very useful summary of the requirements of the various examining bodies in this country in chemistry and physics, and of the courses of lectures and laboratory instruction given at the different colleges and medical schools in London and the provinces. The *British Medical Journal* for Sept. 10th also gives the regulations of the General Medical Council, and Medical licensing bodies, and notes concerning the hospitals and medical schools.

WITH reference to the paragraph in our last number respecting the use of ammonia in Victoria as a cure for snake-bite, we learn that the inhabitants of that colony are so deeply impressed with the great practical value of the discovery, that they are collecting subscriptions for a fitting testimonial to present to Dr Halford, who was the first to suggest and carry out this mode of treatment. Any contributions for this object will be received by Dr. G. E. Day, of Furzewell House, Torquay, who states that it has been the means of saving a number of cases in an apparently hopeless state of collapse.

SOME important experiments are now been conducted with the new description of torpedo submitted to the Government by Mr. Whitehead. The *Oberon* yesterday floated out of dock at Chatham, and will be sent round to Shoeburyness, where the experiments, which are to be carried out under the superintendence of a commission, of which Lieutenant-Colonel Nugent, Royal Engineers, is the president, are to take place. The wooden vessel to be operated upon with the torpedoes, which are fired from the stem of the *Oberon* beneath the water, is *L'Aigle*, which has been placed at the disposal of the committee by the Admiralty for that purpose. These torpedoes are *locomotive*, the motive power being compressed air, and already the results obtained are surprising. The minutes of evidence taken before the select committee on the Abyssinian expedition are published this morning. They fill a blue-book of 600 pages.

A BOTTLE-NOSED whale, measuring eighteen feet in length by eight feet in girth, came ashore near Burntisland, on the Scotch coast, on Thursday afternoon last. It was drawn up on to the beach while still alive. It is to be hoped that some museum will see about securing the skeleton of this whale; it would be a very welcome addition to many museums, and could, we should think, be obtained for a small cost.

THE extreme rarity of well-authenticated examples of the parasitism of the mistletoe on the oak has induced Dr. Bull, of Hereford, to collect the known instances, which he finds to be eight in number, viz., three in Herefordshire, and one each in Gloucestershire, Monmouthshire, Devonshire, Hants, and Surrey. In the most recently-discovered instance, in the Forest of Deerfold in Herefordshire, the mistletoe was found on an oak of the variety *sessiliflora*, some fifty or sixty years old; it is a female plant, growing high up on the main stem, and forming a large spreading branch with a diameter of three-and-a-half feet, and springing from the oak in a single stem nearly four inches in circumference. The mistletoe also grows on a thorn close by, and has probably sprung from a seed dropped by a bird from above.

A NEW process for making steel has been discovered in America, by means of which it is stated that American steel can be made equal to that usually imported into that country. It is manufactured from a peculiar iron ore found in Codorus township, Pennsylvania. The iron is mixed in a reverberatory furnace with middling pig-iron in the proportion of one to six. It is hoped by means of this valuable discovery to manufacture steel rails at a cost of about sixty dollars per ton.

THE BRITISH ASSOCIATION.—LIVERPOOL MEETING, 1870

AS we go to press the great annual scientific meeting has already commenced; and although the President is at the present moment actually delivering his opening address, we are able, through Prof. Huxley's kindness, to give our readers a verbatim report. We believe it will be found to rank in interest and importance along with any of its predecessors. We are also able to give Prof. Roscoe's Address to Section B; the Kew Report lack of space compels us to defer till next week. We have already given the particulars of the places of meeting and officers of the various sections. Not much remains to be added: by the time this is in the hands of our readers the meeting will be in full swing, and those who are attending it will already be at home in all the various arrangements. Among the most interesting occasions will doubtless be Sir John Lubbock's lecture to working men. The Mayor's reception at the Town Hall, continued for two successive evenings, though not open to all who show the ticket of the Association, is virtually so. All who have arrived in time will receive a formal invitation; and any omission, if such occur, will rest with those who should promptly send forward the names. Another entertainment is that to be given in the Philharmonic Hall on Saturday evening, the 17th, by Dr. E. R. Bickersteth. Besides giving a subscription on the largest scale to the local fund, he will entertain about 700 strangers and 300 of our own townspeople. Eight excursions have been arranged for Thursday, September 22nd, in connection with the Association. The first of these is to Cefn Hall, near St. Asaph, where the party will be received at a luncheon by Mrs. Williams Wynne; the excursionists will start from the George's Landing Stage by the railway boat. An excursion party will also leave for Chester by the same boat. An excursion party to Crewe Works will leave the Lime Street Station by an early train. The guests, whose number is limited to one hundred, are invited to a luncheon at Crewe, provided by the London and North Western Railway Company. A fourth excursion will be to Llandudno, and will start from the Prince's Landing Stage in the *Eblana*, kindly lent for the occasion by the City of Dublin Steam Packet Company. Dinner and tea will be provided on board the vessel at hours most convenient to the excursionists. Another party will leave the George's Landing Stage for Llangollen, and have luncheon at the Hand Hotel, Llangollen. A sixth excursion will visit Widnes, where there will be a dinner in the public hall, by invitation of the Widnes committee of reception. There will likewise be an excursion to Wigan, and an excursion up and down the River Mersey. In Liverpool many of the chief works, manufactories, and public institutions will be open to the inspection of the members of the Association all through the week. Among the papers intended to be read, the titles of which have already reached us, the following are among the most interesting:—In Section A, Francis Galton, F.R.S., "Barometric Predictions of Coming Weather."—John J. Hall, "A new Electro-magnetic Electrometer."—A. W. Bickerton, "A new Heat Engine."—W. Rowett, "Ocean Telegraphy."—Henry Hudson, Glenville, Fermoy, Ireland, "On the Wave Theories of Light."—Dr. Joseph Henry, Smithsonian Institution, Washington, U.S.A., who will be present at the meeting, "On the Rainfall of the United States."—R. S. Ball, Royal College of Science, Dublin, "The small Oscillations of a Rigid Body."—S. Hewett, Marlborough, Wilts, "The Earth's Centre of Gravity, Axis of Revolution, and Magnetic Axis or Centre."—W. M. Watts, "The Existence of two Spectra produced by Carbon incandescent at the same Temperature."—In Section B, C. R. Tichborne, F.C.S., "On the Action of Street Dust as a Ferment."—W. H. Perkin, "On Artificial Alizarine."—A. H. Church, "Experiments on the Preservation of Stone," "Contributions to Mineralogical Chemistry."—John G. Macvicar, "On the Structure and Form of an Atom of Moisture" (illustrated by models).—J. H. Lloyd, M.D., Anglesea, "On the Dry System of Sewage."—In Section C, J. Logan Lobley, "On the Stratigraphical Distribution of the British Fossil Gasteropoda."—W. C. Williamson, "On the Organisation and Affinities of the Calamities of the Coal Measures."—G. A. Laborn, "On the Tertiary Coal-field of Southern Chili."—Charles Ricketts, "On a Railway Section across the Prescot Coal-field."—John W. Judd, "On the Age of the Wealden."—Geo. Busk, a paper by Dr. Leith Adams, "On a New Species of Fossil Elephants from Malta."—Charles Jeaks, "On the Norwich Crag."

ADDRESS OF THOMAS HENRY HUXLEY, LL.D., F.R.S., PRESIDENT.

MY LORDS, LADIES, AND GENTLEMEN,—It has long been the custom for the newly installed President of the British Association for the Advancement of Science to take advantage of the elevation of the position in which the suffrages of his colleagues had, for the time, placed him, and, casting his eyes around the horizon of the scientific world, to report to them what could be seen from his watch-tower; in what directions the multitudinous divisions of the noble army of the improvers of natural knowledge were marching; what important strongholds of the great enemy of us all, ignorance, had been recently captured; and, also, with due impartiality, to mark where the advanced posts of science had been driven in, or a long-continued siege had made no progress.

I propose to endeavour to follow this ancient precedent, in a manner suited to the limitations of my knowledge and of my capacity. I shall not presume to attempt a panoramic survey of the world of science, nor even to give a sketch of what is doing in the one great province of biology, with some portions of which my ordinary occupations render me familiar. But I shall endeavour to put before you the history of the rise and progress of a single biological doctrine; and I shall try to give some notion of the fruits, both intellectual and practical, which we owe, directly or indirectly, to the working out, by seven generations of patient and laborious investigators, of the thought which arose, more than two centuries ago, in the mind of a sagacious and observant Italian naturalist.

It is a matter of every-day experience that it is difficult to prevent many articles of food from becoming covered with mould; that fruit, sound enough to all appearance, often contains grubs at the core; that meat, left to itself in the air, is apt to putrefy and swarm with maggots. Even ordinary water, if allowed to stand in an open vessel, sooner or later becomes turbid and full of living matter.

The philosophers of antiquity, interrogated as to the cause of these phenomena, were provided with a ready and a plausible answer. It did not enter their minds even to doubt that these low forms of life were generated in the matters in which they made their appearance. Lucretius, who had drunk deeper of the scientific spirit than any poet of ancient or modern times except Goethe, intends to speak as a philosopher, rather than as a poet, when he writes that "with good reason the earth has gotten the name of mother, since all things are produced out of the earth. And many living creatures, even now, spring out of the earth, taking form by the rains and the heat of the sun." * The axiom of ancient science, "that the corruption of one thing is the birth of another," had its popular embodiment in the notion that a seed dies before the young plant springs from it; a belief so wide spread and so fixed, that Saint Paul appeals to it in one of the most splendid outbursts of his fervid eloquence:—

"Thou fool, that which thou sowest is not quickened, except it die." †

The proposition that life may, and does, proceed from that which has no life, then, was held alike by the philosophers, the poets, and the people, of the most enlightened nations, eighteen hundred years ago; and it remained the accepted doctrine of learned and unlearned Europe, through the middle ages, down even to the seventeenth century.

It is commonly counted among the many merits of our great countryman, Harvey, that he was the first to declare the opposition of fact to venerable authority in this, as in other matters; but I can discover no justification for this wide-spread notion.

* It is thus that Mr. Munro renders

"Linquitur, ut merito maternum nomen adepta
Terra sit, e terra quoniam sunt cuncta creata.
Multaque nunc etiam exsistant animalia terris
Imbribus et calido solis concreta vapore."

De Rerum Natura, lib. v. 793-796.

But would not the meaning of the last line be better rendered "Developed in rain-water and in the warm vapours raised by the sun"?

† 1 Corinthians xv. 36.

After careful search through the "Exercitationes de Generatione," the most that appears clear to me is, that Harvey believed all animals and plants to spring from what he terms a "*primordium vegetale*," a phrase which may nowadays be rendered "a vegetative germ;" and this, he says, is "*oviforme*," or "egg-like;" not, he is careful to add, that it necessarily has the shape of an egg, but because it has the constitution and nature of one. That this "*primordium oviforme*" must needs, in all cases, proceed from a living parent is nowhere expressly maintained by Harvey, though such an opinion may be thought to be implied in one or two passages; while, on the other hand, he does, more than once, use language which is consistent only with a full belief in spontaneous or equivocal generation.* In fact, the main concern of Harvey's wonderful little treatise is not with generation, in the physiological sense, at all, but with development; and his great object is the establishment of the doctrine of epigenesis.

The first distinct enunciation of the hypothesis that all living matter has sprung from pre-existing living matter, came from a contemporary, though a junior, of Harvey, a native of that country, fertile in men great in all departments of human activity, which was to intellectual Europe, in the sixteenth and seventeenth centuries, what Germany is in the nineteenth. It was in Italy, and from Italian teachers, that Harvey received the most important part of his scientific education. And it was a student trained in the same schools, Francesco Redi—a man of the widest knowledge and most versatile abilities, distinguished alike as scholar, poet, physician, and naturalist—who, just two hundred and two years ago, published his "Esperienze intorno alla Generazione degl' Insetti," and gave to the world the idea, the growth of which it is my purpose to trace. Redi's book went through five editions in twenty years; and the extreme simplicity of his experiments, and the clearness of his arguments, gained for his views, and for their consequences, almost universal acceptance.

Redi did not trouble himself much with speculative considerations, but attacked particular cases of what was supposed to be "spontaneous generation" experimentally. Here are dead animals, or pieces of meat, says he; I expose them to the air in hot weather, and in a few days they swarm with maggots. You tell me that these are generated in the dead flesh; but if I put similar bodies, while quite fresh, into a jar, and tie some fine gauze over the top of the jar, not a maggot makes its appearance, while the dead substances, nevertheless, putrefy just in the same way as before. It is obvious, therefore, that the maggots are not generated by the corruption of the meat; and that the cause of their formation must be a something which is kept away by gauze. But gauze will not keep away aëriform bodies, or fluids. This something must, therefore, exist in the form of solid particles too big to get through the gauze. Nor is one long left in doubt what these solid particles are; for the blowflies, attracted by the odour of the meat, swarm round the vessel, and, urged by a powerful but in this case misleading instinct, lay eggs out of which maggots are immediately hatched upon the gauze. The conclusion, therefore, is unavoidable; the maggots are not generated by the meat, but the eggs which give rise to them are brought through the air by the flies.

These experiments seem almost childishly simple, and one wonders how it was that no one ever thought of them before. Simple as they are, however, they are worthy of the most careful study, for every piece of experimental work since done, in regard to this subject, has been shaped upon the model furnished by the Italian philosopher. As the results of his experiments were the same, however varied the nature of the materials he used, it is not wonderful that there arose in Redi's mind a presumption, that in all such cases of the seeming production of life from dead matter, the real explanation was the introduction of living germs from without into that dead matter.† And thus the hypothesis

* See the following passage in Exercitatio I.:—"Item *sponte nascentia* dicuntur; non quod ex *putredine* oriunda sint, sed quod casu, naturæ sponte, et æquivocâ (ut aiunt) generatione, a parentibus sui dissimilibus proveniant." Again, in "De Uteri Membranis":—"In cunctorum viventium generatione (sicut diximus) hoc solenne est, ut ortum ducunt a *primordio* aliquo, quod tum materiam tum efficiendi potestatem in se habet: sitque adeo id, ex quo et a quo quicquid nascitur, ortum suum ducat. Tale primordium in animalibus (*sive ab aliis generantibus proveniant, sive sponte, aut ex putredine nascentur*) est humor in tunicâ aliquâ aut putamine conclusus." Compare also what Redi has to say respecting Harvey's opinions, "Esperienze," p. 11.

† "Pure contentandomi sempre in questa ed in ciascuna altro cosa, da ciascuno più savio, là dove io difettuosamente parlassi, esser corretto; non tacero, che per molte osservazioni molti volti da me fatte, mi sento inclinato a credere che la terra, da quelle prime piante, e da quei primi animali in poi, che ella nei primi giorni del mondo produsse per comandemento del sovrano

that living matter always arises by the agency of pre-existing living matter, took definite shape; and had, henceforward, a right to be considered and a claim to be refuted, in each particular case, before the production of living matter in any other way could be admitted by careful reasoners. It will be necessary for me to refer to this hypothesis so frequently, that, to save circumlocution, I shall call it the hypothesis of *Biogenesis;* and I shall term the contrary doctrine—that living matter may be produced by not living matter—the hypothesis of *Abiogenesis.*

In the seventeenth century, as I have said, the latter was the dominant view, sanctioned alike by antiquity and by authority; and it is interesting to observe that Redi did not escape the customary tax upon a discoverer of having to defend himself against the charge of impugning the authority of the Scriptures;* for his adversaries declared that the generation of bees from the carcase of a dead lion is affirmed, in the Book of Judges, to have been the origin of the famous riddle with which Samson perplexed the Philistines:—

> "Out of the eater came forth meat,
> And out of the strong came forth sweetness."

Against all odds, however, Redi, strong with the strength of demonstrable fact, did splendid battle for Biogenesis; but it is remarkable that he held the doctrine in a sense which, if he had lived in these times, would have infallibly caused him to be classed among the defenders of "spontaneous generation." "Omne vivum ex vivo," "no life without antecedent life," aphoristically sums up Redi's doctrine; but he went no further. It is most remarkable evidence of the philosophic caution and impartiality of his mind, that although he had speculatively anticipated the manner in which grubs really are deposited in fruits and in the galls of plants, he deliberately admits that the evidence is insufficient to bear him out; and he therefore prefers the supposition that they are generated by a modification of the living substance of the plants themselves. Indeed, he regards these vegetable growths as organs, by means of which the plant gives rise to an animal, and looks upon this production of specific animals as the final cause of the galls and of at any rate some fruits. And he proposes to explain the occurrence of parasites within the animal body in the same way.†

It is of great importance to apprehend Redi's position rightly; for the lines of thought he laid down for us are those upon which naturalists have been working ever since. Clearly, he held *Biogenesis* as against *Abiogenesis;* and I shall immediately proceed, in the first place, to inquire how far subsequent investigation has borne him out in so doing.

But Redi also thought that there were two modes of Biogenesis. By the one method, which is that of common and ordinary occurrence, the living parent gives rise to offspring which passes through the same cycle of changes as itself—like gives rise to like; and this has been termed *Homogenesis.* By the other mode the living parent was supposed to give rise to offspring which passed through a totally different series of states from those exhibited by the parent, and did not return into the cycle of the parent; this is what ought to be called *Heterogenesis,* the offspring being altogether, and permanently unlike the parent. The term Heterogenesis, however, has unfortunately been used in a different sense, and M. Milne-Edwards has therefore substituted for it *Xenogenesis,* which means the generation of something foreign. After discussing Redi's hypothesis of universal Biogenesis, then, I shall go on to ask how far the growth of science justifies his other hypothesis of Xenogenesis.

The progress of the hypothesis of Biogenesis was triumphant and unchecked for nearly a century. The application of the microscope to anatomy in the hands of Grew, Leeuwenhoek, Swammerdam, Lyonet, Vallisnieri, Reaumur, and other illustrious investigators of nature of that day, displayed such a complexity of organisation in the lowest and minutest forms, and everywhere revealed such a prodigality of provision for their multiplication by germs of one sort or another, that the hypothesis of Abiogenesis began to appear not only untrue, but absurd; and, in the middle of the eighteenth century, when Needham and Buffon took up the question, it was almost universally discredited.*

But the skill of the microscope-makers of the eighteenth century soon reached its limit. A microscope magnifying 400 diameters was a *chef d'œuvre* of the opticians of that day; and at the same time, by no means trustworthy. But a magnifying power of 400 diameters, even when definition reaches the exquisite perfection of our modern achromatic lenses, hardly suffices for the mere discernment of the smallest forms of life. A speck, only $\frac{1}{25}$th of an inch in diameter, has, at 10 inches from the eye, the same apparent size as an object $\frac{1}{10000}$th of an inch in diameter, when magnified 400 times; but forms of living matter abound, the diameter of which is not more than $\frac{1}{100000}$th of an inch. A filtered infusion of hay, allowed to stand for two days, will swarm with living things, among which, any which reaches the diameter of a human red blood-corpuscle, or about $\frac{1}{3200}$th of an inch, is a giant. It is only by bearing these facts in mind, that we can deal fairly with the remarkable statements and speculations put forward by Buffon and Needham in the middle of the eighteenth century.

When a portion of any animal or vegetable body is infused in water, it gradually softens and disintegrates; and, as it does so, the water is found to swarm with minute active creatures, the so-called Infusorial Animalcules, none of which can be seen, except by the aid of the microscope; while a large proportion belong to the category of smallest things of which I have spoken, and which must have all looked like mere dots and lines under the ordinary microscopes of the eighteenth century.

Led by various theoretical considerations which I cannot now discuss, but which looked promising enough in the lights of that day, Buffon and Needham doubted the applicability of Redi's hypothesis to the infusorial animalcules, and Needham very properly endeavoured to put the question to an experimental test.

ed omnipotente Fattore, non abbia mai più prodotto da se medesima nè erba nè albero, nè animale alcuno perfetto o imperfetto che ci se fosse; e che tutto quello, che ne' tempi trapassati è nato e che ora nascere in lei, o da lei veggiamo, venga tutto dalla semenza reale e vera delle piante, e degli animali stessi, i quali col mezzo del proprio seme la loro spezie conservano. E se bene tutto giorno scorghiamo da' cadaveri degli animali, e da tutte quante le maniere deil' erbe, e de' fiori, e dei frutti imputriditi, e corrotti nascere vermi infiniti—

> 'Nonne vides quæcunque mora, fluidoque calore
> Corpora tabescunt in parva animalia verti'—

Io mi sento, dico, inclinato a credere che tutti quei vermi si generino dal seme paterno; e che le carni, e l'erbe, e l'altre cose tutte putrefatte, o putrefattibili non facciano altra parte, nè abbiano altro ufizio nella generazione degl' insetti, se non d'apprestare un luogo o un nido proporzionato, in cui dagli animali nel tempo della figliatura sieno portati, e partoriti i vermi, o l'uova o l'altre semenze dei vermi, i quali tosto che nati sono, trovano in esso nido un sufficiente alimento abilissimo per nutricarsi: e se in quello non son portate dalle madri queste suddette semenze, niente mai, e replicatamente niente, vi s'ingegneri e nasca."—REDI, *Esperienze,* pp. 14-16.

* "Molti, e molti altri ancora vi potrei annoverare, se non fossi chiamato a rispondere alle rampogne di alcuni, che bruscamente mi rammentano ciò, che si legge nel capitolo quattordicesimo del sacrosanto Libro de' giudici. . . . . ."—REDI, *l.c.* p. 45.

† The passage (Esperienze, p. 129) is worth quoting in full:—

"Se dovessi palesarvi il mio sentimento crederei che i frutti, i legumi, gli alberi e le foglie, in due maniere inverminassero. Una, perchè venendo i bachi per di fuora, e cercando l'alimento, col rodere ci aprono la strada, ed arrivano alla più interna midolla de' frutti e de' legni. L'altra maniera si è, che io per me stimerei, che non fosse gran fatto disdicevole il credere, che quell' anima o quella virtù, la quale genera i fiori ed i frutti nelle piante viventi, sia quella stessa che generi ancora i bachi di esse piante. E chi sà orse, che molti frutti degli alberi non sieno prodotti, non per un fine primario e principale, ma bensì per un uffizio secondario e servile, destinato alla generazione di que' vermi, servendo a loro in vece di matrice, in cui dimorino un prefisso e determinato tempo; il quale arrivato escan fuora a godere il sole.

"Io m' immagino, che questo mio pensiero non vi parrà totalmente un paradosso; mentre farete riflessione a quelle tante sorte di galle, di gallozzole, di coccole, di ricci, di calici, di cornetti e di lappole, che son produtte dalle querce, dalle farnie, da' cerri, da' sugheri, da' lecci e da altri simili alberi da ghianda; imperciocchè in quelle gallozzole, e particolarmente nelle più grosse, che si chiamano coronati, ne' ricci capelluti, che ciuffoli da' nostri contadini son detti; nei ricci legnosi del cerro, ne' ricci stellati della quercia, nelle galluzze della foglia del leccio si vede evidentissimamente, che la prima e principale intenzione della natura è formare dentro di quelle un animale volante; vedendosi nel centro della gallozzola un uovo, che col crescere e col maturarsi di essa gallozzola va crescendo e maturando anch' egli, e cresce altresì a suo tempo quel verme, che nell' uovo si racchiude; il qual verme, quando la gallozzola è finita di maturare e che è venuto il termine destinato al suo nascimento, diventa, di verme che era, una mosca. . . . . Io vi confesso ingenuamente, che prima d'aver fatte queste mie esperienze intorno alla generazione degl' insetti mi dava a credere, o per dir meglio sospettava, che forse la gallozzola nascesse, perchè arrivando la mosca nel tempo della primavera, e facendo una piccolissima fessura ne' rami più teneri della quercia, in quella fessura nascondesse uno de suoi semi, il quale fosse cagione che sbocciasse fuora la gallozzola; e che mai non si vedessero galle o gallozzole o ricci o cornetti o calici o coccole, se non in que' rami, ne' quali le mosche avessero depositate le loro semenze; e mi dava ad intendere, che le gallozzole fossero una malattia cagionata nelle querce dalle punture delle mosche, in quella giusa stessa che dalle punture d'altri animaletti simiglievoli veggiamo crescere de' tumori ne' corpi degli animali."

* Needham, writing in 1750, says:—

"Les naturalistes modernes s'accordent unanimement à établir, comme une vérité certaine, que toute plante vient de sa sèmence spécifique, tout animal d'un œuf ou de quelque chose d'analogue préexistant dans la plante, ou dans l'animal de même espèce qui l'a produit."—*Nouvelles Observations,* p. 169.

"Les naturalistes ont généralement cru que les animaux microscopique étaient engendrés par des œufs transportés dans l'air, ou déposés dans des eaux dormantes par des insectes volans."—*Ibid.* p. 176.

He said to himself, if these infusorial animalcules come from germs, their germs must exist either in the substance infused, or in the water with which the infusion is made, or in the superjacent air. Now the vitality of all germs is destroyed by heat. Therefore, if I boil the infusion, cork it up carefully, cementing the cork over with mastic, and then heat the whole vessel by heaping hot ashes over it, I must needs kill whatever germs are present. Consequently, if Redi's hypothesis hold good, when the infusion is taken away and allowed to cool, no animalcules ought to be developed in it; whereas, if the animalcules are not dependent on pre-existing germs, but are generated from the infused substance, they ought, by-and-by, to make their appearance. Needham found that, under the circumstances in which he made his experiments, animalcules always did arise in the infusions, when a sufficient time had elapsed to allow for their development.

In much of his work Needham was associated with Buffon, and the results of their experiments fitted in admirably with the great French naturalist's hypothesis of "organic molecules," according to which, life is the indefeasible property of certain indestructible molecules of matter, which exist in all living things, and have inherent activities by which they are distinguished from not living matter. Each individual living organism is formed by their temporary combination. They stand to it in the relation of the particles of water to a cascade, or a whirlpool; or to a mould, into which the water is poured. The form of the organism is thus determined by the reaction between external conditions and the inherent activities of the organic molecules of which it is composed; and, as the stoppage of a whirlpool destroys nothing but a form, and leaves the molecules of the water, with all their inherent activities intact, so what we call the death and putrefaction of an animal, or of a plant, is merely the breaking up of the form, or manner of association, of its constituent organic molecules, which are then set free as infusorial animalcules.

It will be perceived that this doctrine is by no means identical with *Abiogenesis*, with which it is often confounded. On this hypothesis, a piece of beef, or a handful of hay, is dead only in a limited sense. The beef is dead ox, and the hay is dead grass; but the "organic molecules" of the beef or the hay are not dead, but are ready to manifest their vitality as soon as the bovine or herbaceous shrouds in which they are imprisoned are rent by the macerating action of water. The hypothesis therefore must be classified under Xenogenesis, rather than under Abiogenesis. Such as it was, I think it will appear, to those who will be just enough to remember that it was propounded before the birth of modern chemistry, and of the modern optical arts, to be a most ingenious and suggestive speculation.

But the great tragedy of Science—the slaying of a beautiful hypothesis by an ugly fact—which is so constantly being enacted under the eyes of philosophers, was played, almost immediately, for the benefit of Buffon and Needham.

Once more, an Italian, the Abbé Spallanzani, a worthy successor and representative of Redi in his acuteness, his ingenuity, and his learning, subjected the experiments and the conclusions of Needham to a searching criticism. It might be true that Needham's experiments yielded results such as he had described, but did they bear out his arguments? Was it not possible, in the first place, that he had not completely excluded the air by his corks and mastic? And was it not possible, in the second place, that he had not sufficiently heated his infusions and the superjacent air? Spallanzani joined issue with the English naturalist on both these pleas, and he showed that if, in the first place, the glass vessels in which the infusions were contained were hermetically sealed by fusing their necks, and if, in the second place, they were exposed to the temperature of boiling water for three-quarters of an hour,* no animalcules ever made their appearance within them. It must be admitted that the experiments and arguments of Spallanzani furnish a complete and a crushing reply to those of Needham. But we all too often forget that it is one thing to refute a proposition, and another to prove the truth of a doctrine which, implicitly or explicitly, contradicts that proposition, and the advance of science soon showed that though Needham might be quite wrong, it did not follow that Spallanzani was quite right.

Modern chemistry, the birth of the latter half of the eighteenth century, grew apace, and soon found herself face to face with the great problems which biology had vainly tried to attack without her help. The discovery of oxygen led to the laying of the foundations of a scientific theory of respiration, and to an examination of the marvellous interactions of organic substances with oxygen. The presence of free oxygen appeared to be one of the conditions of the existence of life, and of those singular changes in organic matters which are known as fermentation and putrefaction. The question of the generation of the infusory animalcules thus passed into a new phase. For what might not have happened to the organic matter of the infusions, or to the oxygen of the air, in Spallanzani's experiments? What security was there that the development of life which ought to have taken place had not been checked or prevented by these changes?

The battle had to be fought again. It was needful to repeat the experiments under conditions which would make sure that neither the oxygen of the air, nor the composition of the organic matter, was altered in such a matter as to interfere with the existence of life.

Schulze and Schwann took up the question from this point of view in 1836 and 1837. The passage of air through red-hot glass tubes, or through strong sulphuric acid, does not alter the proportion of its oxygen, while it must needs arrest or destroy any organic matter which may be contained in the air. These experimenters, therefore, contrived arrangements by which the only air which should come into contact with a boiled infusion should be such as had either passed through red-hot tubes or through strong sulphuric acid. The result which they obtained was that an infusion so treated developed no living things, while if the same infusion was afterwards exposed to the air such things appeared rapidly and abundantly. The accuracy of these experiments has been alternately denied and affirmed. Supposing them to be accepted, however, all that they really proved was that the treatment to which the air was subjected destroyed *something* that was essential to the development of life in the infusion. This "something" might be gaseous, fluid, or solid; that it consisted of germs remained only an hypothesis of greater or less probability.

Contemporaneously with these investigations a remarkable discovery was made by Cagniard de la Tour. He found that common yeast is composed of a vast accumulation of minute plants. The fermentation of must or of wort in the fabrication of wine and of beer is always accompanied by the rapid growth and multiplication of these *Torulæ*. Thus fermentation, in so far as it was accompanied by the development of microscopical organisms in enormous numbers, became assimilated to the decomposition of an infusion of ordinary animal or vegetable matter; and it was an obvious suggestion that the organisms were, in some way or other, the causes both of fermentation and of putrefaction. The chemists, with Berzelius and Liebig at their head, at first laughed this idea to scorn; but in 1843, a man then very young, who has since performed the unexampled feat of attaining to high eminence alike in Mathematics, Physics, and Physiology—I speak of the illustrious Helmholtz—reduced the matter to the test of experiment by a method alike elegant and conclusive. Helmholtz separated a putrefying or a fermenting liquid from one which was simply putrescible or fermentable by a membrane which allowed the fluids to pass through and become intermixed, but stopped the passage of solids. The result was, that while the putrescible or the fermentable liquids became impregnated with the results of the putrescence or fermentation which was going on on the other side of the membrane, they neither putrefied (in the ordinary way) nor fermented; nor were any of the organisms which abounded in the fermenting or putrefying liquid generated in them. Therefore the cause of the development of these organisms must lie in something which cannot pass through membranes; and as Helmholtz's investigations were long antecedent to Graham's researches upon colloids, his natural conclusion was that the agent thus intercepted must be a solid material. In point of fact, Helmholtz's experiments narrowed the issue to this: that which excites fermentation and putrefaction, and at the same time gives rise to living forms in a fermentable or putrescible fluid, is not a gas and is not a diffusible fluid; therefore it is either a colloid, or it is matter divided into very minute solid particles.

The researches of Schroeder and Dusch in 1854, and of Schroeder alone, in 1859, cleared up this point by experiments which are simply refinements upon those of Redi. A lump of cotton-wool is, physically speaking, a pile of many thicknesses of a very fine gauze, the fineness of the meshes of which depends upon the closeness of the compression of the wool. Now, Schroeder and Dusch found, that, in the case of all the putrefiable materials which they used (except milk and yolk of egg), an infusion boiled, and then allowed to come into contact with no air but such as had been filtered through cotton-wool, neither putrefied nor fermented, nor developed living forms. It

* See Spallanzani, "Opere," vi. pp. 42 and 51.

is hard to imagine what the fine sieve formed by the cotton-wool could have stopped except minute solid particles. Still the evidence was incomplete until it had been positively shown, first, that ordinary air does contain such particles; and, secondly, that filtration through cotton-wool arrests these particles and allows only physically pure air to pass. This demonstration has been furnished within the last year by the remarkable experiments of Professor Tyndall. It has been a common objection of Abiogenists that, if the doctrine of Biogeny is true, the air must be thick with germs; and they regard this as the height of absurdity. But Nature occasionally is exceedingly unreasonable, and Professor Tyndall has proved that this particular absurdity may nevertheless be a reality. He has demonstrated that ordinary air is no better than a sort of stir-about of excessively minute solid particles; that these particles are almost wholly destructible by heat; and that they are strained off, and the air rendered optically pure by being passed through cotton-wool.

But it remains yet in the order of logic, though not of history, to show that among these solid destructible particles there really do exist germs capable of giving rise to the development of living forms in suitable menstrua. This piece of work was done by M. Pasteur in those beautiful researches which will ever render his name famous; and which, in spite of all attacks upon them, appear to me now, as they did seven years ago,* to be models of accurate experimentation and logical reasoning. He strained air through cotton-wool, and found, as Schroeder and Dusch had done, that it contained nothing competent to give rise to the development of life in fluids highly fitted for that purpose. But the important further links in the chain of evidence added by Pasteur are three. In the first place he subjected to microscopic examination the cotton-wool which had served as strainer, and found that sundry bodies clearly recognizable as germs, were among the solid particles strained off. Secondly, he proved that these germs were competent to give rise to living forms by simply sowing them in a solution fitted for their development. And, thirdly, he showed that the incapacity of air strained through cotton-wool to give rise to life, was not due to any occult change effected in constituents of the air by the wool, by proving that the cotton-wool might be dispensed with altogether, and perfectly free access left between the exterior air and that in the experimental flask. If the neck of the flask is drawn out into a tube and bent downwards; and if, after the contained fluid has been carefully boiled, the tube is heated sufficiently to destroy any germs which may be present in the air which enters as the fluid cools, the apparatus may be left to itself for any time and no life will appear in the fluid. The reason is plain. Although there is free communication between the atmosphere laden with germs and the germless air in the flask, contact between the two takes place only in the tube; and as the germs cannot fall upwards, and there are no currents, they never reach the interior of the flask. But if the tube be broken short off where it proceeds from the flask, and free access be thus given to germs falling vertically out of the air, the fluid which has remained clear and desert for months, becomes, in a few days turbid and full of life.

These experiments have been repeated over and over again by independent observers with entire success; and there is one very simple mode of seeing the facts for oneself, which I may as well describe.

Prepare a solution (much used by M. Pasteur, and often called "Pasteur's solution") composed of water with tartrate of ammonia, sugar, and yeast-ash dissolved therein.† Divide it into three portions in as many flasks; boil all three for a quarter of an hour; and, while the steam is passing out, stop the neck of one with a large plug of cotton-wool, so that this also may be thoroughly steamed. Now set the flasks aside to cool, and when their contents are cold, add to one of the open ones a drop of filtered infusion of hay which has stood for twenty-four hours, and is consequently full of the active and excessively minute organisms known as *Bacteria*. In a couple of days of ordinary warm weather the contents of this flask will be milky from the enormous multiplication of *Bacteria*. The other flask, open and exposed to the air, will, sooner or later, become milky with *Bacteria*, and patches of mould may appear in it; while the liquid in the flask, the neck of which is plugged with cotton-wool, will remain clear for an indefinite time. I have sought in vain for any explanation of these facts, except the obvious one, that the air contains germs competent to give rise to *Bacteria*, such as those with which the first solution has been knowingly and purposely inoculated, and to the mould-*Fungi*. And I have not yet been able to meet with any advocate of Abiogenesis who seriously maintains that the atoms of sugar, tartrate of ammonia, yeast-ash, and water, under no influence but that of free access of air and the ordinary temperature, rearrange themselves and give rise to the protoplasm of *Bacterium*. But the alternative is to admit that these *Bacteria* arise from germs in the air; and if they are thus propagated, the burden of proof that other like forms are generated in a different manner, must rest with the assertor of that proposition.

To sum up the effect of this long chain of evidence:—

It is demonstrable that a fluid eminently fit for the development of the lowest forms of life, but which contains neither germs, nor any protein compound, gives rise to living things in great abundance if it is exposed to ordinary air, while no such development takes place if the air with which it is in contact is mechanically freed from the solid particles which ordinarily float in it and which may be made visible by appropriate means.

It is demonstrable that the great majority of these particles are destructible by heat, and that some of them are germs or living particles capable of giving rise to the same forms of life as those which appear when the fluid is exposed to unpurified air.

It is demonstrable that inoculation of the experimental fluid with a drop of liquid known to contain living particles gives rise to the same phenomena as exposure to unpurified air.

And it is further certain that these living particles are so minute that the assumption of their suspension in ordinary air presents not the slightest difficulty. On the contrary, considering their lightness and the wide diffusion of the organisms which produce them, it is impossible to conceive that they should not be suspended in the atmosphere in myriads.

Thus the evidence, direct and indirect, in favour of *Biogenesis* for all known forms of life must, I think, be admitted to be of great weight.

On the other side the sole assertions worthy of attention are that hermetically sealed fluids, which have been exposed to great and long-continued heat, have sometimes exhibited living forms of low organization when they have been opened.*

The first reply that suggests itself is the probability that there must be some error about these experiments, because they are performed on an enormous scale every day with quite contrary results. Meat, fruits, vegetables, the very materials of the most fermentable and putrescible infusions are preserved to the extent, I suppose I may say, of thousands of tons every year, by a method which is a mere application of Spallanzani's experiment. The matters to be preserved are well boiled in a tin case provided with a small hole, and this hole is soldered up when all the air in the case has been replaced by steam. By this method they may be kept for years without putrefying, fermenting, or getting mouldy. Now this is not because oxygen is excluded, inasmuch as it is now proved that free oxygen is not necessary for either fermentation or putrefaction. It is not because the tins are exhausted of air, for *Vibriones* and *Bacteria* live, as Pasteur has shown, without air or free oxygen. It is not because the boiled meats or vegetables are not putrescible or fermentable, as those who have had the misfortune to be in a ship supplied with unskilfully closed tins well know. What is it, therefore, but the exclusion of germs? I think that Abiogenists are bound to answer this question before they ask us to consider new experiments of precisely the same order.

And in the next place, if the results of the experiments I refer to are really trustworthy, it by no means follows that Abiogenesis has taken place. The resistance of living matter to heat is known to vary within considerable limits, and to depend, to some extent, upon the chemical and physical qualities of the surrounding medium. But if, in the present state of science, the alternative is offered us, either germs can stand a greater heat than has been supposed, or the molecules of dead matter, for no valid or intelligible reason that is assigned, are able to rearrange themselves into living bodies, exactly such as can be demonstrated to be frequently produced in another way, I cannot understand how choice can be, even for a moment, doubtful.

But though I cannot express this conviction of mine too strongly, I must carefully guard myself against the supposition

* "Lectures to Working Men on the Causes of the Phenomena of Organic Nature," 1863.

† Infusion of hay treated in the same way yields similar results; but as it contains organic matter the argument which follows cannot be based upon it.

* For a full account of the most recent series of experiments of this description see Dr. H. C. Bastian's paper in NATURE, No. xxxv., p. 170; No. xxxvi., p. 193; and No. xxxvii., p. 219.—ED.

that I intend to suggest that no such thing as Abiogenesis ever has taken place in the past or ever will take place in the future. With organic chemistry, molecular physics, and physiology yet in their infancy, and every day making prodigious strides, I think it would be the height of presumption for any man to say that the conditions under which matter assumes the properties we call "vital" may not, some day, be artificially brought together. All I feel justified in affirming is that I see no reason for believing that the feat has been performed yet.

And looking back through the prodigious vista of the past, I find no record of the commencement of life, and therefore I am devoid of any means of forming a definite conclusion as to the conditions of its appearance. Belief, in the scientific sense of the word, is a serious matter, and needs strong foundations. To say, therefore, in the admitted absence of evidence, that I have any belief as to the mode in which the existing forms of life have originated, would be using words in a wrong sense. But expectation is permissible where belief is not; and if it were given me to look beyond the abyss of geologically recorded time to the still more remote period when the earth was passing through physical and chemical conditions, which it can no more see again than a man can recall his infancy, I should expect to be a witness of the evolution of living protoplasm from not living matter. I should expect to see it appear under forms of great simplicity, endowed, like existing fungi, with the power of determining the formation of new protoplasm from such matters as ammonium carbonates, oxalates and tartrates, alkaline and earthy phosphates, and water, without the aid of light. That is the expectation to which analogical reasoning leads me; but I beg you once more to recollect that I have no right to call my opinion anything but an act of philosophical faith.

So much for the history of the progress of Redi's great doctrine of Biogenesis, which appears to me, with the limitations I have expressed, to be victorious along the whole line at the present day.

As regards the second problem offered to us by Redi, whether Xenogenesis obtains, side by side with Homogenesis; whether, that is, there exist not only the ordinary living things, giving rise to offspring which run through the same cycle as themselves, but also others, producing offspring which are of a totally different character from themselves, the researches of two centuries have led to a different result. That the grubs found in galls are no product of the plants on which the galls grow, but are the result of the introduction of the eggs of insects into the substance of these plants, was made out by Vallisnieri, Reaumur, and others, before the end of the first half of the eighteenth century. The tapeworms, bladderworms, and flukes continued to be a stronghold of the advocates of Xenogenesis for a much longer period. Indeed, it is only within the last thirty years that the splendid patience of Von Siebold, Van Beneden, Leuckart, Küchenmeister, and other helminthologists, has succeeded in tracing every such parasite, often through the strangest wanderings and metamorphoses, to an egg derived from a parent, actually or potentially like itself; and the tendency of inquiries elsewhere has all been in the same direction. A plant may throw off bulbs, but these, sooner or later, give rise to seeds or spores, which develop into the original form. A polype may give rise to Medusæ, or a pluteus to an Echinoderm, but the Medusa and the Echinoderm give rise to eggs which produce polypes or plutei, and they are therefore only stages in the cycle of life of the species.

But if we turn to pathology it offers us some remarkable approximations to true Xenogenesis.

As I have already mentioned, it has been known since the time of Vallisnieri and of Reaumur, that galls in plants, and tumours in cattle, are caused by insects, which lay their eggs in those parts of the animal or vegetable frame of which these morbid structures are outgrowths. Again, it is a matter of familiar experience to everybody that mere pressure on the skin will give rise to a corn. Now the gall, the tumour, and the corn are parts of the living body, which have become, to a certain degree, independent and distinct organisms. Under the influence of certain external conditions, elements of the body, which should have developed in due subordination to its general plan, set up for themselves and apply the nourishment which they receive to their own purposes.

From such innocent productions as corns and warts, there are all gradations to the serious tumours which, by their mere size and the mechanical obstruction they cause, destroy the organism out of which they are developed; while, finally, in those terrible structures known as cancers, the abnormal growth has acquired powers of reproduction and multiplication, and is only morphologically distinguishable from the parasite worm, the life of which is neither more nor less closely bound up with that of the infested organism.

If there were a kind of diseased structure, the histological elements of which were capable of maintaining a separate and independent existence out of the body, it seems to me that the shadowy boundary between morbid growth and Xenogenesis would be effaced. And I am inclined to think that the progress of discovery has almost brought us to this point already. I have been favoured by Mr. Simon with an early copy of the last published of the valuable "Reports on the Public Health," which, in his capacity of their medical officer, he annually presents to the Lords of the Privy Council. The appendix to this report contains an introductory essay "On the Intimate Pathology of Contagion," by Dr. Burdon Sanderson, which is one of the clearest, most comprehensive, and well-reasoned discussions of a great question which has come under my notice for a long time. I refer you to it for details and for the authorities for the statements I am about to make.

You are familiar with what happens in vaccination. A minute cut is made in the skin, and an infinitesimal quantity of vaccine matter is inserted into the wound. Within a certain time a vesicle appears in the place of the wound, and the fluid which distends this vesicle is vaccine matter, in quantity a hundred or a thousandfold that which was originally inserted. Now what has taken place in the course of this operation? Has the vaccine matter, by its irritative property, produced a mere blister, the fluid of which has the same irritative property? Or does the vaccine matter contain living particles, which have grown and multiplied where they have been planted? The observations of M. Chauveau, extended and confirmed by Dr. Sanderson himself, appear to leave no doubt upon this head. Experiments, similar in principle to those of Helmholtz on fermentation and putrefaction, have proved that the active element in the vaccine lymph is non-diffusible, and consists of minute particles not exceeding $\frac{1}{20000}$ of an inch in diameter, which are made visible in the lymph by the microscope. Similar experiments have proved that two of the most destructive of epizootic diseases, sheep-pox and glanders, are also dependent for their existence and their propagation upon extremely small living solid particles, to which the title of *microzymes* is applied. An animal suffering under either of these terrible diseases is a source of infection and contagion to others, for precisely the same reason as a tub of fermenting beer is capable of propagating its fermentation by "infection," or "contagion," to fresh wort. In both cases it is the solid living particles which are efficient; the liquid in which they float, and at the expense of which they live, being altogether passive.

Now arises the question, are these microzymes the results of *Homogenesis*, or of *Xenogenesis*; are they capable, like the *Torulæ* of yeast, of arising only by the development of pre-existing germs; or may they be, like the constituents of a nutgall, the results of a modification and individualisation of the tissues of the body in which they are found, resulting from the operation of certain conditions? Are they parasites in the zoological sense, or are they merely what Virchow has called "heterologous growths"? It is obvious that this question has the most profound importance, whether we look at it from a practical or from a theoretical point of view. A parasite may be stamped out by destroying its germs, but a pathological product can only be annihilated by removing the conditions which give rise to it.

It appears to me that this great problem will have to be solved for each zymotic disease separately, for analogy cuts two ways. I have dwelt upon the analogy of pathological modification, which is in favour of the xenogenetic origin of microzymes; but I must now speak of the equally strong analogies in favour of the origin of such pestiferous particles by the ordinary process of the generation of like from like.

It is, at present, a well-established fact that certain diseases, both of plants and of animals, which have all the characters of contagious and infectious epidemics, are caused by minute organisms. The smut of wheat is a well-known instance of such a disease, and it cannot be doubted that the grape-disease and the potato-disease fall under the same category. Among animals, insects are wonderfully liable to the ravages of contagious and infectious diseases caused by microscopic *Fungi*.

In autumn, it is not uncommon to see flies, motionless upon a window-pane, with a sort of magic circle, in white, drawn round them. On microscopic examination, the magic circle is found to consist of innumerable spores, which have been thrown off in all directions by a minute fungus called *Empusa muscæ*, the spore-forming filaments of which stand out like a pile of velvet from the body of the fly. These spore-forming filaments are connected with others which fill the interior of the fly's body like so much fine wool, having eaten away and destroyed the creature's viscera. This is the full-grown condition of the *Empusa*. If traced back to its earlier stages, in flies which are still active, and to all appearance healthy, it is found to exist in the form of minute corpuscles which float in the blood of the fly. These multiply and lengthen into filaments, at the expense of the fly's substance; and when they have at last killed the patient, they grow out of its body and give off spores. Healthy flies shut up with diseased ones catch this mortal disease and perish like the others. A most competent observer, M. Cohn, who studied the development of the *Empusa* in the fly very carefully, was utterly unable to discover in what manner the smallest germs of the *Empusa* got into the fly. The spores could not be made to give rise to such germs by cultivation; nor were such germs discoverable in the air, or in the food of the fly. It looked exceedingly like a case of Abiogenesis, or, at any rate, of Xenogenesis; and it is only quite recently that the real course of events has been made out. It has been ascertained, that when one of the spores falls upon the body of a fly, it begins to germinate and sends out a process which bores its way through the fly's skin; this, having reached the interior cavities of its body, gives off the minute floating corpuscles which are the earliest stage of the *Empusa*. The disease is "contagious," because a healthy fly coming in contact with a diseased one, from which the spore-bearing filaments protrude, is pretty sure to carry off a spore or two. It is "infectious" because the spores become scattered about all sorts of matter in the neighbourhood of the slain flies.

The silkworm has long been known to be subject to a very fatal and infectious disease called the *Muscardine*. Audouin transmitted it by inoculation. This disease is entirely due to the development of a fungus, *Botrytis Bassiana*, in the body of the caterpillar; and its contagiousness and infectiousness are accounted for in the same way as those of the fly-disease. But of late years a still more serious epizootic has appeared among the silkworms; and I may mention a few facts which will give you some conception of the gravity of the injury which it has inflicted on France alone.

The production of silk has been for centuries an important branch of industry in Southern France, and in the year 1853 it had attained such a magnitude that the annual produce of the French sericulture was estimated to amount to a tenth of that of the whole world, and represented a money-value of 117,000,000 of francs, or nearly five millions sterling. What may be the sum which would represent the money-value of all the industries connected with the working up of the raw silk thus produced is more than I can pretend to estimate. Suffice it to say that the city of Lyons is built upon French silk as much as Manchester was upon American cotton before the civil war.

Silkworms are liable to many diseases; and even before 1853 a peculiar epizootic, frequently accompanied by the appearance of dark spots upon the skin (whence the name of "Pébrine" which it has received), had been noted for its mortality. But in the years following 1853 this malady broke out with such extreme violence, that, in 1858, the silk-crop was reduced to a third of the amount which it had reached in 1853; and, up till within the last year or two, it has never attained half the yield of 1853. This means not only that the great number of people engaged in silk growing are some thirty millions sterling poorer than they might have been; it means not only that high prices have had to be paid for imported silkworm eggs, and that, after investing his money in them, in paying for mulberry-leaves and for attendance, the cultivator has constantly seen his silkworms perish and himself plunged in ruin; but it means that the looms of Lyons have lacked employment, and that for years enforced idleness and misery have been the portion of a vast population which, in former days, was industrious and well to do.

In 1858 the gravity of the situation caused the French Academy of Sciences to appoint Commissioners, of whom a distinguished naturalist, M. de Quatrefages, was one, to inquire into the nature of this disease, and, if possible, to devise some means of staying the plague. In reading the Report* made by M. de Quatrefages in 1859, it is exceedingly interesting to observe that his elaborate study of the Pébrine forced the conviction upon his mind that, in its mode of occurrence and propagation, the disease of the silkworm is, in every respect, comparable to the cholera among mankind. But it differs from the cholera, and so far is a more formidable disease, in being hereditary, and in being, under some circumstances, contagious as well as infectious.

The Italian naturalist, Filippi, discovered in the blood of the silkworms affected by this strange disease a multitude of cylindrical corpuscles, each about $\frac{1}{6000}$ of an inch long. These have been carefully studied by Lebert, and named by him *Panhistophyton*; for the reason that in subjects in which the disease is strongly developed, the corpuscles swarm in every tissue and organ of the body, and even pass into the undeveloped eggs of the female moth. But are these corpuscles causes, or mere concomitants, of the disease? Some naturalists took one view and some another; and it was not until the French Government, alarmed by the continued ravages of the malady, and the inefficiency of the remedies which had been suggested, dispatched M. Pasteur to study it, that the question received its final settlement; at a great sacrifice, not only of the time and peace of mind of that eminent philosopher, but, I regret to have to add, of his health.*

But the sacrifice has not been in vain. It is now certain that this devastating, cholera-like Pébrine is the effect of the growth and multiplication of the *Panhistophyton* in the silkworm. It is contagious and infectious because the corpuscles of the *Panhistophyton* pass away from the bodies of the diseased caterpillars, directly or indirectly, to the alimentary canal of healthy silkworms in their neighbourhood; it is hereditary, because the corpuscles enter into the eggs while they are being formed, and consequently are carried within them when they are laid; and for this reason, also, it presents the very singular peculiarity of being inherited only on the mother's side. There is not a single one of all the apparently capricious and unaccountable phenomena presented by the Pébrine, but has received its explanation from the fact that the disease is the result of the presence of the microscopic organism, *Panhistophyton*.

Such being the facts with respect to the Pébrine, what are the indications as to the method of preventing it? It is obvious that this depends upon the way in which the *Panhistophyton* is generated. If it may be generated by Abiogenesis, or by Xenogenesis, within the silkworm or its moth, the extirpation of the disease must depend upon the prevention of the occurrence of the conditions under which this generation takes place. But if, on the other hand, the *Panhistophyton* is an independent organism, which is no more generated by the silkworm than the mistletoe is generated by the oak or the apple-tree on which it grows, though it may need the silkworm for its development in the same way as the mistletoe needs the tree, then the indications are totally different. The sole thing to be done is to get rid of and keep away the germs of the *Panhistophyton*. As might be imagined, from the course of his previous investigations, M. Pasteur was led to believe that the latter was the right theory; and, guided by that theory, he has devised a method of extirpating the disease, which has proved to be completely successful wherever it has been properly carried out.

There can be no reason, then, for doubting that, among insects, contagious and infectious diseases, of great malignity, are caused by minute organisms which are produced from pre-existing germs, or by homogenesis; and there is no reason, that I know of, for believing that what happens in insects may not take place in the highest animals. Indeed, there is already strong evidence that some diseases of an extremely malignant and fatal character to which man is subject, are as much the work of minute organisms as is the Pébrine. I refer for this evidence to the very striking facts adduced by Professor Lister in his various well-known publications on the antiseptic method of treatment. It seems to me impossible to rise from the perusal of those publications without a strong conviction that the lamentable mortality which so frequently dogs the footsteps of the most skilful operator, and those deadly consequences of wounds and injuries which seem to haunt the very walls of great hospitals, and are, even now, destroying more men than die of bullet or bayonet, are due to the importation of minute organisms into wounds, and their increase and multiplication; and that the surgeon who saves most lives will be he who best works out the practical consequences of the hypothesis of Redi.

* Etudes sur les Maladies Actuelles des Vers à Soie, p. 53.

* In NATURE, No. xxxvi., p. 181, will be found a *résumé*, by Prof. Tyndall, of Pasteur's investigations of the silkworm disease,—ED.

I commenced this Address by asking you to follow me in an attempt to trace the path which has been followed by a scientific idea, in its long and slow progress from the position of a probable hypothesis to that of an established law of nature. Our survey has not taken us into very attractive regions; it has lain, chiefly, in a land flowing with the abominable, and peopled with mere grubs and mouldiness. And it may be imagined with what smiles and shrugs, practical and serious contemporaries of Redi and of Spallanzani may have commented on the waste of their high abilities in toiling at the solution of problems which, though curious enough in themselves, could be of no conceivable utility to mankind.

Nevertheless you will have observed that before we had travelled very far upon our road there appeared, on the right hand and on the left, fields laden with a harvest of golden grain, immediately convertible into those things which the most sordidly practical of men will admit to have value—viz., money and life.

The direct loss to France caused by the Pébrine in seventeen years cannot be estimated at less than fifty millions sterling; and if we add to this what Redi's idea, in Pasteur's hands, has done for the wine-grower and for the vinegar-maker, and try to capitalise its value, we shall find that it will go a long way towards repairing the money losses caused by the frightful and calamitous war of this autumn. And as to the equivalent of Redi's thought in life, how can we over-estimate the value of that knowledge of the nature of epidemic and epizöotic diseases, and consequently of the means of checking, or eradicating, them, the dawn of which has assuredly commenced?

Looking back no further than ten years, it is possible to select three (1863, 1864, and 1869) in which the total number of deaths from scarlet-fever alone amounted to ninety thousand. That is the return of killed, the maimed and disabled being left out of sight. Why, it is to be hoped that the list of killed in the present bloodiest of all wars will not amount to more than this! But the facts which I have placed before you must leave the least sanguine without a doubt that the nature and the causes of this scourge will, one day, be as well understood as those of the Pébrine are now; and that the long-suffered massacre of our innocents will come to an end.

And thus mankind will have one more admonition that "the people perish for lack of knowledge;" and that the alleviation of the miseries, and the promotion of the welfare, of men must be sought, by those who will not lose their pains, in that diligent, patient, loving study of all the multitudinous aspects of Nature, the results of which constitute exact knowledge, or Science. It is the justification and the glory of this great meeting that it is gathered together for no other object than the advancement of the moiety of science which deals with those phenomena of nature which we call physical. May its endeavours be crowned with a full measure of success!

PROFESSOR H. E. ROSCOE'S OPENING ADDRESS TO SECTION B.

GENTLEMEN,—In the midst of the excitement of the horrible war in which the two most scientific nations of the continent are now plunged, and in which even the Professors of Chemistry and their students take a humane part, let us endeavour to turn our thoughts into channels more congenial to the scientific inquirer, and allow me to recount to you, as far as I am able, the peaceful victories which, since our last meeting in Exeter, have been achieved in our special department of chemistry. And here may I remind you of the cosmopolitan character of science, of the fact that it is mainly to the brotherly intercourse of those interested in science, and in its applications to the arts and manufactures in different countries, that we must look as the small but living fire which in the end will surely serve to melt down national animosities, and to render impossible the breaking out of disasters so fatal to the welfare of humanity as that of which we are now unfortunately the spectators.

With regard to the position of chemical science at the present moment, it will not take a careful observer long to see, that in spite of the numerous important and brilliant discoveries of which every year has to boast, we are really but very imperfectly acquainted with the fundamental laws which regulate chemical actions, and that our knowledge of the ultimate constitution of matter upon which those laws are based is but of the most elementary nature. In proof of this, I need only refer to the different opinions expressed by our leading chemists in a discussion which lately took place at the Chemical Society on the subject of the Atomic Theory. The President (Dr. Williamson) delivered a very interesting lecture in which the existence of atoms was treated as "the very life of chemistry." Dr. Frankland, on the other hand, states, that he cannot understand action at a distance between matter separated by a vacuous space, and, although generally granting that the atomic theory explains chemical facts, yet he is not to be considered as a blind believer in the theory, or as unwilling to renounce it if anything better presented itself. Sir B. C. Brodie and Dr. Odling both agree, that the science of chemistry neither requires nor proves the atomic theory; whilst the former points out that the true basis of this science is to be sought in the investigation of the laws of gaseous combination, or the study of the capacity of bodies for heat, rather than in committing ourselves to assertions incapable of proof by chemical means.

Agreeing in the main myself with the opinions of the last chemists, and believing that we must well distinguish between fact and theory, I would remind you that Dalton's discovery of the laws of multiple and reciprocal proportions (I use Dr. Odling's phraseology), as well as the differences in the power of hydrogen replacement in hydrochloric acid water, ammonia, and marsh gas, *are facts*, whilst the explanation upon the assumption of atoms is, as far as chemistry is as yet advanced, *a theory*.

If, however, the existence of atoms cannot be *proved* by chemical phenomena, we must remember that the assumption of the atomic theory explains chemical facts, as the undulatory theory gives a clear view of the phenomena of light; thus, for instance, one of the most important facts and relations of modern chemistry, which it appears difficult if not impossible to explain without the assumption of atoms, is that of Isomerism. How otherwise than by a different arrangement of the single constituent particles are we to account for several distinct substances in which the proportions of carbon, hydrogen, and oxygen are the same? Why, for instance, should 48 parts, by weight, of carbon, 10 of hydrogen, and 16 of oxygen, united together, be capable of existing as three different chemical substances, unless we presuppose a different statical arrangement of the parts by which these differences in the deportment of the whole are rendered possible. If, then, it be true that chemistry cannot give us positive information as to whether matter is infinitely divisible and therefore continuous, or consists of atoms and is discontinuous, we are in some degree assisted in this inquiry by deductions from physical phenomena which have been recently pointed out by the genius of Sir William Thomson. He argues from four different classes of physical phenomena, and comes to the conclusion not only that matter is discontinuous, and therefore that atoms and molecules do exist, but he even attempts to form an idea of the size of these molecules, and he states that in any ordinary liquid, transparent or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than the 100 millionth, and greater than the 2,000 millionth of a centimetre. Or, to form a conception of this coarse-grainedness, imagine a raindrop, or globe of glass as large as a pea, to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion, the magnified structure would be coarser grained than a heap of small shot, but probably less coarse grained than a heap of cricket balls. There is, however, another class of physical considerations which renders the existence of indivisible particles more than likely. I refer to the mechanical theory of gases, by means of which, thanks to the labours of eminent English and German philosophers, all the physical properties of gases—their equal expansion by heat, the laws of diffusion, the laws of alteration of volume under pressure—can be shown to follow from the simple laws of mechanical motion. This theory, however, presupposes the existence of molecules, and in this direction, again, we find confirmation of the real existence of Dalton's atoms. Indeed, it has been proved that the average velocity with which the particles of oxygen, nitrogen, or common air are continually projected forwards amounts, at the ordinary atmospheric pressure, to 50,000 centimetres per second, whilst the average number of impacts of each of these molecules is 5,000 million per second.

The mention of the molecular motions of gases will recall to the minds of all present the great loss which English science has this year sustained in the death of the discoverer of the laws of gaseous diffusion. Throughout his life Graham's aim was the advancement of our knowledge in the special subject of the molecular properties of gases. With this intent he unceasingly laboured up to the moment of his death, in spite of failing health and pressure of official business, unfolding for posterity some of the most difficult as well as the most interesting secrets of nature in this branch of our science. "What do you think," he writes to Hoffmann, "of metallic hydrogen, a white magnetic metal?" and yet now, through his labours, the fact of the condensation of hydrogen in the solid state by metallic palladium, and to a less extent by other metals, has become familiar to all of us. Then, again, I would remind you of Graham's recent discovery of the occlusion of hydrogen gas in certain specimens of meteoric iron, whilst earth-manufactured iron contains, not hydrogen, but absorbed carbonic oxide gas, proving that the meteorite had probably been thrown out from an atmosphere of incandescent hydrogen, existing under very considerable pressure, and therefore confirming in a remarkable degree the conclusions to which spectrum analysis had previously led us. The position in the ranks of British science left by Graham's death will not be easily filled up. He accomplished to a certain extent for dynamical chemistry what Dalton did for statical chemistry; and it is upon his experimental researches in molecular chemistry that Graham's permanent fame as one of England's greatest chemists, will rest.

As closely connected with the above subjects I have next to mention a most important research by Dr. Andrews, of Belfast, which, marking an era in the history of gases, shows us how our oldest and most cherished notions must give way before the touchstone of experiment. No opinion would appear to have been more firmly established than that of the existence of three separate states or conditions of matter, viz. the solid, the liquid, and the gaseous. A body capable of existing in two or more of these states was thought to pass suddenly from one to the other by absorption or emission of heat, or by alterations of the superincumbent pressure. Dr. Andrews has shown us how false are our views on this fundamental property of matter, for he has proved that a large number of, and probably all, easily condensible gases or vapours possess a critical point of temperature at and above which no increase of pressure can be made to effect a change into what we call the liquid state, the body remaining as a homogeneous fluid. Whilst below this critical temperature certain increase of pressure always effects a separation into two layers of liquid and gaseous matter. Thus with carbonic acid the point of critical temperature is 30°·92 C., and with each given substance this point is a specific one; each vapour exhibiting rapid changes of volume and flickering movements when the temperature or pressure was changed, but showing no separation into two layers. Under these circumstances it is impossible to say that the body exists either in the state of a gas or of a liquid; it appears to be in a condition intermediate between the two. Thus carbonic acid under the pressure of 108 atmospheres, and at 35° 5′C., is reduced to $\frac{1}{430}$ of the volume which it occupies at one atmosphere: it has undergone a regular and unbroken contraction, and it is a uniform fluid. If we now reduce the temperature below 31° C., the liquid condition is assumed without any sudden change of volume or any abrupt evolution of heat. We can scarcely too highly estimate the value of the researches of Andrews.

As examples of the power which modern methods of research give of grappling with questions which only a few years ago were thought to be insoluble, I may quote the beautiful observations, now well known, by which Lockyer determined the rate of motion on the sun's surface, together with those of Frankland and Lockyer respecting the probable pressure acting in the different layers of the solar atmosphere; and, lastly, the results obtained by Zöllner respecting solar physics, and especially the probable absolute temperature of the sun's atmosphere, as well as that of the internal molten mass. These last results are so interesting and remarkable, as being arrived at by the combination of recent spectroscopic observation with high mathematical analysis, that I may perhaps be permitted shortly to state them. Starting from the fact of the eruptive nature of a certain class of solar protuberances, Zöllner thinks that the extraordinary rapidity with which these red flames shoot forth proves that the hydrogen of which they are mainly composed must have burst out from under great pressure; and, if so, the hydrogen must have been confined by a zone or layer of liquid from which it breaks loose. Assuming the existence of such a layer of incandescent liquid, then applying to the problem the principles and methods of the mechanical theory of gases, and placing in his formulæ the data of pressure and rate of motion as observed by Lockyer on the sun's surface, Zöllner arrives at the conclusion that the difference of pressure needed to produce an explosion capable of projecting a prominence to the height of 3·0 minutes above the sun's surface (a height not unfrequently noticed) is 4,070,000 atmospheres. This enormous pressure is attained at a depth of 139 geographical miles under the sun's surface, or at that of the $\frac{1}{668}$ part of the sun's semi-diameter. In order to produce this gigantic pressure, the difference in temperature between the enclosed hydrogen and that existing in the solar atmosphere amounts to 74,710° C.! In a similar way Zöllner calculates the approximative absolute temperature of the sun's atmosphere, which he finds to be 27,700° C.; a temperature about eight times as high as that given by Bunsen for the oxyhydrogen flame, and one at which iron must exist in a permanently gaseous form.

Passing on to more purely chemical subjects, we find this year signalized by the redetermination of a most important series of chemical constants, viz. that of the heat of chemical combination by Julius Thomsen, of Copenhagen. This conscientious experimentalist asserts that the measurements of the heat evolved by neutralizing acids and bases hitherto considered most correct, viz. those made with a mercury calorimeter by Favre and Silbermann, differ from the truth by 12 per cent.; whilst the determination by these experimenters of the heat of solution of salts is frequently 50 per cent. wrong. As the result of his numerous experiments, Thomsen concludes that when a molecule of acid is neutralized by caustic alkali the heat evolved increases nearly proportionally to the quantity of alkali added until this reaches 1, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$ of a molecule of alkali, according as the acid is mono-, di-, tri-, or tetra-basic. Exceptions to the law are exhibited by silicic, and also partly by boracic, orthophosphoric, and arsenic acids. In the two latter, the heat of combination is proportional for the two first atoms of replaceable hydrogen, but much less for the third atom. A second unexpected conclusion which Thomsen draws from his calorific determinations is, that sulphuretted hydrogen is a monobasic acid, and that its rational formula is therefore HSH.

Another important addition made to chemistry since our last meeting is a new, very powerful, and very simple form of galvanic battery discovered, though not yet described, by Bunsen. In this second Bunsen's battery only one liquid, a mixture of sulphuric and chromic acids, and therefore no porous cells, are employed. The plates of zinc and carbon can all be lowered at once into the liquid and raised again at will. The electromotive force of this battery is to that of Grove (the most powerful of known forms) as 25 to 18; it evolves no fumes in working, and can be used for a very considerable length of time without serious diminution of the strength of the current, so that Bunsen writes me that no one who has once used the new battery will ever think of again employing the old forms. I had hoped to be able to exhibit to the Section this important improvement in our means of producing a strong current; but war has demanded the use of other batteries, and Bunsen has been unable to send me a set of his new cells.

Amongst the marked points of interest and progress in inorganic chemistry during the past year, we have to notice the preparation of a missing link amongst the oxy-sulphur acids by Schützenberger. It is the lowest known, and may be called Hydro-Sulphurous Acid, H_2SO_2. The sodium salt, $NaHSO_2$, is obtained by the action of zinc on the bisulphite. As might be expected, it possesses very powerful reducing properties, and bleaches indigo rapidly. The metallic vanadates have also been carefully examined, and the existence of three distinct series of salts proved, corresponding to the phosphates, viz. the ortho or tribasic vanadates, the pyro or tetra-basic vanadates, and the meta or monobasic vanadates. Of these, the ortho-salts are most stable at a high temperature, whilst at the ordinary atmospheric temperature the meta-salts are most stable. In the phosphorus series, as is well known, the order of stability is the reverse; and thus the points of analogy and of difference between phosphorus and vanadium become gradually apparent.

As an illustration of the results of modern organic research—for in viewing the year's progress in this ever-widening branch of chemistry it is impossible to do more than give a few illustrations—I may quote Baeyer's remarkable investigations on Mellitic Acid. Originally discovered by Klaproth in honeystone or mellite (a substance which yet remains the only source of the acid), mellitic was supposed to be a four-carbon acid. Baeyer has quite recently shown that the acid contains 12 atoms of carbon, or has a molecular weight three times as great as was originally supposed. He has shown that mellitic acid is benzol-hexacarbonic acid, $C_{12}H_6O_{12}$, or benzol in which the 6 atoms of hydrogen are replaced by the monad radical carboxl (COOH); as benzoic is Benzol Monocarbonic acid, or benzol in which one of hydrogen is replaced by carboxyl. The most interesting portion of Baeyer's research, however, lies in the intermediate acids, partly new and partly acids already prepared, which he has shown lie between mellitic and benzoic acid, and in which from 1 to 6 atoms of hydrogen in benzol are respectively replaced by carboxyl. Nor is this all, for he has proved that, with two exceptions, each of these six acids is capable of existing in three isomeric modifications, thus giving us an insight into the arrangement of the molecule of these aromatic compounds. For the simplest mode of explaining these numerous isomers is that given by Baeyer in the different order in which the several atoms of hydrogen in the benzol molecule are replaced. Thus in the first or ortho series, the hydrogen atoms in benzol being numbered in regular succession, they are replaced in the same regular succession. In the second or meta series, the order is 1, 2, 3, 5, &c., whilst the third or para series take open order as 1, 2, 4, 5.

Thus we have :—

	Ortho Series.	Para Series.	Meta Series.
$C_{12} H_6 O_{12}$ Hexeabasic	Mellitic or Benzolhexacarbonic.	—	—
$C_{11} H_6 O_{10}$ Penta .	Unknown.	—	—
$C_{10} H_6 O_8$ Tetra . .	Pyromellitic or Benzoltetracarbonic.	Isopyromellitic.	Unknown.
$C_9 H_6 O_6$ Tri . . .	Trimesinic, or Benzoltricarbonic.	Hemimellitic.	Trimellitic.
$C_8 H_6 O_4$ Di . . .	Phtalic or Benzoldicarbonic	Isophtalic.	Tetraphtalic.
$C_7 H_6 O_2$ Mono . .	Benzoic or Benzol Monocarbonic.	—	—

Amongst the most interesting series of new organic bodies are those in which tetrad silicon partly replaces carbon. Our knowledge of these substances is gradually becoming more complete; the last new member prepared by Friedel and Ladenburg is silico-propionic acid $C_2 H_5 Si O_2 H$, the first of a series of carbo-silicic acids containing the radical $Si O_2 H$.

The interesting researches of Matthiessen and Wright on Morphine and Codeine have thrown a new light on the constitution of these opium alkaloids. Treated with hydrochloric acid, morphine loses one molecule of water, and gives rise to a new base, called apomorphine. Thus :

$$\underset{\text{Morphine.}}{C_{17} H_{19} NO_3} = H_2 O + \underset{\text{Apomorphine.}}{C_{17} H_{17} NO_2}$$

which differs in a remarkable manner from morphine, both in its chemical and physiological actions, being soluble in alcohol, ether, and chloroform, whereas morphine is nearly insoluble, and acting as the most powerful emetic known, $\frac{1}{10}$th of a grain producing vomiting in less than ten minutes. Codeine, which only differs from morphine by CH_2, also yields apomorphine on treatment at a high temperature with hydrochloric acid, methylchloride being at the same time eliminated.

An important application of the dehydrating and carbon condensing power of zinc chloride, long known in its action on alcohol to produce ether, has been made by Kekulé in the reduplication of aldehyde to form croton-aldehyde with loss of water.

$$2 (C_2 H_4 O) - H_2 O = C_4 H_6 O.$$

This croton-aldehyde is also probably formed as an intermediate product in the manufacture of chloral from aldehyde, and gives rise to the formation of crotonchloral

$$C_4 H_3 Cl_3 O.$$

The discovery of the sedative properties of chloral-hydrate by Liebreich marks an era in medical chemistry second only to the discovery of the anæsthetic properties of chloroform. Chloral not only combines with water to form a solid hydrate, but also forms solid alcoholates; but the se bodies appear to possess quite different medicinal properties from the hydrate, and it is important that no alcoholate should be present in the officinal preparation. The chemistry of colouring matters has lately received an enormous impetus in the working of the brilliant discovery of the production of artificial alizarine, the colouring matter of madder, by Messrs. Graebe and Liebermann. This discovery, announced at our last meeting, is of the highest importance, whether we regard its scientific interest or its practical and commercial value, and it differs from all the former results which have been brought about by the application of science to the production of colouring matters, inasmuch as this has reference to the artificial production of a natural vegetable colouring substance which has been used as a dye from time immemorial, and which is still employed in enormous quantities for the production of the pink, purple, and black colours which are seen everywhere on printed calicoes. During the past year much progress has been made in the practical working of the processes by which this colouring matter is obtained from the hydrocarbon anthracene contained in coal tar, and new and more economical plans for effecting the transformation have been independently proposed by Perkin and Caro, and Schorlemmer and Dale. The theoretical investigation of the reaction, and especially of the nature of some other peculiar products formed in addition to alizarine, which render the artificial colouring matter different from natural alizarine, has been carried out by Mr. Perkin, and especially by Dr. Schunck. As we are promised papers on this subject from both these gentlemen, I need not now enter further into these interesting questions.

The surest proof of perfection in a manufacture is the degree in which the waste products are utilised, and in which the processes are made continuous. One by one the imperfections of the original discovery are made to disappear, and the products which were wasted become sources of profit, whilst in many cases their utilisation alone renders possible the continuance of the manufacture in the midst of a rapidly increasing district. The Section will have the opportunity of inspecting the practical working of at least two of the most valuable of these new processes which have lately been introduced into our most important chemical manufacture, that of alkali. The first of these has been at work for some time; it is that of the recovery of sulphur from the vat waste, that *bête noire* of the alkali makers and of their neighbours. Dr. Mond has now, I believe, satisfactorily solved the difficult problem of *economically* regaining the sulphur by oxidising the insoluble monosulphide of calcium in the lixiviating vat itself to the soluble hyposulphite, and decomposing this by hydrochloric acid, when all the sulphur is deposited as a white powder.

The second of these discoveries relates to the recovery or regeneration of the black oxide of manganese, used for the evolution of chlorine in the manufacture of bleaching powder. This subject has long attracted the attention of chemists, and a feasible though somewat costly process, that of Dunlop, has been at work for some time at Messrs. Tennant's works at St. Rollox.

During the last year a very beautifully simple and economical process, proposed by Mr. Weldon, and first successfully carried out on a practical scale in Messrs. Gamble's works at St. Helen's, has quickly obtained recognition, and is now worked by more than thirty-seven firms throughout the kingdom. The principle upon which this process depends was explained by Mr. Weldon at the Exeter meeting. It depends on the fact that although when alone the lower oxides of manganese cannot be oxidised by air and steam under the ordinary pressure to the state of dioxide, yet that this is possible when one molecule of lime is present to each molecule of oxide of manganese. The manganous oxide is precipitated from the still liquors with the above excess of lime, and by the action of steam and air on this a black powder consisting of a compound of manganese, dioxide and lime, $Mn O_2 C_a O$, or calcium manganite, is formed. This, of course, is capable of again generating chlorine, on addition of hydrochloric acid, and thus the chlorine process is made continuous with a working loss of only $2\frac{1}{2}$ per cent. of manganese. The Section will have the advantage of seeing Mond's process at work at Messrs. Hutchinson and Weldon's process, at Messrs. Gaskell, Deacon, and Co.'s, at Widnes.

A third process, which may possibly still further revolutionise the manufacture of bleaching powder, is the direct production of chlorine from hydrochloric acid without the use of manganese at all. In presence of oxygen and of certain metallic oxides, such as oxide of copper, hydrochloric acid gas parts at a red heat with all its hydrogen, water and chlorine being formed. This interesting reaction is employed by Mr. Deacon for the direct manufacture of bleaching powder from the gases issuing directly from the salt-cake furnace. Air is admitted together with hydrochloric acid gas, and the mixture is passed over red-hot bricks impregnated with copper salt. The oxide of copper acts as by contact and remains unaltered, whilst the chlorine, watery vapour, and excess of air pass at once into the lime-chamber. The difficulty in this process is the large volume of diluting nitrogen which accompanies the chlorine, but I believe we shall hear from Mr. Deacon that, notwithstanding this drawback, he has accomplished his end of making good bleaching powder by this process.

THE GOVERNMENT AND THE ECLIPSE EXPEDITION

SEVERAL of the correspondents who have been lately so busily engaged in chronicling the scenes of the present terrible war have wound up their descriptions by the remark that they could scarcely get rid of the impression that they have been all the time the sport of horrid dreams—that the carnage has existed only in their imagination, and that civilised Europe has been uninterruptedly pursuing the arts of peace.

Similarly it is difficult for an English man of science, proud of his nation's past achievements in many of the most noble problems, and among them those which have necessitated voyages to various parts of the world—now to witness a transit of Venus—now to make magnetic observations—now to survey the Polar Regions—and now to observe an eclipse of the sun; to realise the fact that in this present year of grace, 1870, there exists a British Government which in the curtest possible manner has put a stop to an expedition which promised to add as much to our renown in the present as the expeditions to which we have referred, and many others that we might have mentioned, have done in the past.

The proposed expedition now in question had for its object the observation of the approaching Eclipse of the Sun. A brief statement will suffice to show its importance, and how naturally it followed other similar expeditions.

It is now more than a century and a half ago since certain things called *red flames* were seen round the edge of the eclipsed sun; another appearance called the *corona*, sometimes of great irregularity and magnitude, having been noticed from the highest antiquity. Time went on, however, till only as lately as ten years ago a British expedition to Spain determined, to the satisfaction of everybody, that these red flames belonged to the sun, and not to the moon, as had been suggested. Here, then, was one great point gained by the help of the British Government—other European Governments, let us add, assisting. This was in 1860. In 1868 there was another eclipse, this time in India. The Indian side of the Government nobly assisted again by telling off officers, granting money, and affording the use of a ship to a distinguished Frenchman who chose India for his standpoint of observation, the French and German Government expeditions preferring other stations. It is seen, therefore, that the work done at the eclipse of 1868 was Government work, and it was admirable. The nature of the red flames, which had been localised in 1860, was now roughly determined.

There was still another eclipse in 1869, visible in America. Here Government help was not needed at all, as the eclipse swept right over the land; *still it was nobly given*, and one of the most important recent contributions to astronomy is the American Government Report, of the observations made by its officers. The American observers fairly broke ground in another branch of the research, the nature—not of the red flames this time but—of the corona; but they did not settle the question, and it now remained for astronomers to "crown the edifice" of all our eclipse work by settling it at the eclipse next December.

Thanks to the Janssen-Lockyer discovery, we can now study the red flames day by day; and, although the corona resists the new method, the discovery, taken in connection with Frankland and Lockyer's observations of the hydrogen spectrum, has yet thrown much light on its possible nature, so that the new method makes observations next December more precious.

Having shown, then, both the importance of the observations of the next eclipse, and the fact that they are the natural sequel of the work which has been done by Government aid, and which, it is not too much to say, could not have been done without it, let us next state some facts with regard to the proposed Expedition. It was first proposed by the council of the Royal Astronomical Society, who appointed a committee of council to take the necessary steps. The Royal Society followed suit, and next a joint committee was formed. To this joint committee were committed the whole of the arrangements. Here, shortly, is the programme agreed upon:—

1. At least two expeditions would be necessary—one to Spain, the other to Sicily.
2. At least 1,000*l.* would be required for instruments and observatory-building expenses, &c.
3. The presidents of the Royal and Royal Astronomical Societies and the Astronomer Royal were to form a deputation to the Government to ask for two ships and 500*l.*, the remainder being subscribed by the societies themselves.
4. The observers were to be carefully organised, and competent persons placed in charge of each branch of the research in each expedition.

It is clear from this that our scientific bodies have done all in their power.

Unofficial *pourparlers* having led to the belief that the Government would not be found wanting on its part, those interested in the work spared no pains to organise the expedition as minutely as possible, and all the best observers came forward to make it second to none of its predecessors.

Here is the official list of those who were prepared to take part in the observations:—

Spectroscopy.—Mr. Lockyer, Dr. Gladstone, Mr. Buckingham, Lieut. Brown, Mr. T. W. Backhouse, Lieut. Collins, Rev. A. W. Deey, Lieut. Davies, Mr. G. Griffith, Mr. W. B. Gibbs, Rev. H. A. Goodwin, Mr. S. Hunter, Mr. W. A. Harris, Rev. F. Howlett, Mr. W. Ladd, Capt. J. P. Maclear, Rev. S. J. Perry, Mr. A. C. Ranyard, Mr. G. M. Seabroke, Mr. H. Tomlinson, Mr. Pedler.

Polarisation.—Prof. Pritchard, Mr. R. Abbatt, Mr. Bushell, Mr. Chambers, Mr. G. Griffith, Mr. W. B. Gibbs, Rev. F. Howlett, Mr. W. Ladd.

Photography.—Mr. Browning, Mr. Brothers, Lieut. Abney, Mr. Buckingham, Lieut. Brown, Mr. Chambers, Mr. Clodd, Mr. R. Sedgfield.

General Objects.—Mr. Lassell, Col. Strange, Mr. Dallmeyer, Mr. J. Bonomi, Mr. E. J. Lowe, Prof. J. Phillips, Prof. H. E. Roscoe, Mr. G. J. Stoney, Mr. C. G. Talmage, Mr. C. B. Vignoles.

General Assistance.—Mr. R. Abbay, Mr. R. Inwards, Lord Lindsay, Mr. W. J. Lewis, Rev. W. Monk, Mr. R.

S. Newall, Mr. L. B. Phillips, Mr. W. Pole, Mr. F. C. Penrose, Prof. Tyndall, Mr. R. Webster, Mr. J. E. Backhouse, Mr. E. E. Bowen, Col. Drayson, Admiral Ommanney, Mr. Thos. Slater, Mr. P. E. Sewell, Mr. W. Rossiter, Capt. Noble, Mr. W. K. Clifford, Mr. W. H. H. Hudson.

Here was a rich promise of a victorious campaign, and the scientific world already congratulated itself on being able at last to "settle the corona," when suddenly, as a bolt out of the blue, came a letter from the Admiralty *declining even a single ship*, on the ground that such a purpose was entirely foreign to the purpose for which Parliament places funds at the disposal of the Naval Department.

We think we had better leave this astounding statement as it stands. It seems really as if the present Admiralty authorities are in absolute ignorance as to the real facts of the case; as to what England has done before; as to what precedents exist to which men of science can point.

Under these circumstances we trust that an appeal will be made to Mr. Gladstone, whose culture, wider than that of his more prominent colleagues, will at once grasp the huge Philistinism of this proceeding. Should he reverse their decision, which he may fairly do, on the mere ground that it is against all precedent, assuredly the scientific men of Britain will hail it as a happy omen—an indication that the hope experienced by Prof. Huxley at Liverpool the other day will, in time, be realised. If, on the other hand, the decision is to stand, it must be distinctly understood that, both in the judgment of our contemporaries and of posterity, it will, as has been already been pointed out in the daily press, bring shame upon the scientific repute of England, who now, with her forces all ready to achieve another victory over nature, is held back by "My Lords" for the sake of a few pounds sterling. Surely there is little hope for us if in such a campaign as this we are to succumb to a

Lust of gold
And love of a peace that is full of wrongs and shames;
Horrible, monstrous! not to be told.

REPLY TO PROFESSOR HUXLEY'S INAUGURAL ADDRESS AT LIVERPOOL ON THE QUESTION OF THE ORIGIN OF LIFE

I.

SPEAKING with all the authority which years of earnest and successful labour have conferred, and, moreover, "from the elevation upon which the suffrages of his colleagues had for the time placed him," Prof. Huxley has just given us in his Inaugural Address, as President of the British Association for the Advancement of Science, a "history of the rise and progress of a single biological doctrine"—that first proclaimed by Francesco Redi, and to the effect that *Every living thing proceeds from a pre-existing living thing.*

However reluctant to enter a protest against what has been said by an eminent scientific man, for whom I have always entertained the greatest respect and esteem, I feel so strongly that the representations which have been made concerning a subject to which I have directed the most earnest attention for the last eighteen months, are not only inadequate, but altogether incapable of being regarded as an impartial statement of the main points at issue, that I cannot hesitate as to the propriety of publicly expressing this opinion.

Fearful, therefore, lest harm should be done to the cause of science by this address, through the great influence of the speaker, and mindful of the momentous issues which turn upon the proper solution of the question under discussion, I—sinking all personal feelings, risking all imputations, anxious only that the truth should be known—will venture to state what really seems to me to be the true aspect of the problem, and how far the remarks of Prof. Huxley really bear upon this, or have been, in other respects, not sufficiently explicit.

The doctrine, whose history Prof. Huxley professes to trace, and whose probable truth he thinks remains unshaken, has reference to a question which is of more fundamental importance than any other throughout the whole range of Biological science. It is either true that *all* living matter, without exception, comes into being in connection with pre-existing living matter, or else it is true that *some* living matter can arise from non-living materials free from all connection with pre-existing living matter. This alternative is one the full meaning of which may, perhaps, be realised better by putting another, which, though strictly analogous, is somewhat freer from mystery. It may, then, similarly be said, it is either true that *all* crystalline matter, without exception, comes into being in connection with pre-existing crystalline matter, or else it is true that *some* crystalline matter can arise from non-crystalline materials, free from all connection with pre-existing crystalline matter. Matter when it passes into the *crystalline* condition exhibits properties of a certain kind, and when it passes into the *living* condition it exhibits properties of another kind, to which we commonly apply the term "vital." Now the question in each case is, whether by mere concurrence of certain physical conditions, aiding and abetting the inherent properties of the matter itself, some kinds of matter can fall into modes of combination called *crystalline*, whilst other kinds are capable of falling into modes of combination called *living*; or whether, in each case, a pre-existing "germ" of the particular kind of matter is necessary, in order to determine, in suitable media, either of these modes of combination. Are we to believe that crystals can appear in no solution whatsoever without the pre-existence in that solution of certain crystalline germs,* and similarly that living things can arise in no solution whatsoever without the pre-existence in such solution of living germs? To many persons it may at first sight seem that there is no analogy between the two cases; such, however, is not the opinion of very many who are best entitled to speak on the subject.|| It is admitted by them that the analogy is of the closest description; and it is interesting to note that although the actual evidence which can be brought to bear upon these two questions is very similar in kind, and alike conflicting in nature, the generally received opinions as regards the proper answers to be given to these two questions have inclined to the view that, whilst it is possible for crystals to originate *de novo*, it is at present impossible for living things to originate after this fashion.

* It must not be supposed that this is a mere hypothetical case. On the subject of crystallisation generally in supersaturated solutions, I will quote the following passage from Watts' *Dictionary of Chemistry*, Vol. v., p. 349. :—"This sudden crystallisation, if not produced by cold, appears to depend essentially on contact of the solution with small solid, perhaps crystalline particles; for it is not produced by passing air previously purified by oil of vitriol through the solution, or by agitation with a glass rod previously purified from dust by ignition. *According to Violette and De Gernez, the sudden crystallisation is in all cases induced only by contact with a crystal of the same salt*, possessing the same form and degree of hydration as the crystals, which separate out; and in the case of those supersaturated solutions which crystallise suddenly on exposure to the air, it is due to the presence of minute particles of that salt floating in the air. From an experiment of De Gernez it appears that microscopic crystals of sodic sulphate may be obtained by passing air, even in the open country, through pure water, and evaporating the water on a glass plate. Jeannel, however, denies the necessity of contact with the salt actually contained in the solution. He finds, indeed, that a supersaturated solution of sodic acetate may be made to crystallise by contact with any solid substance (a piece of paper for example), and a solution of sodic tartrate by contact with a clean, dry, glass rod" Here, then, we have also a veritable "germ" controversy. I was informed, however, a few weeks ago by Prof. Frankland that even in the case of sodic sulphate it had lately been shown that, *under certain conditions*, crystallisation can certainly take place where no crystalline germ could possibly have existed. The "germ" theory of the origin of crystals in supersaturated solution, has, therefore, been overthrown. This has been possible, however, only because it has been more easy to show that a given set of conditions are inimical to the existence of a crystal, than it has yet been to induce people to believe that any given set of conditions are incompatible with the existence of living matter.

It is worthy of remark, however, that the germ controversy concerning crystals can only be settled in the minds of those who are content to accept the high probability that the properties of any *invisible* portions of crystalline matter would correspond with the properties which similar visible crystalline matter is known to display. It is this reluctance to admit an equally high probability in the case of living matter, which alone causes the sister controversy to continue. Otherwise the question would have been settled long ago.

† The analogy between the supposed possible origins of crystals and organisms in solutions has been rendered much more obvious since the discovery by the late Professor Graham, that when dissolved the saline substance does not remain as such in solution, but that the acid and the base exist separately, and are separable by a process of dialysis. When crystallisation takes place, therefore, we have a combination of materials taking place similar to, though simpler than, what may be presumed to take place in the genesis of a Living thing.

The question is one of much interest, and it may therefore well be asked why such a totally different verdict should have been given in two cases, the analogy of which is so remarkable. The reason is, however, not difficult to find. Mere theoretical considerations have been all-powerful in influencing the verdict, and in inducing those who are informed upon the subject to read the evidence in different ways. Living things manifest such complex properties that the whole notion of Life has been shrouded in mystery. Biologists at first could not bring themselves to believe—some cannot do so now—that the phenomena which living things manifest are absolutely dependent upon the properties of the variously organised matter entering into their composition. They were obliged to have recourse to some metaphysical entity—some "anima," "archæus," or "vital principle"—under whose directing influence the living form was supposed to be built up, and upon whose persisting influence many of the phenomena of Life were supposed to depend. The aid of no similar metaphysical "principle" has, however, been deemed necessary in order to account for crystalline structures and properties. It was in the main conceded by most physicists, and the doctrine remained unquestioned by biologists, that matter of certain kinds might, by virtue of its own inherent properties, aided by certain favouring circumstances—and quite independently of all pre-existing germs—fall into such modes of collocation as to give rise to crystals. But, owing to the influence of the theoretical considerations already mentioned concerning the nature of Life, a similar possibility could not easily be granted in reference to the origin of Living things. Was it not held that the living thing owed its structure or organisation to the active influence of a special and peculiar principle? This "vital principle" was neither ordinary matter nor ordinary force, neither was it in any way derivable from either of these; how then could it be supposed that the coming together of matter of any kind could give rise to a living thing?* The aggregate of properties, which we designate by the word "Life," were not supposed to be dependent upon, to be, in fact, properties of the material aggregate which constituted the Living thing. Life was presumed to be due to the manifestations of a something altogether peculiar—of a "vital principle," which was inseparable from living matter. Doctrines akin to these having been already proclaimed and disseminated by the influential teachings of Paracelsus, Van Helmont, and others, it cannot be a matter for surprise that the brilliant demonstrations of Redi should have had a great influence in their time. Observation after observation appeared now to confirm the existence of a seemingly universal mode of origin of Living things—a mode too which was more in harmony with the philosophical views of the day than that which had hitherto been deemed possible. Doubts, however, soon sprang up. New means of observation opened up new questions for solution. And what has been the result? Many battles have been fought, many victories have been won, and now the biological doctrines of the day have assumed an entirely new form. The ever-increasing strides of Science have wrought the most fundamental changes in our notions concerning Life. Under the influence of the well-established doctrine concerning Persistence of Force—and more especially since the clear recognition of the subordinate doctrine as to the Correlation existing between the Physical and Vital forces—physiologists have now begun to recognise, and most unhesitatingly to express the opinion, that the phenomena manifested by living things are to be ascribed simply to the properties of the matter as it exists in such living things. No one has expressed himself more decidedly on this subject than Prof. Huxley himself, and he may fairly be taken as an exponent of the modern doctrines on this question. He says:†—"Carbon, hydrogen, oxygen, and nitrogen are all lifeless bodies. Of these, carbon and oxygen unite in certain proportions and under certain conditions to give rise to carbonic acid; hydrogen and oxygen produce water; nitrogen and hydrogen give rise to ammonia. These new compounds, like the elementary bodies of which they are composed, are lifeless. But when they are brought together under certain conditions they give rise to the still more complex body, protoplasm; and this protoplasm exhibits the phenomena of life. I see no break in this series of steps in molecular complication, and I am unable to understand why the language, which is applicable to any one term of the series, may not be used to any of the others. We think fit to call different kinds of matter carbon, oxygen, hydrogen, and nitrogen; and to speak of the various powers and activities of these substances as the properties of the matter of which they are composed. . . . Is the case in any way changed when carbonic acid water and ammonia disappear, and in their place, under the influence of pre-existing protoplasm, an equivalent weight of the matter of Life makes its appearance? . . . What justification is there then for the assumption of the existence in the Living matter of a something which has no representative or correlative in the not-living matter which gave rise to it?"

* Buffon, it is true, as Professor Huxley has pointed out, did make an attempt to reconcile two incompatible theories.

† *Fortnightly Review*, Feb. 1869.

For Professor Huxley, then, and for all who hold similar opinions on this subject, the constitution and properties of living things are so far comparable with the constitution and properties of crystals, that both, in each case, are alike supposed to be the products of the combination of ordinary matter of different kinds. And, as might have been expected, nearly all the biologists and physicists who hold these opinions, are now inclined to admit their belief in the *possibility* of the origination of living matter free from the influence, and independently, of all pre-existing living matter. They are quite content to admit that Redi's doctrine may be wrong. Prof. Huxley, indeed, in his recent address, desires us to understand that this is an opinion to which he still adheres; he says:—"I think it would be the height of presumption for any man to say that the conditions under which matter assumes the properties we call 'vital,' may not some day be artificially brought together."

Having reached this stage, having got rid of the supposed necessity for the intervention of a special "vital principle" before living matter can come into existence,* I think it will be seen by all how very important it has become to look into the truth of Redi's doctrine, which has found its best modern expression in the phrase *omne vivum ex vivo*, seeing that that doctrine was born and nourished under the influence of the old, and now well-nigh effete, metaphysical notions concerning Life. Certainly, now that this theoretical barrier has been removed, we ought to inquire more carefully than ever whether there is still a sufficient warrant for the different verdicts which have been given in answer to the questions as to whether crystals on the one hand, or living things on the other, do or do not originate *de novo* in this particular stage of the Earth's history.

Now, at all events, theory inclines no more to the one side than it does to the other; it is quite possible to reconcile this with either view.

Seeing, therefore, that we may now act without fear as impartial judges, let us inquire into the nature of the evidence which alone can be relied upon for the solution of these two questions.

If living things are to come into being *de novo*, they could, or, at all events, are only supposed to originate from the rearrangement of matter which previously existed in a state of solution. And although it is known to be possible for certain kinds of pre-existing solid matter to assume a crystalline form, we will, for the present, confine our attention to the origin of crystals in an apparently homogeneous fluid. Each of these material forms, therefore, would have to commence as a smallest conceivable speck, and each would grow, though differently, by the formation of matter of like kind, under influences generally similar to those which were influential in bringing about the primordial collocation. These primordial collocations, however, are hidden from our view, and will, perhaps for ever, remain so. As a matter of observation, all that we actually know concerning the origin of crystals or of certain living things in solutions is this. In previously homogeneous solutions of crystallisable matter, or in certain apparently homogeneous colloidal solutions, we may, under certain conditions, see the minutest crystals† or living things, respectively, make their appearance. In both cases these are, at first, mere motionless specks, whose *minimum visible* stage may be less than $\frac{1}{100000}$th of an inch in diameter. It must either be presumed, in the case of such embryo living things (as most people do presume in the case of crystals), that these, even then, and however minute, represent stages in the growth of later material collocations which had been initiated under the combined influence of existing matter and "conditions" at a point far beyond the reach of our most aided vision; or, on the other hand, it is equally

* It may perhaps be as well to state here that I have not much expectation of influencing those whose belief in the existence of a special "vital principle" remains still unshaken.

† The appearance of the crystals is best watched in the viscid solutions described by Mr. Rainey; since the rapidity of the process is thereby very much diminished, and the forms themselves are also more akin to those of living things. See his work *On the Modes of Formation of the Shell of Animals*, &c., 1858, p. 9.

open for us to suppose that such minutest visible living things had proceeded from the growth of pre-existing germs which were themselves invisible.

This being, as I conceive, the real state of the case, and Professor Huxley being in the position of a person, admitting* that a crystal can be produced *de novo*, admitting also the *possibility* that a living thing may so arise, but denying that there is any evidence worthy of serious consideration to show that a living thing can at the present time originate *de novo*, let us see on what evidence he has come to this conclusion, and what other evidence he has practically ignored.

In the first place, he does not attempt to deny—he does not even allude to the fact—that *Living things may and do arise as minutest visible specks, in solutions in which, but a few hours before, no such specks were to be seen.* And this is in itself a very remarkable omission. The statement must be true or false, and if true, as I and others affirm, the question, which Professor Huxley has set himself to discuss, is no longer one of such a simple nature as he represents it to be. It is henceforth settled, so far as *visible* germs are concerned, that living things *can* come into being without them. It can now, at all events, be said that *some* Living things do not come from *visible* germs. Who, therefore, in the face of this fact will say that the doctrine *omne vivum ex vivo* remains unshaken? Perhaps, however, this particular case where an exception to the rule is possible, was not known to Professor Huxley. I wish I could bring myself to believe that this was really the case. Certain it is that had he recognised the existence of this apparent exception to the general rule he would then have had to discuss a much more difficult question, and he would have been compelled seriously to inquire into the value of experiments whose existence he has now almost ignored. Again then I affirm that multitudes of minute living things may and do gradually appear in fluids, beneath the microscope, where no *visible* germs previously existed. Here the hypothesis that *every* living thing proceeds from a pre-existing living thing may break down, and those who wish to establish the continuity of this rule are bound to discuss the nature of the existing evidence which is in favour of the notion of the living things in question originating from pre-existing *invisible* germs, as against the opposite *possibility* of their having originated *de novo.* The burden of proof rests as much on the one side as it rests on the other. We cannot safely continue to affirm a rule until the cases in which it seems doubtful have been thoroughly discussed. Analogy is often but a treacherous guide.

And, when we come to the discussion of this hypothesis as to the origin of living things from germs which are *invisible*, all alike are rendered, to a certain extent, helpless. No one, then, can come forward, as Redi is said to have done, "strong with the sense of demonstrable fact," and any one who wishes or calls upon his opponent to demonstrate the truth of his views, when the question is one concerning the presence or absence of *invisible germs*, shows himself to be ignorant as to how the matter in dispute can alone be settled. The subject is one in which direct demonstration must give place to reasoning, although experiment and observation may and must be brought forward in support of this. Let those, however, who wish to proclaim the universality of the rule *omne vivum ex vivo*, recollect that, if they expect to influence reasonable people who are themselves competent to form an opinion on the subject, they are bound to consider the *possible* exception to which their attention is directed, and to weigh the evidence for and against the origin of these minutest visible living specks from germs which are supposed to exist, but which are *invisible*.

The reason, indeed, which seems to induce most people to believe that living things cannot arise *de novo*, is because in 999 cases out of a thousand which come under their actual notice, there cannot be a question that a living thing originates from a pre-existing living thing. A rule, which is of such apparently universal application, they say, is most likely to be the rule which applies to any doubtful case. Much is made out of this argument, which is, of course, a very valid one so far as it goes. But, on the other hand, knowing, as I have pointed out, *that any living things which arise, de novo, from non-living matter, must appear in solutions as minutest visible specks*, it need not be a matter of much surprise that this mode of generation is one which is unfamiliar to the world at large. Have we not seen, indeed, that the most accomplished biologist, provided with the very best microscope hitherto made, though he gets down to a *minimum visible* stage of less than $\frac{1}{100000}$" in diameter is just as powerless in face of the hypothesis of *invisible* germs as those who worked with the rude microscopes which alone were in vogue two centuries ago? And, more especially is this consideration one which presses for earnest attention, when we further consider that some of the minute living things which first appear as tiniest specks in homogeneous solutions grow into *Bacteria*, and that concerning the real origin of these, *in such cases*, we are as ignorant as we were concerning the real origin of crystals, when they appeared in previously homogeneous solutions. The probability that these latter have originated *de novo* has, of late years, had to be established by a process of reasoning similar to what we are obliged to have recourse to, if we wish to throw light on the question of the origin of these specks of Living matter. *Bacteria* grow, and after a time aggregations of them may be converted under our very eyes into *Fungus*-spores * capable of throwing out a filaments and of developing into perfect plants. Nobody pretends to know, however, how, or whether, the *Bacteria* which make their appearance in a homogeneous solution have originated from invisible *Fungus*-emanations: all that we know is, that in suitable solutions, appearing homogeneous to high microscopic powers, in the course of a very short time, a multitude of perfectly motionless specks appear, in situations where previously no specks had existed. Being motionless and diffused their number cannot be accounted for by any supposed rapidity of multiplication—the only possible explanations seem to be, either that the specks have originated from as many pre-existing germs which were invisible, or else that they have proceeded from material collocations, which have been initiated in the fluid itself by virtue of the molecular properties of the substances in solution, and the physical forces or sum total of "conditions," acting thereupon.

And this is really the question which has to be considered. When it is supposed that Living things do appear independently of pre-existing living matter, in certain solutions nothing more than this is supposed to have taken place. New Living matter is presumed to have appeared—independently of germs—in the solutions within these flasks, and to have made *its* appearance as living matter may, in certain other fluids, under our very eyes, in the form of minutest visible specks, which have been exposed to great and long-continued heat in hermetically sealed masses. And similarly such specks, are the only forms of Living matter which are supposed to be capable of arising *de novo.* Once formed, it is true, one of these living specks may develop into a *Bacterium*, and this may develop into a *Vibrio* or a *Leptothrix* filament, whilst another of the living specks may develope at once into a *Fungus*-spore.† It should be clearly understood, however, that *all the Living things which are supposed to arise out of non-living materials, are presumed to appear in fluids, and gradually to emerge from the region of the invisible into that of the visible*; at which latter point they, for us, constitute specks less than $\frac{1}{100000}$" in diameter.

Making no statements whatever upon this subject, however, in support of the doctrine which he considers to remain unshaken, let us see what line of argument Professor Huxley has taken, in order to establish the validity of this belief to the members of the British Association for the Advancement of Science.

The "long chain of evidence" which he considers sufficient to allow us still to place faith in the rule *omne vivum ex vivo*, seems to me, to be, in reality, utterly inadequate for this purpose, and incapable of affecting the real question at issue. Nothing that has been said bears at all upon the problem as to whether it is possible that the minute living specks to which I have referred do or do not originate *de novo*, though, as I have already said, it is these, and such as these only, which are presumed to originate after this fashion. If he had really wished to influence those who are conversant with the subject, it would have been absolutely imperative for Prof. Huxley to have entered fully into the consideration of a subject which I will presently mention, but to which he makes only the most casual allusion. All the facts which he has brought forward—all the references to the investigations of Spallanzani, Schultze and Schwann, Cagniard de la Tour, Helmholtz, Schrœeder and Deutsch, Tyndall and Pasteur—are simply contributions to the "Atmospheric Germ Theory," tending to show that there are germs of living things in the air, and that the living things found in *some* solutions may have been developed therefrom. But although differing

* I suppose this may fairly enough be presumed even in the absence of any specific statement as to his belief on the subject. This is, however, an assumption on my part.

* See NATURE, No. 35, p. 173, Fig. 3.
† See NATURE, No. 37, pp. 221, 223.

from him in my interpretation of the results of some of these investigations,* I am quite content to accept the conclusion which is alone derivable from this long chain of evidence. I am even prepared to grant to Professor Huxley, for the sake of argument, that *Bacteria* may be "suspended in the atmosphere in myriads." The evidence thus referred to, if true in all respects, would have been very valuable if it had been brought against the doctrine that none of the minute living things of infusions derived their origin from atmospheric germs, though it may and does fall utterly powerless before the doctrine which is alone urged, that *some* of the Living things met with in infusions appear to be produced independently of pre-existing living matter. If it could be proved that the air contained five hundred times as many germs as can now be shown to exist therein, this discovery would still be quite compatible with the truth of the other doctrine that under the influence of certain conditions some Living things, appearing as minutest visible specks, do arise *de novo* in solutions.

Whether such an occurrence can or cannot now take place is a question which is not at all dependent upon the prevalence or paucity of germs in the atmosphere. I may also remind Prof. Huxley of a fact which he seems to have forgotten, and that is, that the atmosphere is not the only source of germs. These may be present in the water or in the materials dissolved therein. Seeing, therefore, that in certain experiments which constitute the corner-stones of his edifice of proof, and which are brought forward, I suppose, as being capable of influencing our judgment upon this great question, the materials which were dissolved and the water employed were merely boiled for fifteen minutes, we must look upon this as an admission by Prof. Huxley that in his opinion the exposure of the *solution for such a time to a temperature of* 100° *C. was an adequate precaution to ensure the destruction of all pre-existing living things that may have been contained therein.* This is a most important admission—tacit though it be—in the face of other evidence which can be mentioned, and if Prof. Huxley does not really believe this, how is it possible for us to understand what either his argument or science gains from the citation of the following experiments?

Having boiled portions of "Pasteur's solution" for fifteen minutes, in three separate flasks, he placed in the neck of one of them, whilst ebullition was continuing, a large plug of cotton wool, left another with the mouth of the flask open, whilst into the third, when cool, he placed some *Bacteria* taken from a solution of hay. "In a couple of days of ordinary warm weather," he says, "the contents of this [latter] flask will be milky from the enormous multiplication of *Bacteria.* The other flask open and exposed to the air will, sooner or later, become milky with *Bacteria,* and patches of mould may appear in it; while the liquid in the flask, the neck of which is plugged with cotton wool, will remain clear for an indefinite time." And then Prof. Huxley adds:—"I have sought in vain for any explanation of these facts, except the obvious one, that the *air contains germs* competent to give rise to *Bacteria,*" and similar to those with which one of the solutions was purposely inoculated. Now, with reference to these statements, the possibility at once suggests itself, that had a different solution been used in the case where the neck of the flask was plugged with cotton-wool a very different result might have been obtained. In order to throw light upon this subject I have performed the following experiments:—

Immediately after reading Prof. Huxley's address, I procured a piece of cooked meat, made an effusion of the same, and after filtration put it into a flask. It was then boiled for fifteen minutes, after a large plug of cotton wool, $1\frac{1}{4}''$ in length, had been pushed into its neck. After this time the plug was rendered tighter by pushing in more wool. Another flask was prepared in a similar way, only in this, a strong filtered infusion made from undressed meat was placed. At the expiration of the fourth day (Monday morning, Sept. 17th) the weaker solution, still quite *clear,* was opened, and on microscopical examination of two or three drops of the fluid a multitude of minute motionless particles of various sizes were seen, others in active movement, and two or three *Bacteria* about $\frac{1}{8000}''$ in diameter. The flask containing the stronger solution was opened at the expiration of forty-two hours. The fluid still appeared quite clear, and on microscopical examination of a few drops of the fluid *many* tolerably active Bacteria were found varying between $\frac{1}{6000}''$—$\frac{1}{1000}''$ in length, besides a multitude of particles, some moving and others motionless.

These results seem to me what might have been expected after what I have made known concerning putrefaction *in vacuo.* It could scarcely be expected that mere *filtration* of air should be able to prevent putrefaction when it has been already shown that this will take place in the absence of air.

What conclusion, then, is now deducible from Prof. Huxley's three comparative experiments? Certainly nothing that has any value for the support of his argument.

[A strong point made by Prof. Huxley is the supposed fact that the possibility of preserving meat is a fatal reply to the experiments of myself and others. I shall show next week, that the actual facts strengthen my point of view, and that "perfectly good" cases of meat which I have examined have contained *Bacteria* and *Leptothrix* filaments.]

H. CHARLTON BASTIAN

* Neither time nor space will permit of my mentioning these various points on which I am inclined to differ from him. When Prof. Huxley says, however, after a tragical metaphor, "It must be admitted that the experiments and arguments of Spallanzani furnish a complete and a crushing reply to those of Needham," I will only say that I cannot agree with him, and will remind him that, in this case at least, he is not supported by Pasteur, whose logic is so invincible. Pasteur says (*Ann. de Chim. et de Phys.*, 1861, p. 9):—"Un examen impartiel des observations contradictoires de Spallanzani et de Needham sur le point le plus delicat du sujet, va nous montrer en effet, *contrairement à l'opinion généralément admise* que Needham ne pouvait en toute justice abandonner sa doctrine en presence des travaux de Spallanzani."

I would also call Prof. Huxley's attention, as an impartial historian, to some communications made by M. Victor Meunier to the French Academy (*Comp. Rend.* 1865), from which he will see with reference to the vessels with bent necks, that it is possible to perform these experiments with an "entire success" of a different kind from that to which he alludes. Others besides myself have also performed such experiments with results similar to those of M. Meunier. Much seems to depend upon the nature of the solution employed.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

English Physiology

THE present state of physiology in this country ought to be a matter of regret. Though foremost in many things, Britain is far behind Continental countries in the field of physiological science. We can boast of a few distinguished physiologists, as John Hunter, Sir Charles Bell, and Dr. John Reid; and famous microscopists, as Carpenter and Beale; but a very small number of English names can be cited compared with the host of Continental physiologists, past and present, as Magendie, Müller, Von Beyoid, Von Baer, Béclard, Bernard, Brown-Sequard; Du Bois Reymond, Helmholtz, &c. This discrepancy arises not from want of talent, but from lack of opportunity. The mental qualities required by a physiologist, as observation and memory, are developed separately at different periods of life. Hence there are only a limited number of years during which any such branch of learning can be cultivated with fresh ardour, and during which the power termed originality can be brought into play. The Continental schools make use of these precious years by affording those who are naturally inclined to cultivate any one branch of science, full scope for repeating the observations of their predecessors, and for endeavouring to add to the existing stock of knowledge. By having various laboratories and certain paid appointments connected with their universities, they allow young men to devote their whole time and energy to the study of individual subjects, as physiology. Those who set themselves to work of this kind do not look forward to the practice of the medical profession, but purpose to live and work as physiologists. These young men are known by their labours to be specialists, and are proposed by the senatus with which they are connected for a vacant professorship when it occurs. This is the only method of securing original and extensive work in any one scientific branch, as Physiology. It would be well, therefore, if the approaching Royal Commission of Inquiry into the State of Science in this country would not overlook Physiology, but would make some arrangements whereby Great Britain might no longer be stigmatised by her Continental neighbours as "having no Physiologist."

Dr. Stricker, in the two articles he has already communicated to NATURE on "The Medical Schools of England and Germany," has not referred to the Edinburgh University, which possesses the best furnished Physiological Laboratory to be found in Great Britain, and one equal to most of those met with in Germany. The plan recently introduced into this Scottish University of having salaried assistants to the professors resembles that which exists in the German Universities. This arrangement not only allows opportunity for carrying on original research, but also enables the professors to impart a most beneficial impulse to younger men.

In this country it has hitherto succeeded best, and appears to be most in consistence with our national constitution, to place the pecuniary assistance afforded to scientific men under the control of learned bodies as the Universities and the Royal Society. It is to be hoped, however, that our Government will, ere long, recognise the duty of advancing physiologists by aiding them with grants of money. Every medical school in Britain ought to have a physiological laboratory, well furnished with instruments—electrical, chemical, and physical; and with the view of instituting and supporting these it will be necessary to supply certain sums of money annually from the public exchequer. In addition to money given to Medical Schools for the purpose of buying instruments, two or more grants might be set aside as prizes to be bestowed annually on the schools furnishing the best physiological work, and to be distributed by the governing bodies of the said schools among the workers. The awarding of such prizes might very well be entrusted to the Royal Society.

I trust that this plea on behalf of physiology will not pass unnoticed by you.

Birkenhead P. M. BRAIDWOOD

Mirage

MIRAGE is not, in my experience, an uncommon phenomenon. I saw it this summer on the flats at the mouth of the Dee (Wirral side). It may often be seen, with a bright sun and still air, after heavy rain, on Hartford Bridge Flats, and other level and gravelly heaths in the Bagshot Sand district, where the fir trees may be seen floating in water, or forming promontories jutting out into a lake—a phenomenon similar to, though far less striking than, what I have seen on the Plain of Aan, in Provence.

The most curious mirage-effects I ever saw were on the Wash during hot summer weather. The mirage is there known as the "looming of the land," and when it is about it is impossible at moments to distinguish the sand and weed-banks from the sea, while the distortion, both perpendicular and horizontal, of ship's masts, &c., is ludicrous. In one case I saw a herd of seals on a sand-bank transformed into a row of long-legged monsters, wading in water, or rather rooted by their long legs to the legs of a similar row of monsters below them, which was their distorted reflection in wet mud. I had some difficulty, at first, in making out what they were.

Eversley Vicarage, Sept. 16 C. KINGSLEY

Astronomical Science

IN your number for August 5th, a letter referring to Astrology, signed "C. J. Robinson" ends as follows:—"Astronomical Science is hardly likely for the sake of sentiment to treasure up the discarded swaddling clothes which for so many centuries impeded its onward progress." Surely such language indicates a sad confusion of ideas on the subject, since it is most unquestionable that the belief of antiquity in Astrology—far from retarding—greatly promoted the study of Astronomy. In fact, the names of Ptolemy and Kepler show that the greatest of ancient and the greatest of modern astrologers were at the same time the greatest Astronomers of their era, and the brilliant discoveries of the latter in both sciences suffice to dispose of the "swaddling clothes" theory without citing the instance of Napier, who, it is well known, invented that most admirable scientific expedient and indispensable handmaid to Astronomy, Logarithms, to shorten and facilitate his astrological calculations.

I have not seen Moore's Almanac referred to by Mr. Robinson, but any one by consulting an Ephemeris may verify the following curious facts. War against Prussia was declared by the French Emperor on the 15th July. The preceding lunar change was a total eclipse of the Moon on the 12th, in 20° 15′ of Capricorn, when the Sun and Moon had (substantially) the same declination as Herschel, Saturn, and Jupiter. Between noon on the 14th and noon on the 15th, Mars came to the opposition of Saturn retrogade. On the 15th, Herschel was in conjunction with the Sun, the planet having at the same time the exact parallel of declination of Saturn and Jupiter. So exceptional and extraordinary did these planetary positions and relationships appear to me that more than two years ago I made two crosses at the middle of July in my Ephemeris, and outlined a hand in the margin that I might not omit to note when the time came whether anything unusual occurred. Now the eclipse on the 12th took place on the Ascendant in the Revolutionary Figure of the Emperor Napoleon in square to Mars and opposition to Herschel, and according to the old astrologers "an eclipse of the Moon in Capricorn in evil aspect to Mars causes military disasters," whilst modern astrologers credit aspects of Herschel with producing events of a strange and unexpected character. Again the same figure presents the Moon in conjunction with Saturn retrograde on the place arrived at by Herschel by direction, whilst the Ascendant falls on the place attained by Saturn, the whole presenting, according to the canons of Astrology, a rare combination of evil portents. Probably it is the preceding data taken in conjunction with the primary directions (also of evil import) which have furnished the ground for the predictions of misfortune to the French Emperor to which Mr. Robinson alludes. T. S. PRIDEAUX

7, Eardley Crescent, West Brompton

[We insert this as a specimen of a kind of letter which it should be impossible to write in the nineteenth century.—ED.]

Insects upon a Swallow

DURING the month of August, at Meran, in the Tyrol, a swallow sitting upon a stone at the side of a public thoroughfare let me take it up without showing the least fear, or even moving. The cause of its indifference was immediately apparent; two large insects of a dark slate colour were running about the bird upon the outside of its feathers, their power of adhesion being considerable. While trying to remove them, one got upon my hand and was lost, being thrown some distance by the second of two hasty but vigorous shakes. The other fell to the ground after hanging by a thread, similar to, but much stronger than, a spider's single thread. The form of the insects was quadilateral, the head being at one of the angles, the measurement between the opposite angles being about ¼ inch; the strength of the skin was so great that the insect required three crushing rubs by a lady's foot against the road before its activity was destroyed. The bird seemed conscious of release from its parasites, and struggled to get away, and then was only just able to flutter languidly to a tree about forty yards distant. The toughness of the insect, its activity and power of clinging, fully account for the inability of the bird to free itself.

I have seen an account *somewhere* of a bird, whether a swallow or lark I forget, similarly troubled, and showing the same fearlessness of capture. G. H. H.

Birkenhead, Sept. 8

NOTES

PROFESSOR HUXLEY's presidential address is not his only outcome at Liverpool which it is our duty to chronicle—a duty which we perform with gratitude to him for his plain speaking. At the unveiling of Mr. Gladstone's statue on the 14th inst., Mr. Huxley, after referring to the Compulsory Education measure, which promises in time to rid us of our worse than Eastern degradation, as one of Mr. Gladstone's greatest achievements, added that if he might presume to give advice to a man so eminent as Mr. Gladstone—if he might ask him to raise to a still higher point the lustre which would hereafter surround his name in the annals of the country, it was that he should recollect there was more than one sort of learning, and that the one sort which was more particularly competent to cause the development of the great interests of the country, was that learning which we were in the habit of calling Science. That Mr. Gladstone was profoundly acquainted with literature, that he was an acute and elegant scholar, they all knew, but he suspected that the full importance for the practical interests of the country of developing what was known as Science was not quite so clear to the Prime Minister as it might be But, seeing the great faculty of development which his past career had shown, he had no doubt that such a man would by-and-by see that if this great country was to become what it should be, he must not only put the means of education within the reach of every person in the land, but must take care that the education was of such a nature as to provide those persons with the knowledge which they could apply to their pursuits, and which would tend to make them understand best those laws under which the human family existed.

THERE was still another outcome equally noticeable for its plain speaking, for, addressing the working men of Liverpool, the President of the British Association remarked, and his remarks were responded to by three cheers, that it had been a shock to him, walking through the streets of Liverpool, to see unwashed, unkempt, brutal people side by side with indications of the greatest refinement and the greatest luxury. He remarked upon this to working men because he believed it was the secret of the uneasiness and unrest which betrayed themselves in their political movements. The people who formed what are called the upper strata of society talked of political questions as if they were questions of Whig and Tory, of Conservative and Heaven knows what; but beneath there was the greater question whether that prodigious misery which dogs the footsteps of modern civilisation should be allowed to exist, and whether there should be in those nations which prided themselves most upon being Christian that predominant and increasing savagery of which such abundant specimens were seen in Liverpool. If in the course of history the savagery of nations has been gradually put down by one process only—by learning the laws of nature and the laws of social life, and obeying those laws—he urged upon them that history in this matter did not lie; and if they were to succeed in their great aspiration, they had only one course, and that was to learn the laws of nature and do their best to obey them. To that end all their efforts should be directed; to that end the great educational movement must be directed; and if their efforts were directed wisely and well, he could not doubt they would meet eventually with the most perfect measure of success.

THE war has, unfortunately, much curtailed the Reports of the British Association in the London Press, but this is not all, it is surely a matter for regret that the space given has been devoted to the least important papers. The Liverpool Press, too, has disappointed us, and has fallen far short of what has been done in smaller towns at recent meetings of the Association. We do not blame the editors, they know their public, and this is the real source of the evil: the British public, there is no concealing the fact, have as yet not the least idea of the importance of Science; they do not know what it means, or how it may help them in the daily affairs of life. One of the Liverpool reports has particularly struck us on account of its charming *naïveté*. Speaking of Professor Clerk Maxwell's paper on Hills and Dales, after remarking, with a tone of regret, that in Section A there was only a very small attendance which "consisted exclusively of mathematicians," the report adds, "The whole subject was treated in a very scientific manner, quite unlike what might have been supposed from the plain English title of the paper."

THE five classes of the Institute of France have unanimously resolved to draw up a protest in view of the eventual bombardment of the monuments, libraries, and museums of Paris. The protest will be addressed to every academy in the world, inviting them at the same time to give their adhesion to it. Meanwhile, the Minister of Public Instruction has been given a credit of 50,000f. to enable immediate precautions to be taken.

THE foundation stone of the new building about to be erected for Owens College, Manchester, is to be laid next Friday. His Grace the Duke of Devonshire, K.G., F.R.S., President of the Extension College, the Bishop of Manchester, and the President, and other distinguished members of the British Association are expected to be present and take part in the proceedings.

IT is said to be the intention of the Government to greatly increase the number of medical officers who are employed for the purposes of sanitary supervision under the Privy Council; the whole of the kingdom will be divided into sanitary districts, each under a medical officer with a salary of not less than 600*l.* per annum.

ANOTHER Dutch contribution to Natural History lies on our table in the form of a monograph of the Squirrel, "The Osteology and Myology of *Sciurus vulgaris* L., compared with the Anatomy of the Lemuridæ and the Chiromys, and on the Position of the latter in the Natural System," by Dr. C. K. Hoffmann and H. Weyenbergh, jun. It is a prize essay for the Dutch Academy of Sciences at Haarlem, but is written in German.

PROF. RAULIN'S "Description physique et naturelle de l'île de Crête," is published under the authority of the French Minister of Public Instruction in two thick volumes and an atlas; the first volume including the history, geography, and statistics of the island; the second, its meteorology, geology, botany, and zoology.

THE first annual part of Dr. G. Radde's Report of biological and geographical researches in the Caucasus country includes an account of journeys in the Mingrelian mountains, and the three mountain-valleys Rion, Tskenis-Tsqabi, and Ingur, with maps and plates, the latter beautifully executed and coloured.

A SERIES of experiments has been made at the Government farm in Madras on the applicability of the "gram" plant as fodder for cattle and horses in those districts instead of the seed; it succeeds well on poor soil, and gives four crops in the year. It has been found superior to grass, and can be made into hay.

THERE is good report of the progress of ipecacuanha cultivation in India, where it is found so valuable in that prevalent disease, dysentery. Since Dr. John Murray obtained for it the notice of the Indian Government, it has been successfully planted in the Neilgherries and other of our hill settlements, and in the plains. It has done well even at Calcutta.

A SOLUTION of tannin has been used in the treatment of cotton fabrics, as are hides in the manufacture of leather, and, according to *Cosmos*, the cotton thereby acquires greater strength, and resists moisture and disintegrating effects better. No attempt is made to explain the chemical reaction which produces this important change, but it is believed that the change cannot be great, since it has escaped the notice of practical tanners.

THE Rev. Cyrus Byington's "Grammar of the Choctaw Language," the manuscript of which is in the possession of the American Philosophical Society of Philadelphia, has just been published under the editorial supervision of Dr. D. G. Brinton. Mr. Byington was a native of Stockbridge, Massachusetts, and from 1819 to the close of his life, in 1868, was a missionary among the Choctaws, whose language he studied with so much thoroughness, that when he died he was engaged in revising his grammar for the seventh time; and his family still have a Choctaw dictionary, embracing 15,000 words, which was left, like the grammar, in manuscript. Another work of interest to philologists has been printed at Bogota, in New Granada: a Grammar of the Chibcha Language, by Dr. Ezequiel Uricoechea. The title is:—"Grammatica. Frases, Oraciones, Cathezisms, Confessonario y Boca Bulario de la Lengua Chibcha, 1620. Copiada del Manuscrito Orijinal por E. Uricoechea." The volume fills 64 pages in 8vo.

SALMON, it appears, are found in great abundance on the Pacific coast. The *San Francisco Bulletin* says, "From Mexico to Alaska every clear stream running into the ocean is frequented by salmon. These fish even ascend small streams which one can jump across, and the number which frequent large streams is wonderful. The size, quality, and shape vary considerably in the different streams, the largest being caught in the Sacramento river. While the salmon theoretically must have clear water, it is remarkable that it seems to thrive in the muddy waters of the Sacramento." Here is possibly some news for Mr. Frank Buckland.

THE Government of Honduras, in Central America, has granted to M. de la Roche for ten years the exclusive privilege of planting and exporting Corozo nut, paying two reals each hundred weight as royalty. What Corozo nut may mean, it is not easy to say.

MR. E. G. SQUIER, late commissioner of the United States in Peru, reprints a paper read before the American Geographical Society, containing Observations on the Geography and Archæology of Peru.

PROFESSORS JOHN TORREY and Asa Gray reprint from the Proceedings of the American Academy of Arts and Sciences their "Revision of the Eriogoneæ," a tribe of the order *Polygonaceæ*, first instituted by Mr. Bentham, wholly American, and especially characteristic of the drier western regions of the northern continent. They recognise seven genera, the same number as Mr. Bentham, the number of species being increased from 105 to 115.

THE Quekett Microscopical Club has just issued its fifth Report. The number of members has increased during the last five years from eleven to over 500, "all imbued with a strong desire to seek out the unfathomable stores of interest revealed by the microscope, and all influenced by that insatiable thirst for the observation of the minute and the beautiful that only the microscope can open to view." The club now meets twice a month throughout the year, at University College, Gower Street, and excursions are made during the summer season for the purpose of providing microscopical research.

WE have just received the prospectus of the Ladies' Educational Association, and we are glad to see that the lectures will include two subjects in Science, a chemical course by Professor Williamson, and a course of eighteen lectures on experimental physics, by Professor G. Carey Foster. Both courses will be delivered at University College. By applying to the secretary, a free ticket can be procured for the first lecture of each course ; those requiring class tickets, free tickets for opening lectures, prospectuses, and information, are requested to send to the hon. secretary, J. E. Milne, Esq., 27, Oxford-square, Hyde-park, W.

THE two volumes now published of Willkomm and Lange's "Prodromus Floræ Hispanicæ," include the Ferns, Gymnospermæ, Monocotyledones, Apetalæ, and Gamopetalæ.

EXPERIENCE only too clearly shows that familiarity breeds contempt. Even earthquakes are now quite appreciated in some parts of the world. Thus the *San Francisco Bulletin* of the 11th August says, "Popular prejudice is rather in favour of these lighter demonstrations of subterranean force, as they seem to stave off the heavier shocks." What next?

THE Smithsonian Institute of Washington has appointed a committee of scientific men to make a series of experiments to ascertain the temperature of the earth's crust at a considerable depth below the surface. For this purpose an artesian well at St. Louis is to be utilised, and as this is 3,843 feet deep some interesting results may be looked for.

THE decree of the Committee of the National Defence of Paris announcing that all woods and forests which might endanger the defence of the country will be set on fire on the approach of the enemy, has already been acted upon to a large extent. Independently of the loss in an artistic and æsthetic point of view, we can hardly be aware, probably the Parisians are hardly aware themselves of the amount of self-sacrifice this resolution will entail on themselves, and on their descendants. For some years past the climate of the central regions of France has been rapidly becoming drier, to the serious injury of many of the crops, a result attributed in part to the extensive cutting down of forests. The destruction of the world-famous forests of Fontainebleau, St. Cloud, St. Germain, and the Bois de Boulogne, will involve a material loss to the country, possibly hardly exceeded by the actual expenses of the war itself.

THE BRITISH ASSOCIATION

LIVERPOOL, *Tuesday Morning*

THE Liverpool meeting of the British Association is a great success. Distinguished visitors, a large company, interesting papers, and splendid weather, have all combined in its favour. The hotels are all full to overflowing, and accommodation extremely difficult to get. Almost all our well-known *habitués* are here ; and among foreigners, Henry, Van Beneden, Stricker, Bolzani, and a number of others, lend lustre to the meetings. Professor Huxley's address on Wednesday was listened to by a large and attentive audience, who appeared thoroughly to follow his train of argument. At the general committee some new regulations of considerable importance were proposed, particulars of which will be found in another column. On Thursday a casual visitor to Liverpool would see at once, on emerging from the railway station at Lime-street, that something unusual was stirring. The centre of operations was the space that includes St. George's Hall, where several of the sections are located, and the closely adjoining Derby Museum, where the Biological Section is to be found, and the reception-room, reading-room, and post-office. In this space and the neighbouring streets, the members of the Association may be recognised by the little blue or buff map-cards they carry, as symbolical as Murray in a Continental tour. Taking the various sections in turn, we find three located in St. George's Hall, A, E, and G. The Geographical Section is always a popular one, and attracted the largest audience of any to listen to the well-known and popular president, Sir Roderick Murchison, deliver his opening address. The room selected was the small concert-room—not a very small one, by-the-bye—which was well filled, a large proportion of the audience being ladies, though I am afraid Sir Roderick's failing voice hardly reached the whole of the company. How large a proportion stayed to hear Sir H. Rawlinson's report on the Site of Paradise I did not wait to see. The two other sections in St. George's Hall, the Mathematical and Mechanical, had to be reached by long winding passages, past rooms redolent of the law ; and were, of course, much more thinly attended, but very few ladies being met with here. Crossing over to the Derby Museum, and passing through the Reception Room, we reach the Free Public Library, where Professor Rolleston enchained a large audience by an address of upwards of an hour, which was generally admitted to be *the* address of the day. His commanding presence, measured diction, and his happy hits and classical allusions, exercised a great charm over the meeting, and many were the inquiries where a report of the speech was to be obtained. This section then divided into three sub-sections, under the presidency of Prof. Rolleston, Prof. Michael Foster, and Mr. John Evans, each of which attracted a goodly number of visitors. A very large audience listened to Dr. Brown-Séquard's long but very interesting account of his researches on the nervous system of guinea-pigs, of which little animal it is said, that he has left two thousand behind him in Paris, which, he fears, may fall a prey to the Prussians or to the exigencies of the siege. Those sections which are held at comparatively remote places are at a certain disadvantage, though many of the visitors appeared to avail themselves of cabs or of the luxury of the tramway omnibuses, which London does not yet possess, to visit them. The Geological Section is held in a small and not very convenient room, the Concert Hall, in Lord Nelson Street. Here there was no opening address, and the attendance was small. The most remote of all is the Chemical Section at the Royal Institution in Colquitt Street. At the Section for Economic Science, in the Town Hall, I arrived just in time to hear the venerable Sir John Bowring propose a vote of thanks to the president, Prof. Jevons, for his opening address. The "economic" rule was there laid down, which might have been adopted with advantage in some of the other sections, that, during a discussion, no one was to speak for more than ten minutes. Considering the distance from the central buildings, the attendance here was not small; and the committee of this section appears to contain the largest infusion of the aristocratic element—Lord Derby, Lord Houghton, Sir J. K. Shuttleworth, and Lord Neaves. The first day was closed by a *soirée* given by the Mayor in the Town Hall, where about 1,400 visitors were collected, consisting of members of the Association and the principal visitors in Liverpool. A *soirée* was also held in the Free Public Library, where Mr. Moore and the Rev. H. H. Higgins had got together a very large and interesting collection of scientific objects and works of art, including the well-known and valuable "Mayer collection."

On Friday and Saturday I confined my visits to the several sections comprised under the head of Natural Science. In the Geological Section there have been several papers of great interest, Mr. Judd's having attracted particular attention, and the discussion which followed was thought very interesting. The chemists do not appear to have mustered in force; at all events, that section took a holiday on Saturday, and a good many interested in it have seized the opportunity of visiting some of the numerous chemical works in the neighbourhood. Section D, on the other hand, has suffered from a plethora of papers, notwithstanding its division into three sub-sections. The Geographical Section is always popular. Great disappointment was expressed at the withdrawal of Mr. Hepworth Dixon's paper, which was, however, to some extent compensated by the part he took in the discussion which followed Governor Gilpin's paper on Colorado. But the greatest crush on Friday was in Prof. Rolleston's sub-section; and the interest excited on the subject of Spontaneous Generation, by the president's opening address, was shown by the attention with which the crowded audience listened to a two-hours' discussion, for which purpose the three sub-sections were for a time united. The campaign was opened by a description of some recent experiments by Dr. Child, the well-known advocate of spontaneous generation, on Abiogenesis. This was followed up by an elaborate paper, on the other side, from Mr. Samuelson, which was succeeded by some remarks from Dr. Crace Calvert, who spoke of the extreme difficulty with which the atmosphere can be entirely freed from organic germs. The discussion which followed was sustained by Dr. Hooker, Mr. Bentham, and other distinguished naturalists, entirely on the orthodox side of Biogenesis. In the remarks with which he summed up the debate, Prof. Rolleston complimented Dr. Child on the gallantry with which he had stood in the breach alone against such a consensus of opposition; and expressed his regret at the absence of the great champion of Abiogenesis, Dr. Charlton Bastian—the report of whose experiments in NATURE, he said, it was the bounden duty of every one who had now heard the other side of the question to read. Prof. Huxley was not present during the discussion; and though Mr. Herbert Spencer was, he took no part in it. It is rumoured that the combat is to be renewed to-morrow by the chiefs themselves: if this is the case, probably the whole Association will be there to hear them. In a discussion which took place in the same section on Thursday, Mr. Gwyn Jeffreys spoke of the hindrance which the *Porcupine* dredging expedition in the Mediterranean had experienced from the unfavourable weather. He mentioned the fact, which is but little known to naturalists, and which is not without importance in reference to the theory of glacial epochs, that the species of mollusca dredged up from great depths in the Mediterranean in previous expeditions are identical with Arctic species. It is very gratifying that Prof. Wyville Thomson, who was prevented from taking his share in that expedition through illness, is now completely restored to health. Prof. Tyndall's eloquent discourse on Friday on the scientific uses of the imagination was just of the kind which pleases the audience for whom it was intended, and was rapturously applauded.

At a meeting of the General Committee yesterday afternoon, Prof. Huxley in the chair, invitations were read for meetings of the Association to be held at Edinburgh, Brighton, Bradford, and Belfast. The Scotch metropolis was represented by Prof. Balfour and Sir Walter Elliot, the southern watering-place by Mr. Hallett and Mr. Mayall the photographer, the Yorkshire manufacturing town by the Mayor of Bradford and Mr. Alderman Law, and the Irish city by Dr. M'Gee and Mr. Patterson. In reference to Brighton, it was mentioned that the three south-eastern counties of England have together only enjoyed one meeting of the Association during the last twenty-five years, the Thames appearing to be a kind of Rubicon which the Association has found a difficulty in crossing. It was moved by Sir Roderick Murchison, seconded by Mr. Cowan (who stated that the neighbourhood of Edinburgh manufactured 200 miles of paper per diem), that the next meeting of the Association be held at Edinburgh. Lord Houghton then moved, in accordance with the new resolution passed by the General Committee, that the meeting for 1872 be held at Brighton. This was seconded by Mr. Gassiot, and also carried unanimously. The motion of Prof. Stokes, seconded by Mr. Spottiswoode, that Sir William Thomson be the president-elect, was received with great enthusiasm. Sir Walter Elliot proposed, and Prof. Rolleston seconded, the appointment of the vice-presidents for 1871, viz., the Duke of Buccleuch, the Lord Provost of Edinburgh, the Right Hon. J. Inglis, Sir Alexander Grant, Sir Roderick Murchison, Sir Chas. Lyell, Dr. Lyon Playfair, and Dr. Christison. Prof. Crum Brown, Mr. Ed. Sang, and Mr. T. B. Margaret are to be the local secretaries; and the time fixed was the middle of August, the day to be settled by the Council. The committee then resumed the subject of Vivisection, which had been adjourned from the last meeting. Mr. Johnstone Stoney proposed the resolution of which he had given notice, that "Having regard to the well-known character of the British Association, and to the circumstance that the business of the General Committee is necessarily transacted under pressure of time, it is not expedient, under ordinary circumstances, that it be recommended to this committee to appoint committees or pass votes for investigations to be carried on by the method of vivisection." This resolution Mr. Stoney was anxious to withdraw in favour of two others, but the chairman decided that these could only be brought forward in the form of amendments. The original resolution was therefore seconded, *pro formâ*, by Prof. Stokes. Mr. Samuelson then proposed as an amendment, "That the committee of Section D be requested to draw up a statement of their views upon physiological experiments in their various bearings, and that this document be circulated among the members of the Association, and that the said committee be further requested to consider from time to time whether any steps can be taken by them or by the Association which will tend to reduce to its minimum the sufferings entailed by legitimate physiological inquiries, or which will have the effect of employing the influence of the Association in discouragement of experiments which are not clearly legitimate of living animals." The amendment was seconded by Professor Rolleston, and carried by a large majority. The following appointments were then made :—Council : The President and President elect ; Vice-president and Vice-presidents elect ; General Secretaries and Assistant-secretary ; General Treasurer ; trustees, presidents of former years, and the following gentlemen :—Mr. Bateman, Dr. Beddoe, Mr. G. Busk, Dr. Debus, Mr. Warren Delarue, Mr. J. Evans, Captain Galton, Mr. F. Galton, Mr. Gassiot, Mr. Godwin-Austen, Lord Houghton, Mr. W. Huggins, Sir John Lubbock, Prof. W. A. Miller, Mr. Newmarch, Sir S. Northcote, Prof. Ramsay, Prof. Rankine, Dr. J. Simon, Lieut.-Col. Strange, Col. Sykes, Sir W. Tite, Prof. Tyndall, Mr. A. R. Wallace, Prof. Wheatstone, Prof. A. W. Williamson. General Secretaries, Prof. Hirst and Dr. Thomas Thomson. Assistant Secretary, Mr. Griffiths. Treasurer, Mr. Spottiswoode. Auditors, Mr. G. Busk, Dr. M. Foster, Mr. Gwyn Jeffreys. Mr. J. Evans and Dr. M. Foster were added to the Committee of Recommendations. B.

REPORT OF THE COUNCIL

"The Council have received the usual reports from the General Treasurer and from the Kew Committee. Their reports for the past year will be laid before the General Committee this day.

The Council have to report upon the action they have taken relative to each of the four resolutions referred to them by the General Committee at Exeter.

The first of these resolutions was—

'That the Council be requested to take into their consideration the existing relations between the Kew Committee and the British Association.'

The Council accordingly appointed a Committee of their own body to examine into these relations. This Committee had before them a special report drawn up by the Kew Committee, and, after due deliberation, they recommended—

'That the existing relations between the Kew Observatory and the British Association be continued unaltered until the completion, in 1872, of the magnetic and solar decennial period; but that after that date all connexion between them shall cease.'

The Council adopted this recommendation, and now offer it, as their own, to the General Committee.

The second resolution referred to the Council was as follows:—

'That the full influence of the British Association for the Advancement of Science should at once be exerted to obtain the appointment of a Royal Commission to consider—

First, the character and value of existing institutions and facilities for scientific investigation, and the amount of time and money devoted to such purposes.

Secondly, what modifications or augmentations of the means and facilities that are at present available for the maintenance and extension of science are requisite ; and,

Thirdly, in what manner these can be best supplied.'

By a third resolution the Council was 'requested to ascertain whether the action of Government in relation to the higher scientific education has been in accordance with the principles of impartiality which were understood to guide them in this matter ; and to consider whether that action has been well calculated to utilise and develop the resources of the country for this end, and to favour the free development of the higher scientific education. That the Council be requested to take such measures as may appear to them best calculated to carry out the conclusions to which they may be led by these inquiries and deliberations.'

The Committee of the Council appointed to consider these two resolutions reported their opinion to be favourable to the appointment of a Royal Commission to inquire into the relations of the State to scientific instruction and investigation ; and they added that no such inquiry would, in their opinion, be complete which did not extend itself to the action of the State in relation to scientific education, and the effect of that action upon independent educational institutions.

Your President and Council, acting on the advice of this Committee, constituted themselves a Deputation and waited upon the Lord President of the Council. They are glad to be able to report that their efforts to bring this important subject before Her Majesty's Government have been attended with success. On the 18th of May, Her Majesty issued a Commission "to make inquiry with regard to Scientific Instruction and the Advancement of Science, and to inquire what aid thereto is derived from grants voted by Parliament or from endowments belonging to the several universities in Great Britain and Ireland and the colleges thereof, and whether such aid could be rendered in a manner more effectual for the purpose." The Commissioners appointed by Her Majesty are the Duke of Devonshire, the Marquis of Lansdowne, Sir John Lubbock, Bart., Sir James Phillips Kay Shuttleworth, Bart., Bernhard Samuelson, Esq., M.P., Dr. Sharpey, Professor Huxley, Dr. W. A. Miller, and Professor Stokes. J. Norman Lockyer, Esq., F.R.S., has been appointed Secretary to the Commissioners, who, up to last July, were engaged taking evidence with great assiduity, and have now adjourned their meetings until November. There is every reason to hope that valuable results will follow from their deliberations.

The fourth resolution which the General Committee referred to the Council was—

'That the rules under which members are admitted to the General Committee be reconsidered.'

A Committee of the Council devoted considerable care to a revision of the existing rules. The modified rules approved by the Council are now submitted for adoption to the present General Committee, whose constitution is, of course, not affected thereby. The most important of the proposed changes are that henceforth new claims to membership of the General Committee shall be forwarded to the Assistant General Secretary at least one month before the next ensuing Annual Meeting of the Association ; that these claims shall be submitted to the Council, whose decision upon them is to be final ; and that henceforth it is not the authorship of a paper in the Transactions of a scientific society which is alone to constitute a claim to membership of the General Committee, but the publication of any works or papers which have furthered the advancement of any of the subjects taken into consideration at the Sectional meetings of the Society.

Your Council has, also, had under its consideration the desirability of removing certain administrative inconveniences which arise from the circumstance that the next place of meeting is never decided upon by the General Committee until near the close of the actual meeting. They are of opinion that the arrangements of the General Officers would be greatly facilitated, and at the same time the convenience of those who invite the Association consulted, if the General Committee were to decide upon each place of meeting a year earlier than they do at present. In order to make the transition from the existing practice to the proposed one, your Council recommend that two of the invitations which will be received at the present meetings be accepted, one for 1871, and another for 1872.

It has often been urged that the Association labours under disadvantages in consequence of its not possessing central offices in London, where its Council and numerous committees could hold their meetings, where the books and memoirs which have been accumulating for years could be rendered accessible to Members, and where information concerning the Association's proceedings could be promptly obtained during the interval between annual meetings. The Council have had the subject under consideration, and in the event of the establishment at Kew being discontinued, they are prepared to recommend that suitable rooms, in a central situation, should be procured. The additional annual expenditure which this would involve would probably not exceed 150*l.*

The Council have added the names of Professor H. A. Newton and Professor C. S. Lyman, who were present at the Exeter meeting, to the list of corresponding members."

We append the new rules referred to in the Council's Report.

" *New Rules for Admission to the General Committee*

The General Committee will in future consist of the following classes of members :—

CLASS A.—PERMANENT MEMBERS

1. Members of the Council, presidents of the Association, and presidents of sections for the present and preceding years, with authors of reports in the Transactions of the Association.

2. Members who, by the publication of works or papers, have furthered the advancement of those subjects which are taken into consideration at the sectional meetings of the Association. With a view of submitting new claims under this rule to the decision

of the Council, they must be sent to the assistant general secretary at least one month before the meeting of the Association. The decision of the Council on the claims of any member of the Association to be placed on the list of the General Committee to be final.

CLASS B.—TEMPORARY MEMBERS

3. The president for the time being, or, in his absence, one delegate representing him, of any scientific society publishing transactions. Claims under this rule to be sent to the assistant general secretary before the opening of the meeting.

4. Office-bearers for the time being, or delegates, altogether not exceeding three, from scientific institutions established in the place of meeting. Claims under this rule to be approved by the local secretaries before the opening of the meeting.

5. Foreigners and other individuals whose assistance is desired, and who are specially nominated in writing, for the meeting of the year, by the president and general secretaries.

6. Vice-presidents and secretaries of sections."

SECTIONAL PROCEEDINGS

SECTION A.—*Mathematical and Physical Science.*—President, Prof. J. Clerk Maxwell, F.R.S.

The president delivered the following address:—

AT several of the recent meetings of the British Association the varied and important business of the Mathematical and Physical Section has been introduced by an Address, the subject of which has been left to the selection of the president for the time being. The perplexing duty of choosing a subject has not, however, fallen to me. Professor Sylvester, the president of Section A at the Exeter meeting, gave us a noble vindication of pure mathematics by laying bare, as it were, the very working of the mathematical mind, and setting before us, not the array of symbols and brackets which form the armoury of the mathematician, or the dry results which are only the monuments of his conquests, but the mathematician himself, with all his human faculties directed by his professional sagacity to the pursuit, apprehension, and exhibition of that ideal harmony which he feels to be the root of all knowledge, the fountain of all pleasure, and the condition of all action. The mathematician has, above all things, an eye for symmetry; and Professor Sylvester has not only recognised the symmetry formed by the combination of his own subject with those of the former presidents, but has pointed out the duties of his successor in the following characteristic note:—

"Mr. Spottiswoode favoured the Section, in his opening address, with a combined history of the progress of mathematics and physics; Dr. Tyndall's address was virtually on the limits of physical philosophy; the one here in print," says Professor Sylvester, "is an attempted faint adumbration of the nature of mathematical science in the abstract. What is wanting (like a fourth sphere resting on three others in contact) to build up the ideal pyramid is a discourse on the relation of the two branches (mathematics and physics) to, and their action and reaction upon, one another—a magnificent theme, with which it is to be hoped that some future president of Section A will crown the edifice, and make the tetralogy (symbolisable by $A+A'$, A, A', AA') complete."

The theme thus distinctly laid down for his successor by our late President is indeed a magnificent one, far too magnificent for any efforts of mine to realise. I have endeavoured to follow Mr. Spottiswoode, as with far-reaching vision he distinguishes the systems of science into which phenomena, our knowledge of which is still in the nebulous stage, are growing. I have been carried by the penetrating insight and forcible expression of Dr. Tyndall into that sanctuary of minuteness and of power where molecules obey the laws of their existence, clash together in fierce collision, or grapple in yet more fierce embrace, building up in secret the forms of visible things. I have been guided by Professor Sylvester towards those serene heights

> "Where never creeps a cloud, or moves a wind,
> Nor ever falls the least white star of snow,
> Nor ever lowest roll of thunder moans,
> Nor sound of human sorrow mounts, to mar
> Their sacred everlasting calm."

But who will lead me into that still more hidden and dimmer region where Thought weds Fact; where the mental operation of the mathematician and the physical action of the molecules are seen in their true relation? Does not the way to it pass through the very den of the metaphysician, strewed with the remains of former explorers, and abhorred by every man of science? It would indeed be a foolhardy adventure for me to take up the valuable time of the section by leading you into those speculations which require, as we know, thousands of years even to shape themselves intelligibly.

But we are met as cultivators of mathematics and physics. In our daily work we are led up to questions the same in kind with those of metaphysics; and we approach them, not trusting to the native penetrating power of our own minds, but trained by a long-continued adjustment of our modes of thought to the facts of external nature. As mathematicians, we perform certain mental operations on the symbols of number or of quantity, and, by proceeding step by step from more simple to more complex operations, we are enabled to express the same thing in many different forms. The equivalence of these different forms, though a necessary consequence of self-evident axioms, is not always, to our minds, self-evident; but the mathematician, who, by long practice, has acquired a familiarity with many of these forms, and has become expert in the processes which lead from one to another, can often transform a perplexing expression into another which explains its meaning in more intelligible language.

As students of physics, we observe phenomena under varied circumstances, and endeavour to deduce the laws of their relations. Every natural phenomenon is, to our minds, the result of an infinitely complex system of conditions. What we set ourselves to do is to unravel these conditions, and by viewing the phenomenon in a way which is in itself partial and imperfect, to piece out its features one by one, beginning with that which strikes us first, and thus gradually learning how to look at the whole phenomenon so as to obtain a continually greater degree of clearness and distinctness. In this process, the feature which presents itself most forcibly to the untrained inquirer may not be that which is considered most fundamental by the experienced man of science; for the success of any physical investigation depends on the judicious selection of what is to be observed as of primary importance, combined with a voluntary abstraction of the mind from those features which, however attractive they appear, we are not yet sufficiently advanced in science to investigate with profit.

Intellectual processes of this kind have been going on since the first formation of language, and are going on still. No doubt the feature which strikes us first and most forcibly in any phenomenon, is the pleasure or the pain which accompanies it, and the agreeable or disagreeable results which follow after it. A theory of nature from this point of view is embodied in many of our words and phrases, and is by no means extinct even in our deliberate opinions. It was a great step in science when men became convinced that, in order to understand the nature of things, they must begin by asking, not whether a thing is good or bad, noxious or beneficial, but of what kind is it? and how much is there of it? Quality and quantity were then first recognised as the primary features to be observed in scientific inquiry. As science has been developed, the domain of quantity has everywhere encroached on that of quality, till the process of scientific inquiry seems to have become simply the measurement and registration of quantities, combined with a mathematical discussion of the numbers thus obtained. It is this scientific method of directing our attention to those features of phenomena which may be regarded as quantities which brings physical research under the influence of mathematical reasoning. In the work of the section we shall have abundant examples of the successful application of this method to the most recent conquests of science; but I wish at present to direct your attention to some of the reciprocal effects of the progress of science on those elementary conceptions which are sometimes thought to be beyond the reach of change.

If the skill of the mathematician has enabled the experimentalist to see that the quantities which he has measured are connected by necessary relations, the discoveries of physics have revealed to the mathematician new forms of quantities which he could never have imagined for himself. Of the methods by which the mathematician may make his labours most useful to the student of nature, that which I think is at present most important is the systematic classification of quantities. The quantities which we study in mathematics and physics may be classified in two different ways. The student who wishes to master any particular science must make himself familiar with the various kinds of quantities which belong to that science. When he understands all the relations between these quantities, he regards them as forming a connected system, and he classes the whole system of quantities together as belonging to that particular science. This classification is the most natural from a physical point of view, and it is generally the first in order of time. But when the student has become acquainted with several different sciences, he finds that the mathematical processes and trains of reasoning in one science resemble those in another so much that his knowledge of the one science may be made a most useful help in the study of the other. When he examines into the reason of this, he finds that in the two sciences he has been dealing with systems of quantities, in which the mathematical forms of the relations of the quantities are the same in both systems, though the physical nature of the quantities may be utterly different. He is thus led to recognise a classification of quantities on a new principle, according to which the physical nature of the quantity is subordinated to its mathematical form. This is the point of view which is characteristic of the mathematician; but it stands second to the physical aspect in order of time, because the human mind, in order to conceive of different kinds of quantities, must have them presented to it by nature. I do not here refer to the fact that all quantities, as such, are subject to the rules of arithmetic and algebra, and are therefore capable of being submitted to those dry calculations which represent, to so many minds, their only idea of mathematics. The human mind is seldom satisfied, and is certainly never exercising its highest functions, when it is doing the work of a calculating machine. What the man of science, whether he be a mathematician or a physical inquirer, aims at is, to acquire and develop clear ideas of the things he deals with. For this purpose he is willing to enter on long calculations, and to be for a season a calculating machine, if he can only at last make his ideas clearer. But if he finds that clear ideas are not to be obtained by means of processes, the steps of which he is sure to forget before he has reached the conclusion, it is much better that he should turn to another method, and try to understand the subject by means of well-chosen illustrations derived from subjects with which he is more familiar. We all know how much more popular the illustrative method of exposition is found, than that in which bare processes of reasoning and calculation form the principal subject of discourse. Now a truly scientific illustration is a method to enable the mind to grasp some conception or law in one branch of science, by placing before it a conception or a law in a different branch of science, and directing the mind to lay hold of that mathematical form which is common to the corresponding ideas in the two sciences, leaving out of account for the present the difference between the physical nature of the real phenomena. The correctness of such an illustration depends on whether the two systems of ideas which are compared together are really analogous in form, or whether, in other words, the corresponding physical quantities really belong to the same mathematical class. When this condition is fulfilled, the illustration is not only convenient for teaching science in a pleasant and easy manner, but the recognition of the mathematical analogy between the two systems of ideas leads to a knowledge of both, more profound than could be obtained by studying each system separately.

There are men who, when any relation or law, however complex, is put before them in a symbolical form, can grasp its full meaning as a relation among abstract quantities. Such men sometimes treat with indifference the further statement that quantities actually exist in nature which fulfil this relation. The mental image of the concrete reality seems rather to disturb than to assist their contemplations. But the great majority of mankind are utterly unable, without long training, to retain in their minds the unembodied symbols of the pure mathematician; so that if science is ever to become popular and yet remain scientific, it must be by a profound study and a copious application of those principles of truly scientific illustration which, as we have seen, depend on the mathematical classification of quantities. There are, as I have said, some minds which can go on contemplating with satisfaction pure quantities presented to the eye by symbols, and to the mind in a form which none but mathematicians can conceive. There are others who feel more enjoyment in following geometrical forms, which they draw on paper, or build up in the empty space before them. Others, again, are not content unless they can project their whole physical energies into the scene which they conjure up. They learn at what a rate the planets rush through space, and they experience a delightful feeling of exhilaration. They calculate the forces with which the heavenly bodies pull at one another, and they feel their own muscles straining with the effort.

To such men impetus, energy, mass, are not mere abstract expressions of the results of scientific inquiry. They are words of power which stir their souls like the memories of childhood. For the sake of persons of these different types, scientific truths should be presented in different forms, and should be regarded as equally scientific, whether it appears in the robust form and the vivid colouring of a physical illustration, or in the tenuity and paleness of a symbolical expression. Time would fail me if I were to attempt to illustrate by examples the scientific value of the classification of quantities. I shall only mention the name of that important class of magnitudes having direction in space which Hamilton has called Vectors, and which form the subject-matter of the Calculus of Quaternions—a branch of mathematics which, when it shall have been thoroughly understood by men of the illustrative type, and clothed by them with physical imagery, will become, perhaps under some new name, a most powerful method of communicating truly scientific knowledge to persons apparently devoid of the calculating spirit. The mutual action and reaction between the different departments of human thought is so interesting to the student of scientific progress, that, at the risk of still further encroaching on the valuable time of the Section, I shall say a few words on a branch of science which not very long ago would have been considered rather a branch of metaphysics: I mean the atomic theory, or, as it is now called, the molecular theory of the constitution of bodies. Not many years ago, if we had been asked in what regions of physical science the advance of discovery was least apparent, we should have pointed to the hopelessly distant fixed stars on the one hand, and to the inscrutable delicacy of the texture of material bodies on the other. Indeed, if we are to regard Comte as in any degree representing the scientific opinion of his time, the research into what takes place beyond our own solar system seemed then to be exceedingly unpromising, if not altogether illusory. The opinion that the bodies which we see and handle, which we can set in motion or leave at rest, which we can break in pieces and destroy, are composed of smaller bodies which we cannot see or handle, which are always in motion, and which can neither be stopped nor broken in pieces, nor in any way destroyed or deprived of the least of their properties, was known by the name of the Atomic Theory. It was associated with the names of Democritus and Lucretius, and was commonly supposed to admit the existence only of atoms and void, to the exclusion of any other basis of things from the universe.

In many physical reasonings and mathematical calculations we are accustomed to argue as if such substances as air, water, or metal, which appear to our senses uniform and continuous, were strictly and mathematically uniform and continuous. We know that we can divide a pint of water into many millions of portions, each of which is as fully endowed with all the properties of water as the whole pint was, and it seems only natural to conclude that we might go on subdividing the water for ever, just as we can never come to a limit in subdividing the space in which it is contained. We have heard how Faraday divided a grain of gold into an inconceivable number of separate particles, and we may see Dr. Tyndall produce from a mere suspicion of nitrite of butyle an immense cloud, the minute visible portion of which is still cloud, and therefore must contain many molecules of nitrite of butyle. But evidence from different and independent sources is now crowding in upon us which compels us to admit that if we could push the process of subdivision still further we should come to a limit, because each portion would then contain only one molecule, an individual body, one and indivisible, unalterable by any power in nature. Even in our ordinary experiments on very finely divided matter we find that the substance is beginning to lose the properties which it exhibits when in a large mass, and that effects depending on the individual action of molecules are beginning to become prominent. The study of these phenomena is at present the path which leads to the development of molecular science. That superficial tension of liquids which is called capillary attraction is one of these phenomena. Another important class of phenomena are those which are due to that motion of agitation by which the molecules of a liquid or gas are continually working their way from one place to another, and continually changing their course, like people hustled in a crowd. On this depends the rate of diffusion of gases and liquids through each other, to the study of which, as one of the keys of molecular science, that unwearied inquirer into nature's secrets, the late Prof. Graham, devoted such arduous labour.

The rate of electrolytic conduction is, according to Wiedemann's theory, influenced by the same cause; and the conduction of heat in fluids depends probably on the same kind of action.

In the case of gases, a molecular theory has been developed by Clausius and others, capable of mathematical treatment, and subjected to experimental investigation; and by this theory nearly every known mechanical property of gases has been explained on dynamical principles, so that the properties of individual gaseous molecules are in the fair way to become objects of scientific research. Now Sir William Thomson has shown by several independent lines of argument, drawn from phenomena so different in themselves as the electrification of metals by contact, the tension of soap-bubbles, and the friction of air, that in ordinary solids and liquids the average distance between contiguous molecules is less than the hundred-millionth, and greater than the two-thousand-millionth of a centimètre. This of course is an exceedingly rough estimate, for it is derived from measurements, some of which are still confessedly very rough; but if, at the present time, we can form even a rough plan for arriving at a result of this kind, we may hope that as our means of experimental inquiry become more accurate and more varied, our conception of a molecule will become more definite, so that we may be able at no distant period to estimate its weight. A theory which Sir W. Thomson has founded on Helmholtz's splendid hydrodynamical theorems, seeks for the properties of molecules in the ring-vortices of a uniform, frictionless, incompressible fluid. Such whirling rings may be seen when an experienced smoker sends out a dexterous puff of smoke into the still air, but a more evanescent phenomenon it is difficult to conceive. This evanescence is owing to the viscosity of the air; but Helmholtz has shown that in a perfect fluid such a whirling ring, if once generated, would go on whirling for ever, would always consist of the very same portion of the fluid which was first set whirling, and could never be cut in two by any natural cause. The generation of a ring-vortex is of course equally beyond the power of natural causes, but once generated, it has the properties of individuality, permanence in quantity, and indestructibility. It is also the recipient of impulse and of energy, which is all we can affirm of matter: and these ring-vortices are capable of such varied connections, and knotted self-involutions, that the properties of differently knotted vortices must be as different as those of different kinds of molecules can be.

If a theory of this kind should be found, after conquering the enormous mathematical difficulties of the subject, to represent in any degree the actual properties of molecules, it will stand in a very different scientific position from those theories of molecular action which are formed by investing the molecule with an arbitrary system of central forces invented expressly to account for the observed phenomena. In the vortex theory we have nothing arbitrary, no central forces or occult properties of any other kind. We have nothing but matter and motion, and when the vortex is once started its properties are all determined from the original impetus, and no further assumptions are possible. Even in the present undeveloped state of the theory, the contemplation of the individuality and indestructibility of a ring vortex in a perfect fluid cannot fail to disturb the commonly received opinion that a molecule, in order to be permanent, must be a very hard body. In fact one of the first conditions which a molecule must fulfil is, apparently, inconsistent with its being a single hard body. We know from those spectroscopic researches which have thrown so much light on different branches of science, that a molecule can be set into a state of internal vibration, in which it gives off to the surrounding medium light of definite refrangibility—light, that is, of definite wave-length and definite period of vibration. The fact that all the molecules, say of hydrogen, which we can procure for our experiments, when agitated by heat or by the passage of an electric spark, vibrate precisely in the same periodic time, or, to speak more accurately, that their vibrations are composed of a system of simple vibrations having always the same periods, is a very remarkable fact. I must leave it to others to describe the progress of that splendid series of spectroscopic discoveries by which the chemistry of the heavenly bodies has been brought within the range of human inquiry. I wish rather to direct your attention to the fact that not only has every molecule of terrestrial hydrogen the same system of periods of free vibration, but that the spectroscope examination of the light of the sun and stars shows that in regions the distance of which we can only feebly imagine there are molecules vibrating in as exact unison with the molecules of terrestrial hydrogen as two tuning forks tuned to correct pitch, or two watches regulated to solar time. Now this absolute equality in the magnitude of quantities, occurring in all parts of the universe, is worth our consideration. The dimensions of individual natural bodies are either quite indeterminate, as in the case of planets, stones, trees, &c., or they vary within moderate limit, as in the case of seeds, eggs, &c.; but, even in these cases, small quantitive differences are met with which do not interfere with the essential properties of the body. Even crystals, which are so definite in geometrical form, are variable with respect to their absolute dimensions. Among the works of man we sometimes find a certain degree of uniformity. There is a uniformity among the different bullets which are cast in the same mould, and the different copies of a book printed from the same type. If we examine the coins, or the weights and measures, of a civilised country, we find a uniformity, which is produced by careful adjustment to standards made and provided by the State. The degree of uniformity of these national standards is a measure of that spirit of justice in the nation which has enacted laws to regulate them and appointed officers to test them. This subject is one in which we, as a scientific body, take a warm interest, and you are all aware of the vast amount of scientific work which has been expended, and profitably expended, in providing weights and measures for commercial and scientific purposes. The earth has been measured as a basis for a permanent standard of length, and every property of metals has been investigated to guard against any alteration of the material standards when made. To weigh or measure anything with modern accuracy, requires a course of experiment and calculation in which almost every branch of physics and mathematics is brought into requisition.

Yet, after all, the dimensions of our earth and its time of rotation, though, relatively to our present means of comparison, very permanent, are not so by any physical necessity. The earth might contract by cooling, or it might be enlarged by a layer of meteorites falling on it, or its rate of revolution might slowly slacken, and yet it would continue to be as much a planet as before. But a molecule, say of hydrogen, if either its mass or its time of vibration were to be altered in the least, would no longer be a molecule of hydrogen. If, then, we wish to obtain standards of length, time, and mass which shall be absolutely permanent, we must seek them not in the dimensions, or the motion, or the mass of our planet, but in the wave-length, the period of vibration, and the absolute mass of these imperishable and unalterable and perfectly similar molecules. When we find that here, and in the starry heavens, there are innumerable multitudes of little bodies of exactly the same mass, so many, and no more, to the grain, and vibrating in exactly the same time, so many times, and no more, in a second, and when we reflect that no power in nature can now alter in the least either the mass or the period of any one of them, we seem to have advanced along the path of natural knowledge to one of those points at which we must accept the guidance of that faith by which we understand that "that which is seen was not made of things which do appear." One of the most remarkable results of the progress of molecular science is the light it has thrown on the nature of irreversible processes,—processes, that is, which always tend towards, and never away from, a certain limiting state. Thus if two gases be put into the same vessel they become mixed, and the mixture tends continually to become more uniform. If two unequally heated portions of the same gas are put into the vessel, something of the kind takes place, and the whole tends to become of the same temperature. If two unequally heated solid bodies be placed in contact, a continual approximation of both to an intermediate temperature takes place. In the case of the two gases, a separation may be effected by chemical means; but in the other two cases the former state of things cannot be restored by any natural process. In the case of the conduction or diffusion of heat the process is not only irreversible, but it involves the irreversible diminution of that part of the whole stock of thermal energy which is capable of being converted into mechanical work. This is Thomson's theory of the irreversible dissipation of energy, and it is equivalent to the doctrine of Clausius concerning the growth of what he calls Entropy. The irreversible character of this process is strikingly embodied in Fourier's theory of the conduction of heat, where the formulæ themselves indicate a possible solution of all positive values of the time which continually tends to a uniform diffusion of heat. But if we attempt to ascend the stream of time by giving to its symbol continually diminishing values, we are led up to a state of things in which the formula has what is called a critical value; and if we inquire into the state of things the instant before, we find that the formula becomes absurd. We thus arrive at the conception of a state of things which cannot be conceived as the physical result of a previous state of things, and we find that this critical condition actually existed at an epoch not in the utmost depths of a past eternity, but separated from the present time by a finite interval. This idea of a beginning is one which the physical researches of recent times have brought home to us, more than any observer of the course of scientific thought in former times would have had reason to expect. But the mind of man is not like Fourier's heated body, continually settling down into an ultimate state of quiet uniformity, the character of which we can already predict; it is rather like a tree shooting out branches which adapt themselves to the new aspects of the sky towards which they climb, and roots which contort themselves among the strange strata of the earth into which they delve. To us who breathe only the spirit of our own age, and know only the characteristics of contemporary thought, it is as impossible to predict the general tone of the science of the future as it is to anticipate the particular discoveries which it will make. Physical research is continually revealing to us new features of natural processes, and we are thus compelled to search for new forms of thought appropriate to these features. Hence the importance of a careful study of those relations between mathematics and physics which determine the conditions under which the ideas derived from one department of physics may be safely used in forming ideas to be employed in a new department. The figure of speech or of thought by which we transfer the language and ideas of a familiar science to one with which we are less acquainted may be called scientific metaphor. Thus the words velocity, momentum, force, &c., have acquired certain precise meanings in elementary dynamics. They are also employed in the dynamics of a connected system in a sense which, though perfectly analogous to the elementary sense, is wider and more general. These generalised forms of elementary ideas may be called metaphorical terms in the sense in which every abstract term is metaphorical. The characteristic of a truly scientific system of metaphors is that each term in its metaphorical use retains all the formal relations to the other terms of the system which it had in its original use. The method is then truly scientific, that is, not only a legitimate product of science, but capable of generating science in its turn. There are certain electrical phenomena, again, which are connected together by relations of the same form as those which connect dynamical phenomena. To apply to these the phrases of dynamics with proper distinctions and provisional reservations is an example of a metaphor of a bolder kind; but it is a legitimate metaphor if it conveys a true idea of the electrical relations to those who have been already trained in dynamics. Suppose, then, that we have successfully introduced certain ideas belonging to an elementary science by applying them metaphorically to some new class of phenomena. It becomes an important philosophical question to determine in what degree the applicability of the old ideas to the new subject may be taken as evidence that the new phenomena are physically similar to the old. The best instances for the determination of this question are those in which two different explanations have been given of the same thing. The most celebrated case of this kind is that of the corpuscular and the undulatory theories of light. Up to a certain point the phenomena of light are equally well explained by both; beyond this point one of them fails. To understand the true relation of these theories in that part of the field where they seem equally applicable we must look at them in the light which Hamilton has thrown upon them by his discovery that to every brachystochrone problem there corresponds a problem of free motion, involving different velocities and times, but resulting in the same geometrical path. Professor Tait has written a very interesting paper on this subject. According to a theory of electricity which is making great progress in Germany two electrical particles act on one another directly at a distance, but with a force which, according to Weber, depends on their relative velocity, and according to a theory hinted at by Gauss, and developed by Riemann, Lorenz, and Neumann, acts not instantaneously, but after a time depending on the distance. The power with which this theory, in the hands of these eminent men, explains every kind of electrical phenomena must be studied in order to be appreciated. Another theory of electricity which I prefer denies action at a distance and attributes electric action to tensions and pressures in an all-pervading medium, these stresses being the same in kind with those familiar to engineers, and the medium being identical with that in which light is supposed to be propagated. Both these theories are found to explain not only the phenomena by the aid of which they were originally constructed, but other phenomena which were not thought of, or perhaps not known at the time, and both have independently arrived at the same numerical result which gives the absolute velocity of light in terms of electrical quantities. That theories, apparently so fundamentally opposed, should have so large a field of truth common to both is a fact the philosophical importance of which we cannot fully appreciate till we have reached a scientific altitude from which the true relation between hypotheses so different can be seen.

I shall only make one more remark on the relation between mathematics and physics. In themselves, one is an operation of the mind, the other is a dance of molecules. The molecules have laws of their own, some of which we select as most intelligible to us and most amenable to our calculation. We form a theory from these partial data, and we ascribe any deviation of the actual phenomena from this theory to disturbing causes. At the same time, we confess that what we call disturbing causes are simply those parts of the true circumstances which we do not know or have neglected, and we endeavour in future to take account of them. We thus acknowledge that the so-called disturbance is a mere figment of the mind, not a fact of nature, and that in natural action there is no disturbance. But this is not the only way in which the harmony of the material with the mental operation may be disturbed. The mind of the mathematician is subject to many disturbing causes, such as fatigue, loss of memory, and hasty conclusions; and it is found that from these and other causes mathematicians make mistakes. I am not prepared to deny that, to some mind of a higher order than ours, each of these errors might be traced to the regular operation of the laws of actual thinking; in fact we ourselves often do detect, not only errors of calculation, but the causes of these errors. This, however, by no means alters our conviction that they are errors, and that one process of thought is right and another process wrong. One of the most profound mathematicians and thinkers of our time, the late George Boole, when reflecting on the precise and almost mathematical character of the laws of right thinking as compared with the exceedingly perplexing, though perhaps equally determinate, laws of actual and fallible thinking, was led to another of those points of view from which science seems to look out into a region beyond her own domain. "We must admit," he says, "that there exist laws" (of thought) "which even the rigour of their mathematical forms does not preserve from violation. We must ascribe to them an authority, the essence of which does not consist in power, a supremacy which the analogy of the inviolable order of the natural world in no way assists us to comprehend."

SECTION B.—*Chemical Science.*—President, Professor Roscoe, F.R.S.

Report of the Committee on the Chemical Nature of Cast Iron.—Mr. David Forbes, F.R.S., reported on behalf of Professor Abel, Dr. Matthiessen and himself, that it had not been in their power, as a Committee, to make any important progress in the investigation of the chemical nature of cast iron during the past year. This was partly owing to the dismantled condition of the required apparatus. The Committee asked to be reappointed, so that the experiments might be resumed without much further delay.

On a New Chlorine Process without Manganese.—Mr. Henry Deacon, of Widnes. As the closing paragraph of Professor Roscoe's address briefly and clearly described the essential nature of Mr. Deacon's process, it is not necessary further to refer to it, except to state that hitherto Mr. Deacon has not succeeded in making the process a commercial success, and he prefers in the meantime to employ Mr. Weldon's process, though he is satisfied that his own will yet become practically applicable in the production of chlorine for the manufacture of bleaching powder.

SECTION C.—*Geology.*—President, Sir Philip de Malpas Grey Egerton, Bart., M.P., F.R.S.

The President departed from the practice of giving an introductory address, inasmuch as the time of the Section would be fully occupied with the reading and discussion of the papers to be submitted to it.

On the Glaciated Surface of Triassic Rocks near Liverpool.—Mr. G. H. Morton. The grooves on the rocks were of a uniform direction, 35° W. of N., and were due to the action of land ice.

Mr. Boyd Dawkins and Rev. Mr. Crosskey distinguished between the deposits produced by land ice and the later deposits containing stones dropped from floating ice. Professor Hawkins insisted that the granite boulders of Lancashire and Cheshire were derived from Ravenglass and not from Shapfell as stated; but Professor Williamson and Mr. Dawkins asserted that they had found Shap boulders in the clay.

On Sections of Strata between Huyton and St. Helens, exposed in cuttings in the railway now making between these places.—Dr. Ricketts

Report on Slicing and Photographing of Fossil Corals.—Mr. James Thompson. The continued investigation of these fossils had added greatly to the number of species, and the prepared sections had exhibited indications which supplied characters by which recognised forms could be better distinguished and false species eliminated. The report was accompanied with a large series of slices and exquisite photographs, full of promise for the future students of the group.

Report on the Fossils of Kiltorcan.—Mr. W. H. Bailey. These consisted of specimens of *Cyclopteris hibernica*, the remains of *Sagenaria bayleana*, a freshwater shell, *Anodonta jukesii* a crustacean *Protocaris mchenrici*, and scales of *Coccosteus* and *Glyptolepis*. Mr. R. H. Scott stated that Professor Heer had determined the specific identity of fossils from Bear Island collected by the Swedish Polar expedition in 1869, with those from Kiltorcan. Mr. Carruthers had recently examined the extensive series of Kiltorcan Fossils at Dublin, made by Mr. Bailey. They supplied information regarding all the parts of the *Sagenaria* and *Cyclopteris*, enabling investigators to deal with them almost as satisfactorily as with recent plants.

Fourth Report on the Leaf-beds of the Bagshot Series of Hampshire.—Mr. W. S. Mitchell.

On the Evidences of Recent Changes of Level on the Mediterranean Coast.—Mr. G. Maw. The coast structure, the general absence of sea-cliffs within the straits of Gibraltar, due to the shelving of the contour of the land under the sea were described. The inset current from the Atlantic was considered as indicating a general subsidence of the whole Mediterranean basin. The submarine springs passing through channels of sub-aerial origin occurring in the coast caverns implied a submergence of the coast line. Evidences of upheaval were to be found in the lagoons and flats which abound on the coast of Corsica, and which are covered with long ridges of shingle deposited, it was believed, by streams which debouched on the marsh when it was submerged. Further at Gibraltar a great deposit of stratified sand in Catalan Bay, showing a submergence of 700 feet; and at Cadiz, as well as at Tangiers on the opposite side of the basin, raised sea beaches were found. Sir Charles Lyell thought the out-set current balanced the inset one and destroyed the value of that current as supporting the notion of submergence. Prof. Busk referred to the memoirs of the late Mr. Smith, of Jordanhill, on the Mediterranean basin, and at length gave his own observations on the rock terraces and caverns of the rock of Gibraltar. There were three successive terraces exhibited only on the eastern side of the rock, showing that a barrier extended in recent geological times across the straits confining the Mediterranean to a higher level than the Atlantic. The changes described by Mr. Maw were really the last of a series indicated by the terraces at Gibraltar. Prof. Ansted thought the great power of enormously swollen streams so common in Corsica and neighbouring regions might account for some of the phenomena referred to by the author.

On the Organisation and Affinities of the Calamites of the Coal Measures.—Prof. Williamson. Numerous well preserved and novel forms of stems of *Calamites* were described with great minuteness, and estimates of their systematic position, based on these structures, were suggested. The author described two forms of nodullary rays, and a third set of radiating cellular structure connected with nodes. He considered the phragmas seen on Calamite stems to indicate the attachment of the roots. He suggested that this group of fossils must be separated from the *Equisetaceæ* and placed in an order to which he proposed to join the name *Calamitaceæ*. Mr. Cann thus doubted whether systematic determinations based on stem structure were of value. He preferred the evidence derived from the fruit, and that had been determined to differ very little from the fruit of the living *Equisetum*. The various points of difference pointed out by the author he considered to depend upon the more highly organised vegetative portions of the fossils, and exogenous growth of the stems. Mr. Bentham insisted on the value of fruit characters for determining systematic position, and urged the desirability of employing subgeneric names for imperfectly determined forms.

SECTION D.—*Biological Science*—President, Prof. Rolleston, M.D., F.R.S.

The President delivered the following address:—

AMONGST the duties of the President of a Section the delivery of an Address has in these latter days somehow come to be reckoned, and that I may interpose myself for but as short a time as possible between your attention and the papers announced to you for reading upon your list, I will begin what I have to say without any further preface.

I wish first to make a few observations as to the kind of preparation which is indispensable, as it seems to me as a preliminary to an adequate and intelligent comprehension of the problems of biology; or, in other words, to an adequate and intelligent comprehension of the discussions which will take place in this room and in the two other rooms which will be assigned to, and occupied by, the departments of Ethnology and Anthropology, and that of Physiology Pure and Proper, and Anatomy.

Having made these observations, I propose, in the second place, to enumerate the subjects which appear likely to occupy prominent places in our forthcoming discussions; and thirdly, I will, if your patience allows me, conclude with some remarks as to certain of the benefits which may be expected, as having been constantly observed to flow from a due and full devotion to biological study.

In the first place, then, I wish to say that though the problems of biology have much of what is called general interest; that is to say, of interest for all persons, attaching to them, as indeed how could they fail to have, including as they do the natural history of our own and of all other species of living organisms, whether animal or vegetable; some special preparation must be gone through if that general interest is to be thoroughly and intelligently gratified. I would compare the realm of biology to a vast landscape in a cultivated country of which extensive views may be obtained from an eminence; but for the full and thorough appreciation of which, if necessary, the gazer should himself have cultivated some portion, however small, of the expanse at his feet. It is, of course, a matter of regret to think that persons can be found who look upon an actual landscape without any thought or knowledge as to how the various factors which make up its complex beauty have come to co operate; how the hand of man is recognisable here; how the dip of the strata is visible there; and how this alternation is detectable in another place as the potent agency in giving its distinctive features; but I take it that real and permanent, however imperfect, pleasure may be drawn from the contemplation of scenery by persons who are ignorant of all these things. I do not think this is the case when we here deal with *coup d'œil* views of biology. The amount of the special knowledge, the extent of the special training need not necessarily be great, but some such special knowledge and training there must be if the problems and argumentations familiar to the professed biologist are to be understood and grasped by persons whose whole lives are not devoted to the subject, so as to form for them acquisitions of real and vital knowledge.

The microscope has done very much, indeed I may say it has done almost all that is necessary for enabling all persons to obtain the necessary minimum of practical and personal acquaintance with the arrangements of the natural world of which I am speaking. The Glass trough used in Edinburgh, the invention of John Goodsir, whose genius showed itself, as genius often does show itself, in simple inventions, can be made into a miniature aquarium. I purposely use a word which calls up the idea of an indoors apparatus, wishing thereby to show how the means I recommend are within the reach of all persons; and in it, lying as it does horizontally and underlaid as it is by a condenser, animal and vegetable organisms can be observed at any and at all hours, and continuously, and with tolerably high magnifying powers even whilst undisturbed. Thus is gained an admirable field for the self-discipline in question. The microscope which should be used by preference for exploring and watching such an aquarium should be such an one as is figured in Gaskell's work on the Microscope (p. 58, fig. 36), as consisting of a stem with a stout steadying base, and of a horizontal arm some nine inches long, which can carry indifferently simple lenses or a compound body. I think of the two it is better that the aquarium should be horizontal rather than the microscope; and those who think with me in this matter can nevertheless combine for themselves the advantages of the horizontal position of the instrument with those of the horizontal position of the objects observed by modifying the eye-piece in the way figured by Quekett (p. 381, fig. 266.) It would be a long task to enumerate fully all the scientific lessons which may be gathered, firstly, and all the educational agencies, secondly, which may be set and kept in movement by a person who possesses himself of this simple apparatus. The mutual interdependence of the animal and vegetable kingdoms, their *solidarité* as the French have called it, and as the Germans have called it too, copying herein the French, is one of the first lessons the observer has forced upon him; the influence of physical and chemical agencies upon the growth and development of living beings he soon finds strikingly illustrated; the mysterious process of development itself is readily observable in the eggs of the common water-snails and in those of freshwater fish, so that the way in which the various organs and systems of organs are chiselled out, built up, and finally packed together and stratified can be taken note of in these yet transparent representatives of these great sub-kingdoms which all the while are undisturbed and at peace; and all these points of large interest are but a few of many which these small means will enable anyone to master for himself in the concrete actuality, and thoroughly. The necessity for carefulness and truthfulness in recording what is seen, the necessity for keeping in such records what one observes quite distinct from what one infers, the necessity for patience and punctuality, are lessons which, from having a moral factor as well as a scientific one in their composition, I may specify as belonging to the educational lessons which may be gathered from such a course of study.

I have been speaking of the microscope as an instrument of education, and I wish before leaving the subject to utter one caution as to its use when this particular object of education is in view. If a subject is to act educationally, it must be understood thoroughly; and if a subject is to be understood thoroughly, it must form one segment or stretch in a continuous chain of known facts. Ἀρκτέον ἀπὸ τῶν γνωρίμων, said one of the greatest of educators; you must start from some previously existing basis of knowledge, and keep your communications with it uninterrupted if your knowledge is not to be unreal. And my concrete application of these generalities is contained in the advice that no sudden jump be made from observations carried on with the naked eye to observations carried on with the highest powers of the microscope. I am speaking of the course to be pursued by beginners, and beginners we all were once, and if our places are to be filled, and filled they will be, by better men as we hope than ourselves, they will have to be filled, we also hope, by men who have yet to become beginners. It is in their interest I have been speaking, and I say that a beginner does not ordinarily get an intelligent conception of the revelations of the microscope except in Bacon's words, *Ascendendo continenter et gradatim*, by progressing gradually from observations with the naked eye through observations dependent upon dissecting lenses, doublets and triplets, and the lower powers of the compound microscope, up to observations to be made with the higher and highest magnifying powers.

Unless he ascend by gradations from organs and systems, structures and tissues and cells, his wonder and admiration at the results of the ultimate microscope analysis, of what he had but a moment before knowledge of only in the concrete and by the naked eye is likely to be but unintelligent.

There are three other agencies which can be set into activity with nearly as little trouble and difficulty as the simple apparatus of which I have just been speaking, and which will, like it, secure as a necessary preliminary discipline "*propädeutik*" for their rational comprehension of Biology. These are Local Museums, Local Field Clubs, and Local Natural Histories. Local authorities, persons of local influence, should engage and interest themselves in the starting into life of the two former of these agencies, and if some such person as Gilbert White could be found in each county to write the Natural History of its Selborne, I know not at what cost it could not be well to retain his services. As the world is governed upon each particular area of its surface, there is to be found a certain percentage of the population occupying it who have special calls for particular lines of study. It is the interest of each county to have such means and such institutions in being as will render it possible to detect the existence of persons gifted with such special vocations, to give the talent thus entrusted to them fair scope for development, and to render smaller the risk of their dying mute and inglorious. A young man who is possessed of a talent for Natural Science and Physical Inquiry generally, may have the knowledge of this predisposition made known to himself and to others, for the first time, by his introduction to a well-arranged Loca Museum. In such an institution, either all at once, or gradually, the conviction may spring up within him that this investigation of physical emblems is the line of investigations to which he should be content to devote himself, relinquishing the pursuit of other things; and then, if the museum in question is really a well-arranged one, a recruit may be thereby won for the first and growing army of physical investigators, and one more man saved from the misery of finding, when he has been taken into some other career, that he has somehow or other mistaken his profession, and made of his career one life-long mistake. Here comes the question. What is a well-arranged museum? The answer is, a well-arranged museum for the particular purpose of which we are speaking, is one in which the natural objects which belong to the locality, and which have already struck upon the eye of such a person as the one contemplated, are clearly explained in a well-arranged catalogue. The curiosity which is the mother of science is not awakened for the first time in the museum, but out of doors, in the wood, by the side of the brook, on the hillside, by scarped cliff and quarried stone; it is the function of the museum, by rendering possible the intellectual pleasure, which grows out of the surprise with which a novice first notes the working of his faculty of inspiration, to prevent this curiosity from degenerating into the mere woodman's craft of the gamekeeper, or the rough empiricism of the farmer. The first step to be taken in a course of natural instruction, is the providing of means whereby the faculties of observation and of verification may be called into activity; and the first exercise the student should be set down to is that of recognising in the actual thing itself, the various properties and peculiarities which some good book or some good catalogue tells him are observable in it. This is the first step, and, as in some other matters, *ce n'est que le premier pas qui coute.* And it need not cost much. There is a name familiar to Section D, and indeed not likely for a long while to be forgotten by members of the British Association generally, extrinsic means as well as the intrinsic merits of the well-loved man conspiring to keep his memory fresh among us, and the bearer of that name, Edward Forbes, has left it as his opinion that "It is to the development of the provincial museums that, I believe, we must look in future for the extension of intellectual pursuits throughout the land." (Lecture "On the Educational Uses of Museums," delivered at the Museum of Practical Geology and published in 1853. Cited by Toynbee, "Hints on the Formation of Local Museums," 1863, p. 46.) With the words of Edward Forbes I might do well to end what I have to say, but I should like to say a word as to the policy of confining the contents of a local museum to the natural-history specimens of the particular locality. No doubt the first thing to be done is the collection of the local specimens, and this alike in the interest of the potential Cuviers and Hugh Millers, who may be born in the district, and in the interest of the man of science who may visit the place when on his travels. But so long as a specimen from the antipodes or from whatever corner of our world be really valuable, and be duly catalogued before it is admitted into the museum, so that the lesson it has to teach may be learnable, I do not see my way towards advising that foreign specimens be excluded. It is to my mind more important that all specimens should be catalogued as soon as received, than that any should be rejected when offered.

I must not occupy your time further with this portion of my address. Let me first say that a person who wishes to know what a Field Club can do for its members, and not for them only, but for the world at large, will do well to purchase one, or any number more than one, of the Transactions of the Tyneside Naturalist's Field Club; and that if there be any person who thinks that White's Selborne relates to a time and place so far off that there can be no truth in the book, and who yet would like to try upon himself the working of the fourth disciplinary agencies of which I have spoken; that, namely, of sending some Local Natural History on the spot of which it treats, and comparing it with the things themselves *in situ*, let him repair to Weymouth, and work and walk up and down its cliffs and valleys with Mr. Darwin's book in his hands.

I shall not be suspected in this place and upon this occasion, nor, as I hope, upon any other, of a wish to depreciate the value of scientific instruction as an engine for training the mind. But neither, on the other hand, should I wish to depreciate the value of literary culture, my view of the relations of these two gymnastics of the mind being the very simple, obvious, and natural one that they should be harmoniously combined—

Alterius sic
Altera sic poscit opem vis, et conjuvat amice.

I know it may be said that there are difficulties in the way, and especially practical difficulties, but I have always observed that people who are good at finding out difficulties, and especially practical difficulties, are like people who are good at finding out excuses,—good at finding out very little else. The various ways of getting over these difficulties are obvious enough, and have been hinted at, or fully expressed by several writers of greater or less authority on many occasions. It is, however, of some consequence that I should here say what I believe has not been said before, namely, that a purely and exclusively literary education imperfect and one sided, as it is, is still a better thing than a system of scientific instruction (to abuse the use of the word for a moment) in which there should be no courses of practical familiarising with natural objects, verification, and experimentation. A purely literary training, say, in dialectics, or what we are pleased to call logic, to take a flagrant and glaring instance first, does confer certain lower advantages upon the person who goes through it without any discipline in the practical investigation of actual problems. By going through such a training attentively, a man with a good memory and a little freedom from over-scrupulousness, can convert his mind into an arsenal of quips, quirks, retorts, and epigrams, out of which he can, at his own pleasure, discharge a mitraille of chopped straw and chaff-like arguments, against which no man of ordinary fairness of mind can, for the moment, make head. It is true that such sophists gain this dexterity at the cost of losing, in every case, the power of fairly and fully appreciating or investigating truth; of losing in many cases the faculty of sustaining and maintaining serious attention to any subject; and of losing in some cases even the power of writing. A well-known character in an age happily, though only recently, gone by, who may be taken as a Cæsar worthy of such Antonies, used to speak of a pen as his torpedo. Still they have their reward, they succeed now and then in convincing juries, and they are formidable at dinner tables. It would not be fair, however, not to say that a purely literary training can do much better things than this. By a purely Classical Education a man, from being forced into seeing and feeling that other men could look upon the world, moral, social and physical, with other (even if not with larger) eyes than ours, attains a certain flexibility of mind which enables him to enter into the thoughts of other and living men, and this is a very desirable attainment. And, finally, though I should be sorry to hold with a French writer that the style makes the man, the benefit of being early familiarised with writings which the peculiar social condition of the classical times, so well pointed out by De Tocqueville (*De la Démocratie en Amérique*), conspired and contributed not a little to make models of style, is not to be despised. Such a familiarity may not confer the power of imitating or rivalling such compositions, but it may confer the power of appreciating their excellences, the one power appearing to us to be analogous to the power of the experimenter, and the other to that of the pure observer in Natural Science; and we should undervalue neither.

Masters of Science, it must be confessed, are not always masters of style; let not the single instance of last night tempt you to generalise, it was but a single instance, the writings of the man whom we in this Section are most of us likely to look upon as our master in Science have been spoken of by our President in his recently published volume as "intellectual pemmican;" and if scientific reading and teaching is to be divorced from scientific observation of natural objects and processes, it is better that a man, young or old, should have in his memory something which is perfect of its kind, entire and unmutilated, such as the opening of sentences of the *Brutus* of Cicero, which Tacitus, I think, must have had in his memory when he wrote his obituary of Agricola, or as the opening sentences of the *Republic* of Plato, or the conclusion of the *Ajax* or Sophocles, than that he should have his memory laden with a consignment of scientific phrases which *ex hypothesi* have for him no virtual reality. I have already said that I am strongly of opinion that literary should always be combined with scientific instruction in a perfect educational course; these somewhat lengthy remarks refer therefore only to systems in which it is proposed that we should have not only a bifurcation but a radical separation of studies and students, and the moral of this may be summed up by saying that a purely scientific education must be a thoroughly practical one, familiarising the student with actual things as well as with words and symbols. It was upon the solid ground that Antæus learnt the art of wrestling, it was only when he allowed himself to be lifted from it that he was strangled by Hercules.

Coming now to the second part of my address, I beg to say that the word Biology is at present used in two senses, one wider, the other more restricted. In this latter sense the word becomes equivalent to the older, and till recently more currently used word "Physiology;" it is in the wider sense that the word is used when we speak of this as being the section of Biology; and this wider sense is a very wide one, for it comprehends animal and vegetable Physiology and Anatomy, firstly; Ethnology and Anthropology, secondly; and thirdly, Scientific Zoology and Classificatory Botany, inclusively of the Distribution of Species. It may have been possible in former times for a single individual of great powers of assimilation to keep himself abreast of, and on a level with, the advance of knowledge along all these various lines of investigation; but in those times knowledge was not, and could not, owing to difficulties of intercommunication, the dearness of books, the costliness or the non-existence of instruments, have been increased at the rate at which it is now being, year by year, increased; and the entire mass of actually existing and acquired knowledge was of course much smaller, though man's power of mastering it was no smaller than at present. It would now be an indication of very great ignorance in anybody which should pretend that his own stock of information could furnish him with something in each one of the several departments of knowledge I have just mentioned, which should be worthy of being laid before such an assembly as this. As will have been expected, I shall not presume to do more than glance at the vegetable kingdom, large as is the space in the landscape of life which it makes. What I do propose to do is merely to draw your attention to a very few of the topics of leading interest, which are at the present moment being, or rather will shortly begin to be, discussed by experts in the Department of Physiology and Anatomy; in the Department of Ethnology and Anthropology; and thirdly, in the Department of Scientific Zoology.

Under the head and in the Department of Physiology Proper and Anatomy, our list of papers and, I am happy to add, the circle of faces around us suggests to us the following subjects as being the topics of main interest for the present year: the questions of Spontaneous Generation; that of the influence of organised particles in the production of disease; that of the influence of particular nervous and chemical agencies upon functions; that of the localisation of cerebral functions; that of the production and indeed of the entire *role* in the economy of creation of such substances as fat and albumen; and, finally, that of the cost at which the work of the animal machine is carried on.

The question of Spontaneous Generation touches upon certain susceptibilities which lie outside the realm of science. In this place, however, we have to do only with scientific arguments, and I trust that the Section will support the Committee in their wish to exclude from our discussions all extraneous considerations. Truth is one; all roads which really lead to it will assuredly converge sooner or later; our business is to see that the one we are ourselves concerned with is properly laid out and metalled.

Upon this matter I am glad to be able to fortify myself by two authorities; and first of these I will place an utterance of Archbishop Whately, which may be found in the second volume of his Life, pp. 66–68, æt. 57, an. 1844. "A person possessing real faith will be fully convinced that whatever suppressed physical fact appears to militate against his religion will be proved by physical investigation either to be unreal or else reconcilable with his religion. If I were to found a church, one of my articles would be that it is not allowable to bring forward Scripture or any religious considerations at all to prove or disprove any physical theory or any but religious and moral considerations." My second quotation shall be taken from the great work of one of the first, as I apprehend, of living theologians, John Macleod Campbell, "The Nature of the Atonement," pp. xxxii.–xxxiii. Introd., and it runs thus:—There are "other minds whose habits of pure scientific investigation are to them a temptation to approach the claim of the Kingdom of God on our faith by a wrong path, causing them to ask for a kind of evidence not proper to the subject, and so hindering their weighing fairly what belongs to it. No scientific study of the phenomena which imply a reign of law could ever have issued in the discovery of the kingdom of God. But neither can it issue in any discovery which contradicts the existence of that kingdom; nor can any mind in the light of the kingdom of God hesitate to conclude that if such seeming contradictions arise there is implied the presence of error either as to the facts or as to conclusions from the facts." These are valuable words and weighty testimonies. But in a matter of this importance one must not forbear to point out what may seem to be wanting even in the dicta of such men as the two I have quoted. Neither of them have allowed the possibility of error attaching itself to the utterances of more than one of the two parties in such issues as those contemplated. Neither appears to have thought of the cases in which religious men, if not theologians, have brought war on the world because of the offences they have with ill-considered enunciations created. And, whilst fully sympathising with all that the Archbishop and Mr. Campbell have said, I must say that they appear to me to have left something unsaid, and this something may be wrapped up in the caution that there may be faults on both sides. But at any rate this Section cannot be considered a fit place for the correction of errors save of the physical kind; and all other considerations are for this week and in this place extraneous. In some other week or in some other place it will be, if it has not already been, our duty to give them our best attention.

To come now to the kind of considerations which are the proper business of Section D, let me say that for the discussion of the question of Spontaneous Generation very refined means of observation, and, besides these, very refined means of experimentation, are necessary. And I shall act in the spirit of the advice I have already alluded to as given to the world by one of her greatest teachers, if I put before you a simple but a yet undecided question for the solution of which analogous means of a far less delicate character would appear to be, but as yet have not proved themselves to be, sufficient. Thus shall we come to see very plainly some of the bearings, and a few of the difficulties, of the more difficult of the two questions. What an uneducated person might acquiesce in hearing spoken of as Spontaneous Generation, takes place very constantly under our very eyes, when a plot of ground which has for many years, or even generations, been devoted to carrying some particular vegetable growth, whether grass or trees, has that particular growth removed from it. When such a clearing is effected, we often see a rich or even a rank vegetation of a kind previously not growing on the spot spring up upon it. The like phenomenon is often to be noted on other surfaces newly exposed, as in railway cuttings and other escarpments, and along the beds of canals or streams, which are laid bare by the turning of the water out of its channel. Fumitory, rocket, knotgrass, cowgrass, *Polygonum aviculare*, and other such weeds, must often have been noted by every one of us here in England as coming into and occupying such recently disturbed territories in force; whilst in America the destruction of a forest of one kind of wood, such as the oak or the chestnut, have often been observed to be followed by an upgrowth of young forest trees of quite another kind, such as the white pine, albeit no such tree had been seen for generations growing near enough to the spot to make the transport of its seeds to the spot seem a likely thing. In one case referred to by Mr. Marsh, the hickory, *Carya porcena*, a kind of walnut, was remarked as succeeding a displaced and destroyed plantation of the white pine. Now the advocates of Spontaneous Generation must not suspect me of hinting that there is any question, except in the minds of the grossly ignorant, of the operation of any such agency as spontaneous generation here; no one would suggest that the seeds of the *Polygonum aviculare*, to say nothing of those of the Hickory, were produced spontaneously; but what I do say is, that the question of how those seeds came there is just the very analogue of the one which they and their opponents have to deal with. And it is not definitely settled at this very moment. Let us glance at the instructive historical parallel it offers. For the very gross and palpable facts of which I have just spoken there are two explanations offered in works of considerable authority. The one which has perhaps the greatest currency and commands the largest amount of acceptance is the one which, in the words of De Candolle, regards *la couche de terre végétale d'un pays comme un magazin de graines*, and supposes that in hot summers and autumns, such as the present, the fissures in the ground, which have proved so fatal this year to the young partridges, swallow up a multitude of seeds, which are restored again to life when the deep strata into which they are thus introduced, and in which they are sealed up as the chasms close up, come in any way to be laid open to the unimpeded action of the sun and moisture. Squirrels, again, and some birds resembling herein the rodent mammalia, bury seeds and forget to dig them up again; and it is supposed that they may bury them so deep as to be protected from the two physical agencies just mentioned. Now Germination cannot take place in the absence of oxygen, and I would add that well-sinkers know to their cost how often the superficial strata of the earth are surcharged with carbonic acid. The rival explanation and the less popular—I do not say the less scientific—looks to the agency of transportation as occurring constantly, and sufficing to explain the facts. By accepting this explanation, we save ourselves from running counter to certain experiments, some of which were carried out, if I mistake not, under the auspices of this Section (see British Assoc. Reports), and which appear to curtail considerably the time during which seeds retain their vitality, and to multiply considerably the number of conditions which must be in force to allow of such retention for periods far shorter than those which have to be accounted for. A better instance of the expediency of checking the interpretations based merely upon observations however accurately made by putting into action experiments, cannot be furnished than by recording the fact put on record by Mr. Bentham, when discussing this question in his last year's address to the Linnæan Society.

"Hitherto direct observation has, as far as I am aware, only produced negative results, of which a strong instance has been communicated to me by Dr. Hooker. In deepening the lake in Kew Gardens, they uncovered the bed of an old piece of water, upon which there came up a plentiful crop of *Typha*, a plant not observed in the immediate vicinity; and it was therefore concluded that the seed must have been in the soil. To try the question, Dr. Hooker had six Ward's cases filled with some of the soil remaining uncovered close to that which had produced the *Typha*, and carefully watched; but not a single *Typha* came up in any one of them." (Note in President's address May 24th, 1869, page 72 of Linnæan Society's Proceedings.)

To this I would add that experiments with a positive result, and that positive result in favour of the second hypothesis, if hypothesis it can be called, are being constantly tried in our colonies for us, and on a large scale. I had taken and written here of the *Polygonum aviculare*, the "knot" or "cowgrass"—having learnt on the authority of Dr. Hooker and Mr. Travers (see Natural History Review, January 1864, p. 124, Oct. 1864, p. 619), that it abounds in New Zealand, along the roadside, just as it does in England—as a glaring instance, and one which would illustrate the real value of the second explanation even to an unscientific man and to an unassisted eye. But on Saturday last I received by post one of those evidences which make an Englishman proud in thinking that whithersoever ships can float thither shall the English language, English manners, and English Science be carried, in the shape of the second volume of the Transactions of the New Zealand Institute, full like the first, from beginning to the last page with thoroughly good matter. In that volume, having looked at its table of contents, I turned to a paper by Mr. T. Kirk on the Naturalized Plants of New Zealand, and in this, at p. 142, I find that Mr. T. Kirk prefers to regard the *Polygonum aviculare* of New Zealand as indigenous in New Zealand. Hence that illustration which would have been a good one falls from my hands. And I must in fairness add, that because one agency is proved to be a *vera causa*, it is not thereby proved that no other can by any possibility be competent simultaneously to produce the same effect, whatever the Schoolmen with the law of Parsimony ringing in their ears may have said to the contrary. I have dwelt upon this subject at this length with the purpose of showing how much difficulty may beset the settlement of even a comparatively simple question which involves only the use of the unassisted eye, or at most of a simple lens. The *a fortiori* argument, I leave you to draw for yourselves with the simple remark, that the question of Spontaneous Generation is now at least one to be decided by the microscope, and by the employment of its highest powers in alliance with other apparatus of all but equal complexity.

We come, in the second place, to say a word as to the extent of the influence which organic and living particles, of microscopic minuteness but solid for all that, have been supposed, and in some instances at least have been proved, to exercise upon the genesis and genesiology of disease, and so upon the fortunes of our race, and our means for bettering our condition, and that of our fellows. I need not refer to Dr. Sanderson's valuable Report (just published in the Privy Council's Medical Officer's Blue Book, Twelfth Report, 1870, p. 229, upon those contagion particles which he proposes to call by the convenient name, slightly modified from one invented by Professor Bichamp, of Microzymes; for Dr. Sanderson is here to refer to the matter for himself and for us; and when this meeting is over we shall all do well to lay to heart what he may tell us here and now, and besides this, to study his already printed views upon the matter. It may be perhaps my business to remind you that these views, so far as they are identical with Professor Halliers' as to the importance of those most minute of living organisms, the micrococcus of his nomenclature, the microzymes of Mr. Simon's Blue Book, were passed in review as to their botanical correctness by a predecessor of mine in this honourable office—namely, by the Rev. J. M. Berkeley, at the meeting held two years ago at Norwich; and that some of the bearings of the theory and of the facts, howsoever interpreted, upon the Theory of Evolution, were touched upon by Dr. Child in his interesting volume of Physiological Essays, p. 148, published last year. It would not perhaps be exactly my business to express my dissent from any of these results or views put forward by any of these investigators I have mentioned; but I wish to point out to the general public that none of these inquirers would affirm that the agencies shown by them to be potent in the causation of certain diseases were types and models of the agencies which are, did we but know it, could we but detect them, potent in the causation of all diseases. Many diseases, though possibly enough not the majority of the strictly infectious diseases, are due to material agents quite distinct in nature from any self-multiplying bodies, cytoid or colloid. To say nothing of the effects of certain elements—and elements, it will be recollected, in their singleness and simple atomicity have, as the world happens to be constituted and governed, never been honoured with the office of harbouring life—which when volatised, as mercury, arsenic, and phosphorus may be, or indeed which, when simply dissolved, may be most ruinous to life, there are, I make no doubt, animal poisons produced in and by animals, and acting upon animal bodies which are neither organised nor living, neither cytoid nor colloid. Dr. Charlton Bastian is not likely to underrate the importance of such agents, howsoever produced, in the economy, or rather in the waste, of Nature, yet from his very careful record of his own very closely observed and personal experience we can gather that he would not demur to conceding that non-vitalised, however much animalised, exhalations may be only too powerful in producing attacks, and those sudden and violent and fever-like attacks, of disease. Dr. Bastian tells us (Phil. Trans. for 1866, vol. 196, pt. ii. pp. 583-584) that whensoever he employed himself in the dissection of a particular nematoid worm, the *Ascaris megalociphala*, he found occasion to observe, and that in himself, and very closely, the genesiology of a spasmodic and catarrhal affection, not unlike hay-fever as it seems to me, but under circumstances which appear to preclude the possibility of any living organisms being the cause of it as they have been supposed, and by no less an authority than Helmholtz, to be of the malady just mentioned. For in Dr. Bastian's case this affection was produced, not only when the *Ascaris megalocephala* was dissected when fresh, but "after it had been preserved *in methylated spirit for two years, and even then macerated in a solution of chloride of lime for several hours before it was submitted to examination.*" Could any microzyme or megalozyme have survived such an amount of antizymotic treatment—such a pickling as this? This is not exactly a medical association, and I have entered upon this discussion not altogether without a wish to show how subjects of apparently the most purely scientific and special interest, as Mycology and Helminthology, the natural history, that is to say, and the morphology of the lowest plants and of the lowest vermes, may come when we least expect it, come or be brought to bear upon matters of the most immediate and pressing practical importance. And in this spirit I must say a word upon the way in which the pathology of snake-bites bears upon the matters I have been speaking of, and the extent of the debt which practical men owe to such societies as our Ray Society, and to such publications as their colossal volume on the snakes of India, in which Dr. Günther's views as to the real history of the striking and terrible yet instructive phenomena alluded to, are combined ("Snakes of India," Ray Society, 1864, p. 167). That the snake-poison is an animal poison is plain enough; that it is fatal to men and animals everybody knows; but I rather think that these two facts relative to it are not equally notorious, rich in light though they be, viz., that the potency of this particular animal poison varies in direct ratio to the quantity imbibed or infused, just as though it were so much alcohol, or so much alcoholic tincture of musk or cantharides; or secondly, that its potency varies in direct ratio to another varying standard, viz., the size of the animal producing it. Now, the vaccine matter from the arm of a child is as potent as the vaccine matter from the arm of any giant might be, if such a large creature could in these days escape the operation of the vaccination laws; and whether a grain or a gramme of it be used, will make no difference, so long as it be used rightly. There is a contrast indeed between the *modus operandi* of these two animal poisons. I would add that in the Edinburgh *Monthly Medical Journal* for the present month there is a very valuable paper, one of a series of papers, indeed, of the like character, by Dr. Fayrer, where at page 247, among much of anatomical and other interest, I find the following important statement:—"This poison may be diluted with water, or even ammonia or alcohol, without destroying its deadly properties. It may be kept for months or years, dried between slips of glass, and still retain its virulence. It is capable of absorption through delicate membranes, and therefore it cannot be applied to any mucous surfaces, though no doubt its virulence is much diminished by endosmosis.* It appears to act by a catalytic form; that is it kills by some occult influence on the nerve centres." There is such a thing as an ignorance which is wiser than knowledge, *for the time*, of course, only; such an ignorance is wisely confessed to in these words of Dr. Fayrer's:—An explanation may be true for some, yet not thereby necessarily for all, the facts within even a single sphere of study, even a true explanation may have but a very limited application, as a tangent cannot touch a circle at more than a single point. The memoirs, published in our own reports by Dr. R. W. Richardson, on the action of the nitrites, and those published by Dr. A. Crum Brown and Dr. Fraser, there and elsewhere, on the connection between chemical constitution and physiological action, deserve especial study as bearing on the other side of this discussion; whilst Prof. Lister's papers show how the reference of certain diseases to inhalistic agencies may become o most useful importance in practice. There exists, as is wel known, a tendency to involve all Physiological into Physico-chemical phenomena; undoubtedly many have been, and some more may still remain, to be so ordered, but the public may rest assured that in the kingdom of Biology no desire for a rectification of frontiers will ever be called out by any such attempts at, or successes in the way of, encroachment; and that where physics and chemistry can show that physico-chemical agencies are sufficient to account for the phenomena, there their claim upon the territory will be acceded to, as in the cases we have been glancing at; and where such claims cannot be established and fail to come up to the quantitative requirements of strict science, as in the cases of continuous and of discontinuous development or self-multiplication of a contagious germ, and in some others, they will be disallowed.

(*To be Continued.*)

SECTION E.—*Geographical Science.*—Sir Roderick Murchison, K.C.B., F.R.S., President.

In opening his address, after alluding to the more recent geographical discoveries which had been made, and to the geographical expeditions now in progress in Asia and Africa, and of which a much fuller account is to be found in his recent address to the Geographical Society, the President passed on to the subject of Deep Sea Soundings and their relation to Geology. Here he said he dissented most strongly from the views held by Dr. Carpenter and others, that in a broad sense we may be said to be in the Cretaceous epoch, since so many of the marine forms met with were similar to, if not identical with, those which lived at that time. Thus he says, "May we not indeed by a similar bold hypothesis affirm that we still live in the older Silurian period? for albeit no bony fishes then existed, many globigerinæ and creatures of the lowest organisation have been found in these old rocks associated with terebratulidæ and dingulæ, the *generic* forms of which still live." Surely we need not point out to Sir Roderick Murchison that *generic* forms are one thing and *identical species* another, and that whilst the former are evidence of *similarity of condition*, the latter are evidence of *persistency of conditions.* From this Sir Roderick passed to the subject of the Physical Geography of the Ocean, and paid a great compliment to the valuable work lately published by Mr. J. K. Laughton, on "Physical Geography in its Relation to the Prevailing Winds and

* Diapedesis may account for what virulence remains, and the poison may therefore possibly be a cytoid.

Currents;" and after referring to the various papers about to be read to the Section, he concluded his address by expressing his conviction, founded on all recent information, that Dr. Livingstone was alive and amongst friendly natives, and that Sir Samuel Baker would shortly meet him with fresh stores of provisions, &c.

SECTION F. —*Economic Science.*—President, Prof. W. Stanley Jevons.

In the President's address, which was of some length, after some introductory remarks, tending to show that the Economic Section has to deal with a class of subjects capable of strictly scientific treatment, and that the social are the necessary complement to the physical sciences, Professor Jevons proceeded to state that in this kingdom during the last thirty or forty years we had tried a mighty experiment, and to a great extent had failed. The growth of the arts and manufactures and the establishment of free trade had opened the widest means of employment, and brought an accession of wealth previously unknown; the frequent remission of taxes had left the working classes in fuller enjoyment of their wages; the poor laws had been reformed and administered with care, and the emigration of millions might well have been expected to leave room for those that remained. Nevertheless within the last few years we had seen pauperism almost as prevalent as ever, and the slightest relapse of trade threw whole towns and classes of people into a state of destitution little short of famine. This state of things was exactly what Malthus would have predicted of a population which, while supplied with easily earned wealth, is deprived of education and bribed by the mistaken benevolence of the richer classes into a neglect of the future. We now had an Education Act, but this ought not to withdraw attention from many other causes of evil still existing in full force. Amongst these was the mistaken humanity of charitable people. The amount extended by the upper to the lower classes was almost incredible; but it did more harm than good. The helpless poor were most numerous precisely in those towns where charitable people and institutions most abounded. But far worse than private charity were the innumerable small charities established by the bequests of mistaken testators. It would be well worthy of Mr. Goschen's attention whether all such charities might not be transferred to the care of the guardians of the poor, so as to be brought under the supervision of the Poor Law Board, and distributed in accordance with sound principles. The State, which undertook the ultimate support of the poor, was bound to prevent its own efforts to reduce pauperism from being frustrated, as they are at present. As regards medical charities, Professor Jevons said no one could for a moment propose to abolish hospitals and numerous institutions absolutely necessary for the relief of accidental suffering; but no working man was solvent who did not lay aside so much of his wages as would meet the average amount of sickness falling to the lot of the man and his family. So it was not easy to determine this amount. There were or might be sick clubs which would average the inequalities of life. Hospitals need not be self-supporting, and in cases of severe and unforeseen suffering they might give the most lavish aid; but they ought not to relieve slight and ordinary disease without a contribution from those benefited. With respect to the Poor Law medical service, every one admitted that where medical aid is given it ought to be good and sufficient; but, on the other hand, the better we make that service the more do we tend to increase and perpetuate that want of self-reliance and providence which is the crowning defect of the poorer classes. In this and many other cases we ought to regulate our humane impulses by a stern regard to the real results of our actions. Referring to the financial policy of the kingdom, Professor Jevons pointed out that in Cobden's sense free trade is now actually achieved. For the future the remission of customs duties would be grounded on other motives than it has often been in the past. It was a mistake to suppose that foreign trade ought to be encouraged before everything else. The internal trade and industry of the country were at least equally deserving of attention, and it might be that there were stamp duties, licence duties, rates, and other taxes which, in proportion to the revenue they returned, did far more injury than any customs duties now remaining. The question of local taxation was one which especially required attention. The amount raised by local rates was more than equal to the whole of the customs duties; nevertheless they continued to be levied substantially according to an Act passed in the reign of Queen Elizabeth. There was sure to be a continuous increase of local taxation. Turning to the question of surplus revenue, Professor Jevons said that there probably now existed no grievous pressure of taxation, and no considerable inequality as regards the several classes of the people. He calculated that average families spending 40*l.*, 85*l.*, and 500*l.* a year, consuming moderate quantities of tobacco and spirituous liquors, all paid about 10 per cent. of their income in general or local taxation. Only the taxation of the middle classes was mostly unavoidable, whereas at least half the taxation of the poorer classes depended upon the amount of tobacco and spirituous liquors consumed. The present incidence of taxation, therefore, was such that it seemed inexpedient to proceed further in the reduction of the customs and excise duties. To do so would be to throw the whole cost of Government upon the wealthier classes, and especially those who have tangible property. Besides, when really hurtful taxes were removed, the working classes were not sufficiently temperate and educated to render it certain that the further remission of taxes would lead to the profitable expenditure of income. The true channel for surplus revenue was the reduction of the national debt. The wars at the commencement of this century had secured for us fifty years or more of nearly unbroken peace, and yet at the end of this period of ever-advancing wealth the great debt stood almost at the same figure as at the beginning. We enjoyed the peace and left our descendants to pay its cost. If it was said that this country is now far wealthier and better able to endure the annual charge of the debt than ever before, it must be remembered that the expense of war is also grtealy increased. In a great war we should now have to incur an expenditure of hundreds of millions, or else relinquish our prominent position. In dealing with the subject of the excessive mortality in great towns, Prof. Jevons expressed his surprise that more attention had not been drawn to the probable influence of a poor Irish population in raising the death-rate. According to the census returns of 1861, the unhealthy towns of Liverpool, Manchester, Salop, Glasgow, Dundee, &c., were all distinguished by possessing a large Irish population, whereas the healthy towns of London, Birmingham, Bristol, Hull, Aberdeen, &c., had less than 7½ per cent. of adult Irish residents. Sheffield was the only remarkable exception to this indicated. Prof. Jevons referred to the approaching census of 1871, as likely to afford many data for the investigations of economists, and insisted that it ought to be taken in as nearly as possible a uniform manner in all the three parts of the United Kingdom. He also directed attention to the copious and excellent statistical publications now provided by Government; referred to the efforts which were being made, previous to the present war, to facilitate the adoption of an international currency; and concluded with some remarks on the transference of the telegraphs to Government control. Many people looked forward to the time when the uniform cost of a telegram would be 6*d.*; but such a reduction of the rate, by bringing an increase of work, would greatly augment the expenses of the department, and inflict a loss upon the nation.

THURSDAY, SEPTEMBER 29, 1870

HOUSE ACCOMMODATION FOR LEARNED SOCIETIES

THE movement which originated with the Statistical Society about three months ago for bringing under the shelter of one roof various learned societies of the metropolis, has already made that progress which gives the best assurance of ultimate success.

The "Learned Societies' Accommodation Committee" is at present constituted by delegates from the under-mentioned bodies:—The Anthropological Society; the British Archæological Association; the East India Association; the Ethnological Society; the Institute of Actuaries; the Iron and Steel Institutes; the Juridical Society; the Meteorological Society; the Photographic Society; the Royal Colonial Institute; the Society of Arts; the Social Science Association and Law Amendment Society; the Statistical Society; and the Victoria Institute.

Each of these Societies is represented on the Committee by one delegate. The President of the Statistical Society, Mr. Newmarch, has been chosen chairman, but as this Society had already a delegate, the Chairman has no vote, otherwise the Society would have two voices at the Board, while the others were restricted to one each.

The Committee reserve to themselves the "power to add representatives from other learned Societies." By this resolution the combining societies may be increased, and probably will be, as the scheme approaches nearer accomplishment.

One body named in the list above has so large a fellowship, and so wide a scope in its objects, that its wants are consequently great and peculiar. The Society of Arts is likely to need house room in, we believe, a year or two. This society, Mr. Le Neve Foster remarks, would require "all the room we have at present and something more." When their extensive premises in the Adelphi are brought to mind, it is at once felt that Mr. Foster's society stands apart by the magnitude of its essential wants from all the others just named. To a certain degree the needs of the Society of Arts do not accord with the humbler demands of the other societies. The latter may be housed in a moderately capacious building, with a common meeting room or theatre, capable of accommodating from 150 to 200 members. Hence, these smaller scientific bodies offer a much easier undertaking to organise and manage. In London the difficulties of obtaining an appropriate site are enormously multiplied by any large increase of required frontage. On the other hand, the union of the Society of Arts with the other learned bodies presents the opportunity of a bolder enterprise. A comprehensive project for lodging all the London societies lacking house-room in one mansion is, doubtless, an attractive idea to many minds. Thus, it would appear at first sight, that, under these circumstances, two courses emerge: a moderate plan, with proximate execution, for the smaller societies; a grander scheme, with, in all probability, indefinitely remote accomplishment.

The Committee have avoided, by the unanimous resolutions of the 1st July, any conflict between these views. They have resolved in effect:

1. That convenient and permanent accommodation should be provided in a distinct building for societies that do not require extensive museums and libraries.
2. That the Committee express their earnest desire to co-operate with societies requiring larger accommodation for libraries and museums, either by "a combined application to Government for a site or building, or by joint action for the purchase of a convenient site."

The Committee think that if the wider co-operation spoken of in the second resolution should be successful, the plan for the smaller societies "may be either treated as a separate block in an associated group of buildings, or as a constituent part of one large building."

The Committee have taken the necessary step of giving instructions for the preparation by a competent architect of sketch plans and the elevation of a building adapted to the requirements of the smaller societies. These plans, it is understood, will be laid before the Committee when it re-assembles in October. Further, the Committee determined that the first subject for consideration at their next meeting "be the appointment of one or more of its members to represent its view and wishes to *The Aid to Science Commission*."

If, eventually, only the smaller scheme be adopted, it is thought the cost of the whole building and the purchase of the site could be compassed by an outlay which would offer no pecuniary impediment. In the absence, however, of working plans any stated sum can only be regarded as roughly approximate. The site itself may prove a business not so easily dealt with. Position is a matter of such precious importance to the utility of the undertaking that it is not likely to be undervalued—success or failure very much hangs upon the local habitation.

The proceedings of the committee seem to have been thus far, prompt and business-like. We have no doubt, therefore, that their efforts to economise the resources, and thereby augment the utility of the scientific societies of the metropolis, will speedily bear good fruit.

THE BERLIN WORKING MEN'S CLUB

FOR some years past there has been carried on at Berlin a Working Men's Club (for so it seems best to translate *Der Berliner Handwerker Verein*), established, we are told in its Reports, by working men and friends of labour, in order to promote general culture, sound technical knowledge, and good manners, among its members. This it attempts to do by means of popular lectures, classes for serious instruction, gymnastics, a library and reading-room well stocked with books and journals, concerts and social gatherings, or pleasure parties in which the wives and children of members take part. In many respects it resembles our own Mechanics' Institutes and Working Men's Clubs; but there are several features deserving special attention.

Not the least noteworthy point about it is its success. The average number of members at any one time is about 4,000, of whom nine-tenths at least are *bonâ fide* working men; but owing to the migratory habits of the German artizans, no less than 10,000 names are placed on their books every year. Well worthy of attention is the essentially democratic nature of the constitution and management. It is founded on the principle of self-help;

every man over 17 years of age, and unconvicted of crime, is eligible for membership, and after election continues to be a member so long as he pays his three silver groschen (somewhat less than 4*d.*) every month. The affairs are not conducted *for* the members by the philanthropic nobility, clergy, and gentry of the place, but *by* the members, through a representative assembly chosen annually, two-thirds at least of whom must be engaged in trade, and through a triennial committee, two-thirds of whom must also be engaged in trade. There is also a president, with vice-presidents, and a teacherhood, chosen either directly or indirectly by the members.

Yet in spite of, or rather perhaps because of, this working of self-help, they are enabled to enrol among their members, and receive active support from, the best and most active minds of Berlin. The leading professors of the University, the energetic young literary and scientific men of the city, the chief men of industry and commerce, all come forward to help them; and in their lists of popular lectures we find many names of European reputation.

The lectures, free to all members, and delivered in the club building, are intended to stir up the minds of the members to what is going on around them; while all those who are alert to the value of knowledge have access, on the payment of a small fee, to classes in which such subjects as reading, writing, arithmetic, geometry, mechanics, book-keeping, &c. &c., are taught in a thoroughly earnest and business-like manner. There are, besides, technical practical classes in construction and architecture; and the managers, having very definite views about play and work, take the greatest care that the musical and social gatherings shall be eminently successful in giving delight, and helpful in building up those "good manners" which are so desirable.

Then again, it is thoroughly catholic in spirit. It belongs to no religious or anti-religious party, advocates no political views, democratic, socialistic, or conservative; and, in fact, has no shibboleth of any kind whatever. It does not try to introduce serious learning and sound knowledge under false pretences. It does not call its members together to hear music, and then give them the stones of science. Every one can do as he likes. If he desire solid knowledge, there it is. If he care only for music or for a promenade, he can listen to the very best of the former, and walk about on fixed days among a crowd of comrades, all bent on pretending to be happy. He may, if he like, take out the whole of his monthly three groschen worth in abundant exercise on the parallel bars. So long as in any wholesome way the heavy burden of the artizan's daily life is lessened, and his dull life lighted up, the club thinks that it has in a measure accomplished its ends.

We imagine that most of our readers have read the article by Mr. James Stuart in No. 3 of NATURE, and they who have any experience of English workmen will, we venture to think, agree with nearly all that is there laid down. Putting together the burden of that article and the Report of this Berlin Working Men's Club, the question naturally suggests itself, Could we not in England do as much and a great deal more than is done in Berlin? It is one of the qualities of science, that he who has any is always anxious to give to others; and there surely could be no difficulty in establishing in London and in other large cities scientific teacherhoods willing to hold out the right hand of fellowship to all working men's clubs which were felt to be really acting on the principle of self-help.

There are many excellent and flourishing working men's clubs in London and elsewhere, and more than one working men's college. But we believe we are not going beyond the truth in stating that they lack the catholicity of the Berlin society. They are not all free from the suspicion of *arrière pensée* of some kind or other. Moreover, as separate institutions they tend to distract efforts, and cannot make a united appeal to the whole body of scientific men; while some of them at least are worked from above, the principle of dependence being more conspicuous than that of self-help. And so it comes to pass that those who are eager for knowledge have to struggle on without the counsel which they might otherwise share, often drawing their truth from wells by no means undefiled, and the dull unawakened multitude but rarely hear the voices which might rouse them from their sleep, and which now are wasted on the listless ears of fashionable audiences.

It is true that our scientific men are burdened far more than their German brethren with work undertaken for the sake of getting their daily bread, and for that alone; and so far unremunerative labour is to them a double task. But we have no doubt that, in spite of this, many would be led to come forward by the strong convictions they have that the welfare of their countrymen and their country is tottering for the lack of knowledge. By means of a little organisation, in which our artizans are pre-eminently skilled, much work might be got out of such teacherhoods, with the least possible wear and tear. They might deliver occasional lectures both for instruction and for rousing attention; but their chief use would be to advise the various clubs in their more serious work of class instruction, directing their studies, and assisting them in the selection of teachers.

Far be it from us to throw the slightest obstacle in the way of imperial secular education; but while waiting for the good time coming—in which the ladder of learning, from the lowest to the topmost rung, shall be free to every man, of every rank—much lies in the hands of the working men themselves. Let them show that they are ready for instruction, and have adopted the principle of self-help, and we believe that they will find scientific men ready to meet them half-way. It will not cost the workmen much to establish schools; it will not cost the teacherhood very much to give counsel; and the machinery for the payment of the actual class teachers is already in large measure provided for by the Science and Art Department of the Government.

The lamentable war that is now desolating some of the fairest provinces of Europe, and the unproductive current in which the energies of all Germans are at present conducted, must necessarily throw back this movement on the Continent. As long as we hear of peasant and professor working together in the field and on the ramparts, we cannot expect that they will also co-operate in the pursuit of scientific knowledge. But when this war-cloud has passed away, when France and Germany alike again turn to the arts of peace, it will be, we trust, with a renewed determination to persevere in that road which can alone lead to true national greatness.

Our own mechanics' institutes and kindred undertakings are just now commencing their autumnal session. We commend to them the consideration whether the principle of self-help cannot be more definitely recognised than has hitherto been the case. We hear with pleasure that the Working Men's College in Great Ormond Street is projecting an extension of its scientific programme in the approaching session. Let men and women be treated, not as artisans, mechanics, or gentlemen, but simply as men and women, standing toward the teacher only in the position of recipients of something which he feels the power and necessity of imparting; let no thought of any other relationship enter into this connection; and we predict for this and other equally admirable institutions a far wider popularity and usefulness than they have hitherto enjoyed.

REPLY TO PROFESSOR HUXLEY'S INAUGURAL ADDRESS AT LIVERPOOL ON THE QUESTION OF THE ORIGIN OF LIFE

II.

THE main argument must now be resumed: this having been only temporarily laid aside in order to inquire how far Prof. Huxley's "long chain of evidence" touched the real point at issue.

Having shown that, in reality, this has no immediate bearing upon the question in dispute, and having endeavoured to show to what extent the burden of proof rests with Prof. Huxley and others who affirm the universality of Redi's doctrine, it has now to be shown what evidence can be brought forward which may influence our judgment in the selection of one or other of the two possible modes by which alone the minute motionless specks of Living matter appearing in certain solutions can be supposed to originate. We must inquire, as much as possible independently of theoretical considerations, towards which of the two modes of origin—the germ or the germless—the evidence should induce us to lean.

It will be well, however, in the first place, to submit the following considerations to those who wish to form an unbiassed opinion upon the subject. Supposing that the minutest visible specks of living matter have originated from the growth of pre-existing *invisible* germs, there is still no reason whatever to induce us to believe that the invisible portions of Living matter would differ from visible portions in their power of resisting the destructive influence of heat. Whether visible or invisible, we are supposed only to have to do with Living matter, and it cannot be supposed that the qualities of this matter would vary simply *because* it existed in a state so minute as to elude our observation. What has been found to hold good, therefore, concerning the inability of visible Living matter to resist the destructive agency of heat may also be presumed to hold good for any invisible portions of Living matter. Invisible germs must be supposed to be amenable to the same influences as those which affect visible germs.* If the latter are destroyed by any given amount of heat, we should have every reason to expect that the former would also be destroyed under similar circumstances.†

It seems to me that *the only means* which we at present possess of throwing light upon this question, as to whether the minute Living things which appear under our eyes, in certain solutions, really derive their origin from pre-existing Living things, or spring into being *de novo*, is to subject other suitable solutions within hermetically sealed flasks, to a degree of heat which, on good evidence, is deemed adequate to kill all pre-existing Living things. If Living things are, notwithstanding the destructive exposure, subsequently to be found in the fluids when the flasks are opened, the evidence would seem to be strongly in favour of the *de novo* origination of such Living things—more especially if the heat employed had been great and long-continued. So far as all direct experiment and observation has hitherto gone, no Living thing whatsoever has been found to survive in a fluid which has been exposed for two or three minutes to a temperature of 110° C. And if we couple this fact with a due consideration of the fundamental unity in Nature of all Living matter, the supposition that any Living things—found in solutions that had been submitted to a *far greater* heat for two, three, or four hours—had braved this heat with impunity, would be an assumption seemingly much more improbable* than the only possible counter supposition, viz., that the Living things had been evolved *de novo*. The former supposition would be less likely to be true, because, instead of being consistent or harmonising with our general knowledge, it would seem to be a mere isolated fact bearing on its face the impress of grave improbability. *Bacteria* and fungus-spores which cannot, when made the subject of direct observation, resist the influence of a lower temperature, *are*, however, to be supposed capable of resisting the influence of a much higher temperature when their behaviour is watched by no human eye, though at a juncture when human prejudice emphatically requires that they should do so.† This extreme improbability—this isolated and otherwise unsupported notion—is cherished, whilst the other supposition, which is consistent with direct observation so far as it can go, and which is thoroughly in harmony with a great mass of scientific truth, is rejected. And why is it rejected? Because it is alleged that a great mass of human experience, having no immediate bearing upon this particular subject, and which is only related thereto by analogy, *seems* to make it improbable. And yet, as a matter of fact,—and although precisely the same reasoning is applicable against the alternative which they adopt—if the probability of a present *de novo* origination of Living things, after the fashion which is alone maintained, were to be admitted by every scientific man to-morrow, the whole body of human experience would remain perfectly undisturbed. A new probability, akin to a fact,‡ and one of the most extreme importance, would, it is true, have been added to the sum-total of human knowledge, and the only loss or contradiction would be, that those who had hitherto cherished the formula *omne vivum ex vivo* as the expression of a fundamental truth, would have to give it up. Like many another dogma, which in the course of time is toppled over, this expression of an over-hasty, though formerly justifiable, generalisation, now that it has been shown to be incompatible with the latest teachings of science, would have to fall into the shade of cold neglect.

* It was suggested to me by a friend that extreme smallness of size might be a protection against the influence of heat; in illustration of which possibility my attention was called to the fact that the water in capillary tubes will not freeze at times when that in larger vessels will become solidified. But although the water in the capillary tube does not freeze, this is due rather to some altered molecular condition of the fluid, and not because its temperature is not lowered just as much as that contained in the larger vessel which does freeze. I cannot see how smallness of size can confer immunity from alterations of temperature—more especially of any particles, however minute, which are contained within hermetically sealed flasks retained at a given heat for *four hours*.

† I have already pointed out (note p. 410) that the problem is utterly impossible to be solved if this be not granted as a probability; and that, similarly, without the concession that *invisible* crystalline matter resembled in its properties *visible* crystalline matter, it would be equally impossible to consider it as *proved* that a crystal can originate in a solution *de novo*, independently of a pre-existing crystalline germ.

* Although "germs," so far as we know them, are incapable of resisting the influence of great and prolonged heat, it was suggested by Prof. Rolleston, in the discussion which took place in the Biological Section on Sept. 21, that some germs *might* exist which were less amenable to the influence of heat, owing to the protein substances entering into their composition being in some peculiar isomeric state. We know for instance that *peptone*, which is a modification of albumen, is not coagulable by heat. All that we should deduce from this fact, however, seems to be this, that whereas ordinary albumen can, under the influence of heat, be made to undergo a certain isomeric modification by which it is rendered *insoluble*; this same albumen may, by a different process, be converted into *peptone*, a modification which is *not* capable of being converted into the *insoluble* isomeric condition by the application of heat. Too much stress must not be laid upon mere coagulability; and we must be, as it seems to me, further careful not to mix up our conception of this property too closely with another which is quite distinct, viz., as to the ability of Living things to withstand the influence of heat.

† Here we are brought face to face with the real difficulty. In order to explain the results of certain experiments, we *must* accept an apparent infraction of one or other of two rules which have hitherto been found to be universal, so far as human experience has gone. A Living thing has no more been known to be capable of surviving a temperatue of 150° C., than another Living thing has been *known* to arise *de novo*. Prof. Huxley, and those who think with him, appear to forget, in their present extreme unwillingness to give up the doctrine *omne vivum ex vivo*, that they can only retain it by abjuring another doctrine which has a similar seeming universality, so far as human experience has gone. We have nothing, then, but *probabilities* to guide us in our choice. Hence much difference of opinion will probably exist, till scientific men in general have come to adopt such physical doctrines concerning Life as those which Prof. Huxley has hitherto so ably taught.

‡ All so-called "facts" are, to the philosopher, only possibilities which vary in their degree of probability. This is inevitable, owing to the "Relativity of Knowledge," so that possibilities, probabilities, and facts, merge insensibly into one another.

What, then, are the facts which have been made known bearing upon the solution of this question?

Before the date of M. Pasteur's researches, it was generally supposed that Living things were incapable of surviving in a fluid which had been raised even for a few minutes to the temperature of 100° C.; but, after the results of his experiments, he claimed* to have a right to conclude therefrom that, whilst Living things were destroyed in acid fluids which had been raised for a few minutes to the temperature of 100° C., they were not certainly killed in alkaline fluids unless these had been raised for a few minutes to a temperature of 110° C.

This, however, is the point at which Prof. Huxley has chosen to close what he considers to be the history of the rise and progress of the doctrine expressed by the phrase *omne vivum ex vivo.* Then, ignoring all † that had been done in the interval between the years 1862 and 1870, he concludes a long but almost irrelevant chain of evidence with an account of three recent (?) experiments of his own, concerning the cogency and worth of which I have already spoken.

But let us briefly glance at the most important work which has been done, in order to throw light upon the subject in dispute, in the interval between the appearance of M. Pasteur's memoir in 1862 and the three experiments made by Prof. Huxley himself—work which he so summarily dismisses from notice.

I will say nothing now concerning the various experiments which have been made similar to those of M. Pasteur, but with contradictory results; I will refer rather to experiments in which the flasks and solutions employed have been exposed to a degree of *heat much higher and much more prolonged* than that which was proclaimed by M. Pasteur to be adequate to prevent the occurrence of all organisms in the solutions, and in which, nevertheless, Living things have been found on opening the flasks. As I have elsewhere mentioned,‡ Prof. Jeffries Wyman,§ of Cambridge, U.S., published an account in 1862 of experiments in which he had boiled fluids containing organic matter for a period of two hours, under a pressure of two atmospheres, that is to say, at a temperature of 120°·6 C. To the fluid so treated, no air was allowed access except what had passed through the capillary bores of white-hot iron tubes. And yet, when, after a certain time, the flasks were broken, Living organisms were found in the fluids contained therein. Prof. Mantegazza,|| of Turin, has obtained Living organisms from the fluids of hermetically closed flasks after these, containing the putrescible fluids and common air at ordinary atmospheric pressure, had been subjected for some time to a temperature of 140° C. Prof. Cantoni,** of Pavia, has found Living bacteria and vibrios in the fluids of similarly-prepared closed flasks, after these had been exposed in a Pepin's digester to a temperature of 142° C. for four hours. And, lastly, I have myself recorded experiments, †† made with the kind assistance of Prof. Frankland, showing that Living organisms almost similar to those which have been ascertained to be incapable of resisting the influence of a fluid raised to the temperature of 100° C. for a few minutes may be met with, after a time, in solutions which had been exposed in hermetically-sealed and airless flasks, to a temperature varying between 146° and 153° C. for a period of four hours. Whilst, by another experiment,‡‡ it was found that a fungus and spores, as nearly as possible similar to that which had been found in a living state in one of the former experiments, were all *completely disintegrated,*§§ after exposure for an equal period, and in a flask containing a similar solution, to the same temperature of 146° to 153° C.

Now, in reference to these results, it should be remarked that there is not one tittle of evidence, so far as I am aware, which can be adduced tending to show that any single Living thing can continue to *live* in a fluid which is exposed even for a few minutes to a temperature of 110° C.—the degree of heat which M. Pasteur thought necessary to ensure the destruction of all pre-existing Living things. And also it has been shown just as definitely that none of the lower Living things which have been submitted to the test, have ever been found to survive an exposure in *dry air** for 30″ to a temperature of 130° C. Still less, therefore, would they be capable of withstanding the influence of an *extremely condensed vapour* at a temperature of 150° C., or even at 140° C., for a period of *four hours.*† There is, at present, no reason whatever for inducing people to believe that the living things met with in the experiments of Professors Wyman, Mantegazza, Cantoni, and those made by myself in concert with Prof. Frankland, had been derived from germs which were capable of living through the fiery ordeal to which the flasks had been submitted, save the extreme reluctance of these people to bring themselves to believe that Livings things can now‡ arise independently of pre-existing Living matter. Moreover, it should be understood, that experiments of this kind seem to be such as are alone capable of aiding us to come to a conclusion on this, the only question in dispute—whether the motionless specks which appear in previously homogeneous solutions, are more likely to have proceeded from the growth of pre-existing *invisible* germs, or to have arisen quite independently of pre-existing Living matter, under the influence of molecular affinities analogous to those which are believed to lead to the formation of similar specks of crystalline matter.

And yet, without one word concerning the limits of vital resistance; with what must be considered as a tacit admission that the very organisms in question are destroyed in a fluid maintained at a temperature of 100° C., for 15 minutes; without a single explicit mention of the experiments to which I have just been referring; with a seeming utter inappreciation of their important bearing upon the great question at issue—Prof. Huxley, closing his historical summary with a notice of the labours of M. Pasteur, ends an almost completely irrelevant statement with the mention of three experiments of his own, which, if they are not to be considered as altogether worthless, are, certainly, of no conceivable value for the establishment of the doctrine which he supports, or for the overthrow of the supposition that Living things can at the present time arise *de novo.*

Surveying the field of science from the elevated "position in which the suffrages of his colleagues had, for the time, placed him," recognising it as one of his privileges and duties, with "due impartiality," to declare "where the advanced posts of science had been driven in, or a long-continued siege had made *no* progress," Prof. Huxley ventures, in the face of the facts above-

* That M. Pasteur's experiments did not warrant him, however, in coming to the conclusion that Living things were capable of living in an alkaline solution when this was exposed to a temperature of 100° C., I have endeavoured to show in NATURE, No. 37, pp. 224—228.

† With the exception of the recent investigations of Prof. Tyndall, which Prof. Huxley considers capable of supporting his own view of the question, although Prof. Tyndall has really done nothing whatever to convince the public that the organic dust which exists in the atmosphere is even in part made up of the "germs," about which he talks so freely.

‡ NATURE, No. 35, p. 175.

§ "*Experiments on the Formation of Infusoria, &c.*" Cambridge, U.S.

|| These experiments were not made in the interval above referred to, but even ten years before the publication of M. Pasteur's memoir. See *Journal de l'Institut, Lombard*, t. iii., 1852.

** See Gaz. Med. Ital. Lombard. Ser. Der. v. t. i, 1868, and two communications made to the Royal Lombard Institute, one in April 1868, and one in November 1869.

†† NATURE, No. 36. ‡‡ Ibid.

§§ See NATURE, No. 37, p. 219. The experiment in which the somewhat similar fungus was met with was No. 19 (NATURE, No. 36, p. 200), and to this I would particularly direct the reader's attention. The mode of appearance of the fungus, its gradual increase in size, as well as its microscopical characters, all point to its having been *a living fungus.* Whilst the partial preservation of the vacuum for 65 days shows pretty plainly that there was no unobserved crack in the glass. The partial destruction of the vacuum was most probably *due to the liberation of gases within the flask*, owing to some decomposition of the tartrate of ammonia during the growth of the fungus. *It is not likely that germs contained in the air could get through a crack, if any such existed, which was impervious to the air itself.*

* NATURE, No. 35, p. 170.

† Prof. Tyndall seemed to have completely forgotten all this during the discussion which took place in the Biological Section of the British Association on Wednesday, September 21. He there alleged as his principal reason why the conclusions which I am inclined to draw from my experiments should not be drawn—after I had pointed out to him that *I had no wish to exclude "germs" or Living things* from the flasks which were hermetically sealed,—that germs might have adhered to the upper portion of the flask, and might never have come into contact with the heated fluid. But this objection was seen to be futile in the face of the work which had been done concerning the influence of *dry heated air* upon lower kinds of Living things—work of whose existence Prof. Tyndall seemed to be in ignorance, or which he had entirely forgotten, until he was reminded of the opinions of M. Pasteur on this subject. Prof. Tyndall, indeed, *seemed* to know very little more of M. Pasteur's views than he did of my own. Until it can be shown, however, that any single minute Living thing *can* withstand the influence of a *condensed vapour* at 150° C., for four hours, the objection which he started so triumphantly remains and exists only as a *highly improbable supposition*, in the face of which I can again fearlessly state my conclusion—that, taking all the *evidence* as it at present exists, I am as much, even more, entitled to believe that the organisms found in my flasks had been evolved *de novo*, than that they had been produced from pre-existing germs of Living matter, seeing how universally destructible this has been shown to be by heat.

‡ Even though some of these are quite willing to admit the *possibility* of such an occurrence, and are ready to accept the notion that in past ages of the earth the first Living matter did so originate from a combination of mere non-living materials.

mentioned, to tell the British Association for the Advancement of Science, and the public generally, that Redi's great doctrine appears to be "victorious along the whole line;" whilst the views and experiments of those who think differently are thus referred to:—"On the other side the sole assertions worthy of attention are that hermetically sealed fluids which have been exposed to long-continued heat have sometimes exhibited Living forms of low organisation when they have been opened."

All comments on such a proceeding seem needless—the facts speak only too plainly for themselves.

I will, however, say a few words concerning the mere empty generalities which Prof. Huxley opposes to the definite results of an honest band of workers.

He commences in this way:—"The first reply that suggests itself is the probability that there must be some error about these experiments, because they are performed on an enormous scale every day with quite contrary results. Meat, fruits, vegetables, the very materials of the most fermentable and putrescible infusions, are preserved to the extent, I suppose I may say, of thousands of tons every year by a method which is a mere application of Spallanzani's experiment. The matters to be preserved are well *boiled* in a tin case provided with a small hole, and this hole is soldered up when all the air in the case has been replaced by steam. By this method they may be kept for years without putrefying, fermenting, or getting mouldy." This is a very plausible statement, certainly; and one apparently tending to confirm Prof. Huxley's views. But what are the real facts of the case? I have made many inquiries and some microscopical examinations during the last three days, the results of which I will now communicate to Prof. Huxley and others.

Having visited one of the largest establishments in London, and seen the whole process to which the meats and vegetables are submitted for preservation, the information I have to convey is of the most authentic description. For this opportunity, and for many particulars communicated in a long conversation, I am much indebted to the courtesy of Mr. McCall, of Houndsditch.*

A number of cases, enclosing the provisions, instead of being simply heated to a temperature of 212° F. as most people would understand from what Prof. Huxley said, are first heated in a large chloride of calcium bath (warmed by steam) to a temperature of 230° to 235° F. for more than an hour and a half. The hole through which the steam has been issuing is then closed with solder, and as soon as the last of the set has been thus hermetically sealed, a higher pressure of steam is turned on, by which the bath is quickly raised to a temperature of from 258° to 260° C.†—at which temperature it is maintained for more than half an hour. Thus it is now learned that the meats are exposed to a heat of 230° to 235° F. for more than one and a half hours, and then to a temperature of 258° to 260° F. for another half hour at least. All this is very different from the simple statement that the provisions are "boiled," for a time not specified. Prof. Huxley, in the next place, mentions the possibility of failure, though he seems to attribute all these to "unskilfully closed tins." Now, on inquiry, it appears that the number of unmistakable failures even in the very best establishments is very appreciable, and although many of these failures may be accounted for by defective closure, Mr. McCall assured me that in a certain number of cases, where not the smallest defect could be detected in the tin, where the mode of preparation was unexceptionable, and the provisions originally of the best description, yet for some inscrutable reason some of these tins did prove utter failures. Gas was found to be evolved within, causing them to bulge at the extremities, and when opened the meats either showed a central decomposition of a most fœtid character without mould, or else mould might be found on some portions of the surface. He further assured me that certain tins which had been thoroughly well prepared, and in which the provisions seemed to remain in a perfect state of preservation ‡ for two or even three years, might more or less suddenly show signs of a considerable evolution of gas within, owing to the provisions having fallen into a state of putrefaction. In other instances provisions would keep for ten years

* And also for the kind permission to make known what he had told me.

† Whilst I was in this establishment one of the baths was seen to have reached a temperature of 263°. F. It was boiling very briskly. The more or less solid contents of the tins would require a longer time to be raised to any given temperature than a fluid; so that, practically, the meats may have been exposed only for a comparatively short period to the higher temperatures mentioned. I may state that 230° and 260° Fahr., correspond to 110° and 126·6° C.

‡ As judged by evidences of a vacuum within.

or more without any appreciable change. I was informed also that turtle, and all the soups which solidified when cold, invariably remained good. Amongst these there were no failures. Mr. McCall was somewhat doubtful as to whether in hot weather, provisions were more prone to fail after severe thunder storms. He had, however, "often thought that electricity" had something to do with the failures. Some of the large retail sellers spoke much more decidedly to me as to the number of failures after thunder. On this question, however, I lay no stress—I merely repeat what I was told.

Wishing to learn what microscopical appearances would be presented by provisions which were sold as being "perfectly good," I procured three specimens from two of the most esteemed retail establishments, informing the original owners that I wished to submit them to a microscopical examination. One of these was a tin of "Julienne Soup," which had been prepared ten months; the second, "Salmon," prepared six months; and the third, "Lobster," only six weeks old. The "Salmon" when opened, had not an altogether pleasant smell; the other two seemed quite fresh. In portions taken from the surface of each, I found the most unmistakable evidences that slight changes had taken place. All presented an abundance of flat granular aggregations,* figure-of-8 bodies, and a very appreciable quantity of *Bacteria* and *Leptothrix* filaments—some of these latter being plain and others jointed. The *Leptothrix* filaments were mostly about $\frac{1}{30000}$" in diameter. Some of the *Bacteria* were $\frac{1}{8000}$" in length, and many were moving pretty actively in the specimens taken from the "Julienne" and the "Lobster" figure-of-8 particles. In the "Salmon," I also found, during my comparatively short examination, two or three portions of *Fungus*-filaments, having dissepiments within, and measuring $\frac{1}{6000}$" in diameter.

Thus, to sum up, it appears that provisions, prepared as above described,† which have been exposed for more than two hours and twenty minutes to a temperature varying from 110° to 126° C. do, not unfrequently, *for no discoverable reason*, fall into a state of decomposition which renders them useless, and that the only specimens which I have examined microscopically, three in number, all presented evidences that Living things had been growing and developing in the hermetically sealed tins.‡ Why, in some cases, the changes should be so small in extent as not to impair the value of the provisions, and in other cases these changes—passing through the more intermediate grades—should render the provisions utterly useless, I, or others holding similar opinions, can scarcely be called upon fully to explain. Certain it is, however, that the facts above mentioned, including the circumstance that the failures sometimes take place after the tins have been hermetically sealed for two or three years, and that gelatinous§ substances are the least prone to change—are all

* Some of these had undoubtedly arisen from a granular degeneration of the meats themselves. Some muscular fibres presented a healthy appearance, while others were more or less completely granular.

† I may state in reply to what was said by Mr. Eddowes in the discussion on Sept. 21, that the provisions examined by me had all been prepared by a process essentially similar to that adopted by Mr. McCall. I took care to ascertain this. The "salmon" was not prepared, as he supposed, in Canada, but by a well-known Scotch house.

Since the above was written, I have (Sept. 26) examined two tins which were prepared by Mr. McCall in 1861. One containing "Lamb and Vegetables" was perfectly good. It contained not a drop of fluid, though some glutinous matter was present. On microscopical examination I could find *no trace* of organisms. The other tin, containing "Veal and Peas," was also perfectly good; the odour was just like that of fresh meat. The contents were very dry, not a drop of fluid could be procured, although the surface was bedewed with a slight moisture. When a small portion, scraped from the surface and mixed with a drop of water, was examined microscopically, hundreds of extremely minute *Bacteria* and monilated chains were seen—all either dead, or else extremely languid. These results are very interesting when compared with what was found in the three other tins, whose contents were much more moist and contained actual fluid.

‡ Without reference to the question whether the *Bacteria* and *Leptothrix* filaments were living when seen by me, the very fact of their having been formed in such a very appreciable quantity, seems to make it more probable that they had been *developed* after the exposure to the heat within the hermetically closed tins, than that they had pre-existed in the fresh provisions in the state in which they were found. There was, however, no reason whatever for supposing that the *Leptothrix* filaments were dead, or that the slow movements of the *Bacteria* were not *languid vital* movements; between which and Brownian movements it is impossible to draw any line of demarcation.

§ It could not be supposed that a gelatinous substance would afford facilities for the molecular rearrangements to take place, without which no new evolution of Living matter would seem possible. On the other hand, if the Living things which are sometimes found in these cases are derived, as many will suppose, from undestroyed germs, it does not seem so easy to understand why they should not germinate on the surface of a gelatinous substance. The "Julienne soup" examined was not gelatinous, it rather resembled a moderately thick solution of gum in consistence.

rather strongly in favour of my view of the case, and will continue to be so, so long as our *knowledge* concerning the inability of Living things to resist the destructive influence of very high temperatures remains in anything like the same condition as it is at the present day.

Prof. Huxley is inclined to believe that there has been some error about the experiments recorded by myself and others. With regard to my own experiments, however, the chances of error were certainly diminished to a minimum. Certain fluids were placed in glass vessels, and were handed over to one of the most accomplished chemists in this country, with the simple request that he would extract most of the atmospheric air from the flasks, would seal them hermetically, and would then expose them to a temperature of 150° C. for four hours. All this is certified by Prof. Frankland to have been faithfully done.* One of the flasks was opened in the presence of Prof. Huxley himself, whilst another of them was opened in the presence of Prof. Sharpey; and although the others were opened when I was alone, I hope the results are none the less reliable. In the face of these facts, and of what has been detailed elsewhere, it seems difficult to imagine that the experiments are not really trustworthy.†

Prof. Huxley then concludes his observations on these experiments by saying :—"But if, in the present state of science, the alternative is offered us, either germs can stand a greater heat than has been supposed, or the molecules of dead matter, *for no valid or intelligible reason that is assigned*, are able to rearrange themselves into living bodies, exactly such as can be demonstrated to be frequently produced in another way, I cannot understand how choice can be even for a moment doubtful."

Although this climax is thoroughly consistent with the style of the preceding remarks, I find it very difficult to understand why Prof. Huxley should have so much departed from his usual method of argumentation. I should like to ask him, however, whether he considers it the function of a scientific investigator to believe *only* in such seeming possibilities as he can at the time explain or account for; and also whether he who believes in the analogy between crystals and organisms,‡ can "assign any valid or intelligible reason" which is likely to be satisfactory to himself or to others, why the constituents of common salt, when in solution, should under certain circumstances aggregate into crystals of a cubical form; and why, on the other hand, the constituents of sulphate of soda should aggregate into rhombic crystals. Notwithstanding his inability to explain these facts, I suppose he nevertheless accepts them *as facts*, even although in the case of sulphate of soda, *almost exactly the same kinds of crystals result, whether they have proceeded from pre-existing crystalline germs, or whether they have arisen de novo.*§ Prof. Huxley seems only too much to overlook the fact that what may be perfectly inexplicable from one point of view, may, on the contrary, flow as a necessary consequence from one of an opposite nature. Although, therefore, as a disciple of Redi, the facts to which he has alluded may seem difficult to explain, Prof. Huxley must recollect that two rival doctrines are in question. And having two doctrines of almost equal probability to decide between, it seems to me mere childishness to reject a certain well-supported interpretation simply because it is inexplicable on the one hypothesis, and to think that this inexplicability is an argument against the interpretation given, when, so far from being inexplicable, this, *in the light of the counter hypothesis*, is nothing else than a logical consequence. That some such similarity as that which is alluded to should exist, is only to be expected by those who believe that the lowest living things are but the products of the molecular properties of a complex matter, and the "conditions" acting thereupon.* I entirely agree with Mr. G. H. Lewes, when, in a most valuable essay,† he points out that "similarity in the laws and conditions of Organic Combination must produce similarity in organisms, independently of relationship, just as similarity in the laws and conditions of inorganic combination will produce identity in chemical species." It is the extreme complexity of the materials in the one case, and their corresponding sensitiveness to modifying influences, which make it hopeless for us to think of ever getting the same uniformity of results, which we *are* able to attain when we have to do with simple inorganic materials. The difference, however, is one of degree, not of kind.

I enter a protest, therefore, against the first portion of Prof. Huxley's Inaugural Address, for the following reasons :—

1. Because it does not seem to be characterised by "due impartiality."

2. Because it is calculated to mislead the public; since what is represented as relevant and of first importance, has only an indirect bearing on the subject: *Abundance or paucity of germs in atmosphere.*

3. Because the real issues having already been pointed out by others, Prof. Huxley ignoring these, approaches the problem as though they had never been stated, and as though he himself were not aware of them: *Mode of origin of specks of Living matter in apparently homogeneous solutions.*

4. Because it allows room for the inference, and even suggests it, that evidence which is generally admitted to be of the greatest importance for the solution of the question in dispute, is really of little or no importance: *Limits of vital resistance to heat, and presence of Living organisms in closed vessels which had been previously exposed to great heat.*

5. Because, without any sufficient warrant, it throws doubt upon the "trustworthiness" of certain experiments, of whose real nature his audience and the public are not informed: *Experiments of Wyman, Mantegazza, Cantoni,* &c.

6. Because it opposes the definite results of these experiments by nothing but insufficient statements, and what appear to be crude suppositions: *Statements and assumptions concerning preserved meats.*

The general effect being, I conceive, an entire misrepresentation of the present state of knowledge upon the questions concerning the Origin of Life, which are at present under discussion.

H. CHARLTON BASTIAN

* See his description of the process, NATURE, No. 36, p. 199.

† The possibilities of error, which in a previous discussion (on Sept. 20) in the Biological Section, seem to have been suggested by Prof. Huxley, were two in number. First, that unperceived cracks may have been present in the hermetically sealed flasks, and second, that objects supposed to have been *Living*, may not have been so in reality. I have already spoken of these possibilities with reference to *Exp.* 19, and there is no better ground for either of the suppositions in reference to *Exps.* 17, 18, and 20. (See NATURE, No. 36, pp. 199—201.)

‡ See quotation, NATURE, No. 46, p. 411.

§ There is a very slight difference in the form of the crystals in the two cases, because in order to make sure of the absence of crystalline germs, the new crystals have to form under a different and exceptional set of conditions. But, notwithstanding what Prof. Huxley says, we find even a more striking divergence occasionally, in the case of organisms, which possibly have been evolved from similar materials though under different conditions. I have elsewhere said (NATURE, No. 37, p. 223):—"We find also associated with different sets of conditions, different kinds of Living things. In none of the crystals of tartrate of ammonia have I ever found a single distinct bacterium, and there has been the same complete absence of organisms of this kind in all my experimental fluids containing tartrate of ammonia and phosphate of soda, which have been sealed up *in vacuo*. This agreement is very striking, seeing that whenever a similar fluid, or a solution of tartrate of ammonia alone, is exposed to the air, then bacteria appear in abundance. There is a marked accordance, then, between the organisms which are produced in the experimental tubes *in vacuo*, and those which come from the cavities within the crystals," whilst these differ altogether from those which are met with in a similar solution exposed to the air. (See also what is said in *Note* on same page concerning the occurrence of *Sarcina*.)

* It is difficult, almost impossible, for us to say how far seemingly great differences in conditions, are really very different in respect to the influences which are most potential in leading the not-living to assume Living modes of combination, because we do not know for certain what these *most* potential factors are, and therefore how far these may be present or absent under circumstances apparently dissimilar.

**** *Owing to the great pressure on our space, we are compelled to postpone several articles of real value which are already in type.*

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

University College Lectures for Ladies

IN this week's number of NATURE I see it noted that among the courses of lectures announced for the ensuing winter by the Ladies' Educational Association in connection with University College, are included two upon scientific subjects (chemistry and experimental physics). May I venture to point out that the prospectus makes mention also of a third, namely, on logic, introduced by ten lectures on the psychology of intellect? This course was, certainly, designed as a scientific one, and indeed as a substitute for the course on mathematics suspended temporarily by force of circumstances. My own motive for drawing attention to the point will not, I think, be misunderstood, when so lately I had occasion in your columns to say a word for psychology as a natural science.

University College, Sept. 23 G. CROOM ROBERTSON

Mirage

IN connection with Mr. Kingsley's letter in your number of to-day on Mirage, I may mention that when in a steamer going up the Throndhjem Fiord, in Norway, last July, I saw some remarkable Mirage effects. In one case there appeared to be a large city, which altered as the ship advanced into a long line of very white cliffs of basaltic formation and then disappeared, and nothing was seen but very some low rocks; in other cases there appeared to be rocks suspended in the air at some distance from the surface of the water. It was a fine afternoon, and the sea very calm. W. P. M.

Liverpool, Sept. 22

Meteor

AT 8.30 p.m. on Sunday the 11th, a fine meteor was seen in the zenith traversing from East to West. It had a comet-like tail, and a star-like head; visible altogether for about ten seconds. In passing there was a "hish" sound, as of a rocket.

At 8 p.m. on Thursday the 15th, the Aurora or Northern Lights were very bright—mostly red, divided by rays of whiter light. Many persons, who were upon the pier, thought there was "a fire somewhere!"

Lowestoft, Sept. 16 SEPTIMUS PIESSE

Origin of Species and of Languages

THE extreme brevity of my former letter on this subject seems to have hindered Mr. Ransom, and perhaps other readers, from appreciating the analogical argument I used. Will you, in consideration of the importance of the inquiry, allow me now to illustrate that argument at greater length?

There are two sets of facts that stand out in marked contrast. No irrational animal has ever formed a language. Man alone, in all his varieties, has.

I agree with Mr. Ransom that no language has originated from an *intention* to form a new language; I see no reason to doubt that languages have arisen from the gradual variation, selection, and combination of a few primary sounds; and I think that existing languages are constantly undergoing change through the operation of physical, physiological, and other natural causes, irrespectively of reason. But the fact remains to be accounted for, that no animal unendowed with reason has ever selected and combined sounds into a language.

The cause does not lie in a want of significant sounds to begin with. No one who has ever owned a dog is ignorant how many emotional sounds—sounds, too, that vary greatly in individuals and varieties—*he* makes use of; but he has never even begun to make a language of them. Neither does the cause lie in a want of power to distinguish, and in the case of some animals, to imitate very accurately the natural sounds they hear, so as to have a supply of vocal symbols for things and occurrences ready for adoption if they will. But can any irrational animal be named that has ever begun to use such sounds as symbols denoting things or events, still less to modify them in order to express modified meanings, and far less to combine them into symbols of complex things, or into phrases, propositions, and sentences? The mocking-bird mimics the song of the whip-poor-will, the creaking of the wheelbarrow, the lowing of the ox, and the pattering of the rain; but does it ever, like the Greeks, Romans, and Gaels, speak of the ox by the name of *bo*; or, like us, speak of the rain as *pattering*; or modify that sound, like the Hebrew and the Teutonic races, into a name for the substance that patters (*matar, water, Wasser*), and use it to tell that it wants a drink? Least of all, has any irrational animal ever juxta-placed sounds, as the Chinese do, in different orders to express different relations between the things they denote; or with Aryans, modified sounds into prefixes and terminations to express metaphorically such abstract relations?

Every step in these processes involves an exercise of reason. True, there is no grand intention on the part of one man or nation to form a language, but there are countless intentions of individual men to express individual ideas and thoughts as they emerge, or to express them more accurately than before; and then, when one man by an exercise of reason devises and uses a new symbol or phrase, others imitate and adopt it. And so, while I admit that there are unintentional variations of words, and consequently (by degrees) of languages; and while I admit that there has been no intention to form a language as a whole, I think we must say that it is by countless intentions of rational beings that languages have been gradually formed.

It may be objected that savages possess languages, and that *they* are not rational. "My monkey *Wallady*," writes Sir Samuel Baker, "looks like a civilised being in comparison with the Nuehr savages." And yet, while the Neuhr savages have a language, Wallady has none, any more than my terrier Shag, knowing fellow though he be. Why this contrast, but because the most savage man is differenced from all other animals by the possession of reason?

Now, then, the argument against the theory of the formation of the species, or of their endowment with new organs, by a reasonless process, is this:—The experiment of the possibility of such a thing has been actually tried on the most extensive scale in the analogous matter of language, *and has failed*—failed in every instance except where reason has been at work to prompt and direct. Ought we not then to pause, while our data are so imperfect, and while science is making strides that may soon bring her to a point of view that will show her present logic to have been utterly at fault—to pause before entertaining a thought so revolutionary and perilous as that an eye, a beast, a man has been formed without presiding intelligence or design at all.

The subject is seductive; but I fear I have already encroached too much on your space. WILLIAM TAYLOR

The Cockroach

THE cockroach (*Blatta orientalis, Linn.*) has found an apologist in Dr. Norman Macleod, who asserts his incredulity in the current stories of this insect's bad habits. Cockroaches look, he says, like black priests among the beetles, and, like the priesthood generally, have been made the objects of misrepresentation and slander. Anyhow, the doctor treats as mythical the tradition, constant on ship-board, that cockroaches are in the habit of nibbling the nails of those who sleep with their feet uncovered. Not only are they harmless, but they are absolutely useful, inasmuch as they may be readily trod upon and killed by all who are willing to gratify their feelings of disgust and benefit society. In the history of the cockroach we can trace the origin of the nail-nibbling myth, if myth it be. The insect is indigenous in the warmer parts of America, and, in spite of its Linnean name, is only oriental through having been carried to the East by shipping. It has a natural love for warmth and for sweet things, and can indulge the latter taste by feasting on the feet of natives engaged in sugar manufacture. If Gilbert White is correct in his surmise that the insect was not introduced into England until late in the last century, its powers of reproduction and adaptation must be very large. It is, of course, very difficult to identify with absolute certainty the insects mentioned in classical authors, but there is a good deal to lead one to suppose that the μυλακρὶς mentioned by Aristotle and the *Blatta histrinorum* of Latin writers was the same as our loathsome pest. The English name is curious and worth investigation, but unhappily there is so much guess-work employed in derivations that this branch of philology cannot claim to be recognised as one of the "exact sciences."

Norton Court, Weobley C. J. ROBINSON

On the Dissipation of Energy

THE value of the successive numbers of NATURE is not a little enhanced by the papers of Professor Balfour Stewart on "Energy," which also lead us to long for his forthcoming volume on "Physics." If that work prove equal to that which he has already published on "Heat," it will give us a manual which may well compare with the best of those which have been published abroad, and it will besides possess a freshness of its own.

But is it desirable that the doctrine of the conservation of energy should be represented everywhere as a modern discovery? No doubt *the experimental verification* of the transformability of equivalent quantities of mechanical power of various kinds into equivalent temperatures is a modern discovery. But *the doctrine itself* belongs to the epoch of Leibnitz, and was deliberately set forth by that great philosopher himself. "I do not" (says he) "undertake [in his last correspondence with Dr. S. Clarke] to establish my dynamics or my doctrine of forces. This would not be the proper place for doing so. However, I can very well reply here to the objection that has been made to me. *I have maintained the conservation of active forces in the world.* It was objected to this, that two soft non-elastic bodies on meeting lose some of their force. I answer no. It is true that the masses lose it as to their entire movement, but their particles receive it, being internally agitated by the force of the meeting. Thus the loss is only in appearance. The forces are not lost but only dissipated among the small particles. Now this is not to be lost, but to act as those do who change a piece of money into small coin." * Is it said that in the above words Leibnitz does not state that one of the principal forms of the incident force when dissipated in bodies is heat, which is known now to be the fact, or that perhaps he did not know that heat was a mode of action at all? the answer is, that it was never doubted by any philosopher of that epoch that heat is a mode of motion. And in the *Micrographia* of R. Hooke (see specially Obs. 6, 7, and 8), there is a discussion of phenomena from this point of view as interesting and as accurate as any that is to be found in any modern book.

But a no less important consideration for science is the decision of Sir W. Thomson, Professor B. Stewart, and other physicists of this school, that the doctrine of the dissipation of energy is co-ordinate with its conservation, and that the destiny of the universe is to become its own cemetery! This theory, expressed in its most general terms is to the effect that all rectilinear motions (locomotion) naturally tend to be transformed into intimately reciprocating motions (heat) which are naturally irrecoverable into their first forms, and which tend to be ultimately so distributed that externally universal repose or death must ensue. Now, in view of all the experiments that have as yet been made, and all the results of equivalent transformations between foot-pounds and temperatures which have been obtained, this is surely a very bold generalisation. It is an inference from what man finds in his *work* as to what nature must do in her *play*. But there are differences between the two which have not been duly considered. Thus to us the concrete state is everything, for we are ourselves concretes. We live from moment to moment only by condensing and concreting the aeriform. But Nature delights in the aeriform. And such is the tendency of material elements in general to the aeriform state, as to lead legitimately to the inference that the concrete state is a forced and a defective state of matter which is possible to the material elements only when somewhat of their full complement of virtue has gone out of them. As to heat, has not the production of heat in a concrete body expressly for its function to emancipate the constituent particles more or less, so as to put them in the way of gaining the aeriform state? Are not almost all concretes at almost all known temperatures continually giving off particles into the aeriform state, and that all the more the hotter they are? Even iron and clay are not without a smell in a damp atmosphere. Adopting then, as is now generally done, the aeriform or nebular state as primeval, is not the proper corollary of the doctrine of the conservation of force—not the reduction of the system to a dead mass, but its restoration to a fully aeriform nebular or ætherial state, with new fitness for producing all those phenomena which the nebular hypothesis supposes? Would not such be the issue supposing the cosmical action to be all in one direction? And if that action be not, as we see it is not, all in one direction, but in two reciprocal directions, is not the corollary of the doctrine of the conservation of force to the effect that in its general features the mundane system shall remain as it is?

As to the sun to which we in this planet owe everything, since there is no actual evidence that his action upon us now is less powerful than it ever was, would it not be well, instead of being so much concerned in producing fuel for him (with such indifferent success), rather to take into consideration Dr. Clarke Maxwell's formulæ in physical optics, which lead to the conception that the solar radiation is an electro-magnetic action? If so, then the sun would be always receiving as much as he was giving, and would not be wasting his energy save on the dissimilar bodies (the planets) which circle round him. With respect to the celestial spaces in general he may possibly be insulated in the æther by his own heat like a drop of water in the spheroidal state. Meantime the 22nd of December may bring us some discovery as to his structure. J. G. M.

* See "A Sketch of a Philosophy," part I. p. 2. (Williams and Norgate.)

NOTES

THE foundation stone of the new building for Owens College, Manchester, was laid on the site which has been purchased in Oxford Street on Friday last. The ceremony was performed by the Duke of Devonshire, K.G. The building has been designed by Mr. Waterhouse, the architect of the Manchester Assize Courts and of the new Town-hall. The style of the building is Gothic. It will have accommodation for 600 day students, and for a much larger number of evening students. A sum of 102,000*l*. has been placed at the disposal of the building committee, 67,000*l*. of which is at present available for the erection of the college. The cost of the building is 90,000*l*., so that a sum of from 25,000*l*. to 30,000*l*. is still required for building purposes.

WE greatly regret to have received intelligence of the death at Geneva, on the 18th inst., of Dr. Augustus Waller, F.R.S. Dr. Waller held a high place among those physiologists who have enriched their science by original research. He is best known for his important contributions to the physiology of the nervous system, and especially for the introduction of a new method of investigation applicable to various important objects of neurological inquiry, which, not only as used by himself, but in the hands of others, has tended materially to advance the knowledge of that department. We owe also to Dr. Waller original and valuable observations on various other physiological questions. In acknowledgment of his scientific labours he twice received the Monthyon Prize of the French Academy of Sciences, first in 1852 for a research, in which he was assisted by Prof. Budge, of Bonn, and again in 1856 for experiments, exclusively his own, showing an important relation between the nutrition of nerve-fibres and their connection with nervous centres. For these and other researches in Experimental Physiology the Royal Society awarded him one of the royal medals for 1860. Dr. Waller began professional life as a general practitioner in Kensington, but his growing passion for original inquiry in science led him to devote himself to it entirely, and with the exception of a short time that he was Professor of Physiology in Queen's College, Birmingham, he resided abroad, and enjoyed the intimacy of the most celebrated Continental physiologists, who thoroughly appreciated his merits. Latterly he went to reside at Geneva, and commenced practice as a physician, still, however, continuing his physiological pursuits. He died quite suddenly in a fit of Angina pectoris, to which complaint he had been for some time subject.

WE are able to state that the *Quarterly Journal of Science* has passed into the hands of Mr. W. Crookes, F.R.S., who will from the present time be sole proprietor and editor.

THE American Science Association met at Troy, N.Y., on August the 17th. Professors Agassiz, Dana, and Henry were unavoidably absent. Papers on subjects of scientific interest were read by Professors Stimson of Boston, Winchell of Michigan, Orton of Vassar, Bradley of Jersey City, and many others.

IN addition to the professorial chairs already instituted at the University of Otago, New Zealand, the council of that University have now resolved to institute a chair of natural science, the salary of which will be 600*l*. per annum, besides class fees, &c., commencing to run from the day of embarkation. No religious test will be required of candidates.

THE programme of the lectures of the Birmingham and Midland Institute for the forthcoming session include a large proportion of a scientific character, as will be seen from the following list:—1870. October 3 and 10, "The Movements of Gases," by Professor Odling. October 17 and 24, "Extinct Animals intermediate between Reptiles and Birds," by Professor Huxley. October 31 and November 7, "Erasmus Darwin and Anna Seward, their Works and their Friends," by George Dawson. December 5, "The Lost Tribes of Tasmania," by James Bonwick. 1871. February 13, "Primitive Civilisation," by E. B. Tylor. March 13 and 20, "The Astronomy of Comets," by Professor Robert Grant. March 27, "War Ships and their Guns," by E. J. Reed. March 3 and 10, "Recent Researches in Physical Science," by W. F. Barrett.

AMONG the lectures to be delivered during next session before the Exeter Literary Society are "Recent Researches in Spectrum Analysis," by Rev. R. Kirwan; "Queer Flames, and what they have to say for themselves," by C. Meymott Tidy; "The Orbs of Heaven," by W. F. Quicke; and "Stonehenge compared with some other megalithic monuments," by Rev. R. Kirwan.

WE have received a prospectus of a new American Scientific Journal, to be called the *American Journal of Microscopy*. It will endeavour to create an elevated taste for microscopic science among the people. It will give full descriptions of the construction and ways of using the various kinds of microscopes and other optical instruments, the selection, gathering, and mounting of the most beautiful and interesting microscopic objects, microscopical diagnosis of diseases, reports of microscopical societies, and, in short, everything pertaining to microscopy. This journal will be ready for subscribers and agents about the 1st of October, and will be issued in neat quarto form of sixteen pages, of suitable size for preserving and binding, printed on fine white paper, in clear type, at one dollar per year. It will be published at Chicago.

WITH respect to the "whale of the bottle-nose species" said to have come ashore at Burntisland, Prof. Turner states that the animal is not one of the toothed whales, but a small whalebone whale. The plicated belly and the fatty fin on the back, placed it amongst the *Balænopteridæ* or finner whales. The white baleen, dashed here and there with pink, the form of the skull, and the elongated cruciform breast-bone, proved it to be the *Balænoptera rostrata* or piked whale—the smallest in the baleen whales inhabiting the North Sea. The specific distinction of this cetacean was first established by the late Dr. Robert Knox, from a specimen taken in 1834 in the stake nets at Queensferry, who named it the *Balæna minimus borealis*. Several specimens have since that time been stranded on the coasts of the Firth. Mr. Prentice has, with great liberality, presented the skeleton to the Anatomical Museum of the University of Edinburgh.

MR. W. G. SMITH'S "Clavis Agaricinorum," a paper originally presented to the Woolhope Naturalists' Field Club, and already printed in the *Journal of Botany*, will be very acceptable to mycologists in the separate and more complete form in which it is now published. Mr. Smith follows essentially the system of Fries and Berkeley, in dividing the enormous genus of *Agaricus* (numbering 450 British species alone) into five series, termed partly from the colour of the spores, *Leucospori*, *Hyporhodii*, *Dermini*, *Pratellæ*, and *Coprinarii*. Each of these five series he then divides into ten sub-genera, distinguished by characters of the hymenophorum, each of the five series of ten sub-genera closely corresponding to every other such series. Out of the fifty sub-genera which would thus be derived, only thirty-two are at present known, the remaining eighteen links in the chain remaining to be discovered. A number of very clear and carefully-executed diagram-plates which are appended will be of great service in rendering intelligible to beginners the principles of the arrangement of this exceedingly difficult genus.

PROF. O. C. MARSH has reprinted from the *American Journal of Science and Arts* several papers of considerable interest of American palæontology; Notice of some fossil Birds from the Cretaceous and Tertiary formations of the United States; Notice of some new Mosasauroid Reptiles from the Greensand of New Jersey; and a description of a new and gigantic fossil Serpent (*Dinophis grandis*) from the Tertiary of New Jersey.

WE are informed from American sources that the Western Union Telegraph Company in America propose to co-operate with the War Department, for the rapid transmission of telegraphic reports of "the operation and reports of storms for the benefit of commerce on our Northern lakes and sea-board." The practical value of the Meteorological information that can thus be rapidly sent across the great continent of America, from the Pacific to the Atlantic, cannot but be very great, and there is every hope that the War department will close with the offer.

SIR RODERICK MURCHISON announced to the Geographical Section of the British Association at Liverpool the receipt of the following telegram relating to the safety of the *Germania*—a little vessel which sailed some time ago on an expedition to the Arctic regions, chiefly at the expense of the German geographers and naturalists:—"Freeden to General Sabine. Koldeway—wintered in East Greenland, 70°; sledged to 77°. Arrived at Bremen last night. Extensive results—best health. Hamburgh, Sept. 12."

THE Consul-general of Chile at Bogota, the capital of Columbia, has written to his government to ask for particulars on the "Baldia" plant, reputed to be a great specific against liver complaint.

THE Economic Society of Guatemala is endeavouring to promote agricultural education there by means of books.

ONE of the most disastrous earthquakes we have lately recorded is that in the large city of Batang, on the Kin-sha river in Tibet. It began on the 11th April, and there were various shocks until the 9th May at 10 A.M., when it shook the whole city, causing a universal conflagration. Above 10,000 people were burnt to death. Several neighbouring villages shared the same fate. Many public buildings were destroyed, including those of the French millionaires. After the great shock others came on, and the people remained camped out for five days.

A SLIGHT earthquake is reported on the 26th July at 11 to 5 P.M., at Managua in Nicaragua, produced it is supposed by the volcano of Momstombe, from which subterranean rumblings were heard nearly every night. The people of Leon state that they have noticed flames and smoke proceeding from the crater. This seems to be the same earthquake that is reported from the neighbouring Republic of San Salvador on the 27th July. There it was strong, and lasted some seconds. On the 28th there was another, at 11.30 A.M., of a more violent character, but no serious damage was done.

ON the morning of the 1st August there was a slight shock of earthquake at Calcutta at about 5 minutes to 10.

THE Arabian Nights are in progress of realisation. Deposed sultans and princesses in disguise are not wanting; and the gold diggings furnish nuggets as large as any holder of a magic lamp can want. Aladdin's jewellery is now under realisation. The Diamond diggings in the Vaal River are the scene of successful venture, and one company in six months has got 22,000*l* worth of diamonds. Women and babies are now taken to this scene of fortune, where bands of music, billiard tables, and other accessories of pleasure, have already appeared. Aladdin had not a billiard table when shut up in the cave of diamonds.

THE BRITISH ASSOCIATION

LIVERPOOL, *Wednesday*

THE number of tickets issued has now increased to 2,800, very considerably more than was expected either by the officers of the Association or by the Liverpudlians. The roll of eminent foreigners is also much larger. In addition to those mentioned in my first letter we have now the company of Prof. Tchebichef, of St. Petersburg, one of the most distinguished of living mathematicians, Prof. Plateau of Bruges, Dr. Anton Dohrn of Jena, Prof. Von Baumhauer of Leyden, and others. Some of these have added greatly to the interest of the sections in which they took part, and have been very warmly received. Dr. Dohrn in particular was greeted with much warmth, from the fact that three weeks ago he was summoned to join the German army and had not since been heard of by his English friends. The statement of a local paper that Prof. Hofmann of Berlin is here is incorrect. A letter was, however, read from him in the Chemical section, soliciting contributions in kind from our chemical manufacturers for the needs of the German hospital service. A large audience met to-day in the Geographical section to hear Lord Milton read his paper on "Railway Routes across America;" and the lecture-room in which the Ethnological sub-section holds its meetings was crammed whilst Sir John Lubbock was discoursing on "Stone Implements from Western Africa." The small and inconvenient Crown Court in St. George's Hall devoted to Section A had a much larger complement than usual while the Rev. F. Howlett read his paper on "Solar Spots," and exhibited his elaborate diagrams, showing the great interest now taken by the public in solar phenomena; although, at the same time, Section G offered a counter attraction, especially to the members connected with the town, in Mr. Mackie's and Sir E. Belcher's papers on "The Unprotected State of Liverpool." The heavy rain and thick fog of yesterday morning have both cleared off, and the weather is again everything that could be desired.

The subject of Spontaneous Generation is undoubtedly *the* question of the meeting of the British Association for 1870. The title of the paper by Professor Huxley which headed yesterday's list in the department of Zoology and Botany, did not appear to bear directly upon it, and yet it was generally understood that it would reopen the subject. The President's discourse, for he had scarcely a note before him, was a popular account of the mode of development and form of those minute structures which the microscope reveals in such prodigious numbers in infusions containing organic matter, *Penicillium*, *Torula*, *Bacterium*, and *Vibrio*. He adduced arguments in favour of the theory that these various bodies are not distinct organisms, but are different modes of development of the same substance, and a more admirable and luminous exposition, it was generally admitted, has seldom been delivered. In the course of his remarks, Prof. Huxley took occasion to explain the difference between the "Brownian" motion of the molecules of inorganic matter, and the vital motions of living matter, and expressed his conviction that the motions observed by Dr. Bastian in the infusions which had been subjected to long-continued high temperatures, were referable to the former and not to the latter cause. During the discussion which followed, Dr. Bastian entered the room, but when called on by the president of the section, preferred deferring his reply till the following day. This morning Dr. Bastian gave an account of his experiments on the contents of hermetically sealed cases of preserved meats, with which the readers of NATURE are already familiar, and reiterated his conclusion that the facts he had elicited were such as to throw on the Biogenists the burden of proof that life did not really, as was apparently the case, originate *de novo* from lifeless materials. Professor Huxley was not able to be present at this discussion, but a somewhat sharp passage of arms took place between Dr. Bastian and Professor Tyndall, each maintaining his well-known view respecting the atmospheric germ theory. The reply of Prof. Tyndall, "Prof. Huxley's lieutenant," as he was described by the president of the section, was not generally accepted as conclusive, in consequence of his apparently not having made himself thoroughly acquainted with the facts of the series of experiments performed by Dr. Bastian.

Several of the sections had got through their programme of papers yesterday, but the majority sat this morning, and Section D even intruded into the time fixed for the meeting of the General Committee which concluded the business of the meeting. In opening the business of the committee, Professor Huxley remarked that whatever reports are issued in the name of the committee of recommendations, it should be clearly understood that they are issued without any sanction of the Association, and that the responsibility of these reports, and the conclusions that may be drawn from them, rest entirely with the authors of the reports. The Association does not for one moment endorse views on subjects on which persons of eminence may hold different opinions. All that the Association is responsible for, is to place in a position for making reports gentlemen who are competent to make them; what these gentlemen say is entirely on their own responsibility. Grants were then ordered for various purposes, as recommended by the committee of recommendation, in accordance with the list which will be found in another column. A number of resolutions not involving grants of money, which came up from the various sections, were also passed.* The most important among these were:—A resolution on the subject of Vivisection, and appointment of a committee, from Section D; a resolution, brought up from Sections A and B, requesting the Council to co-operate with the Councils of the Royal and Astronomical Societies urging on the Government the propriety of reconsidering their refusal to aid in the observation of the approaching Total Eclipse of the sun by the grant of a vessel; a resolution from Sections A, B, and G, with reference to the proposed foundation by the Government of an Engineering College, to the effect that it is undesirable that any fresh grants should be made for purposes of scientific instruction until the Royal Science Commission has reported. The only resolution which excited much discussion was one from Section F in favour of the adoption of a compulsory metric system of weights and measures. An amendment was moved by Mr. Hawksley, and seconded by Professor Rankine, that the recommendation should be limited to the adoption of the metric system for international purposes, on the ground that a binary system is now, and always will be, the mode adopted by uneducated persons in all countries for their own purposes, as being the simplest. The amendment was adopted by a considerable majority.

Saturday

Those who were present at the meeting of the British Association which has just concluded its sittings, speak of it as presenting some points of favourable contrast with preceding meetings. There were still a good many papers presented of a purely technical character, which would have been far more suitable for the transactions of one of the learned societies, and which were perfectly unsuited for the miscellaneous audience collected to hear them. On the other hand there were not a few, perhaps a larger number than on previous occasions, which treated purely scientific subjects in a philosophical manner, calculated not only to interest but to enlarge the minds of all who had the pleasure of listening to them. I may illustrate my remark by reference to one division only, Section D. A glance over the titles of the papers read in this section will at once suggest several belonging to the former category. On the other hand, Dr. Brown-Sequard's paper on "Various Alterations of Nutrition due to Nervous Influence," and Prof. Flower's on the "Connection of the Hyoid Arch with the Skull," though treating of subjects belonging to pure science, were discussed in a manner which carried with them a non-scientific audience, who cannot have failed to carry away some ideas altogether new to them. In the same manner Prof. Huxley's

* Owing to these resolutions not having been yet sanctioned by the Council, we are compelled to defer their publication for the present.

"History of the Development of the Lowest Forms of Infusorial Life" was a model of clearness and succinctness; and the President himself paid a compliment to Mr. Bennett's paper, which followed, on the "Theory of Natural Selection looked at from a Mathematical Point of View," as the first attack on the hypothesis conceived in a philosophical spirit, and such a paper as it is the special object of the Association to bring out. The great question of the meeting, that of "Spontaneous Generation," has already occupied sufficient space in our columns; we look to the Liverpool meeting as the starting-point from which the discussion must in future be carried on in a truly philosophical and inductive spirit, free from the dogmatism which has hitherto surrounded it.

The attitude of Liverpool towards the Association has been somewhat of a puzzle to its members. If we were to judge from the remarks heard in the streets and from the ordinary visitors at the hotels, and the "intelligent policemen" who were posted here and there to direct the wandering visitor, we might suppose that a meeting of the British Association was a monthly occurrence in Liverpool, so utterly indifferent did they appear to it. The prevalent opinion appeared to be that we were another Church Congress in some sort of disguise. That there is a public in Liverpool who watched its proceedings with intelligence and interest was evident; but this, at least, is certain, that such a public has no representative in the Liverpool press. Let any one who wishes to see what the papers say about the Association take up the *Liverpool Courier* of this morning, where they will find a leader devoted to a ponderously jocose reply to an innocent remark of ours last week. "Save us from our friends" was the remark with which we laid down the following comment on the Association:—"The philosophers have come and gone, and Liverpool is at peace. They had a week of tremendous talk—tremendous not only as regards volubility, which is a blight we are well accustomed to in Liverpool, but also as regards the technical ponderosity of the themes. However, it is over at last, and though we entertain the most devout admiration for science and scientific people, a sigh of relief escapes involuntarily as we speed the parting guest. It was impossible that we could live long at the high pressure of the past week. It was more than human nature—of course we except scientific human nature, which is on a higher round in the Darwinian ladder than we poor cotton-dealers and traffickers—could bear for another seven days. The philosophy was too exalted for our earthy intellects, and we are bound to confess that the local savans—we have quite a battalion of the genus, such as they are—manifested signs of weariness under the tempest-torrent of imported intelligence. Of course it was right that the personages who hang on to the skirts of philosophy should be members of the British Association; but what a change between the first and the last day! Mathematics and biology were a gay pastime in the initial stage, the wise men and the learned ladies were positively vivacious over the germ-theory, and not a few were prepared to enter the lists against any opponent of abiogenesis. But this enthusiasm could not be sustained, for there was no basis of real intelligent interest, and the animation waned as the stream of science still flowed on."

The reporter of the *Courier* clearly found that he was getting beyond his depth, and wisely absented himself from the sittings during the last few days, or he would have known that the interest showed no signs of abatement. I venture to predict that those Liverpudlians for whom the meeting was not altogether "caviare" have been so well pleased with the success of the meeting that in due time we shall have another invitation to pay the town a visit, when I hope large numbers of those who have now dispersed will again meet.

It will be seen that the annual grant of 600*l.* for the purposes of the Kew Observatory has only two more years to run. We must trust that the additional means thus placed at the disposal of the Council will be applied to purposes directly connected with the real advancement of science, and will not be frittered away in bricks and mortar.

After holding the concluding general meeting which followed that of the general committee, the visitors to the Association rapidly dispersed; a small proportion, however, staying to avail themselves of one or other of the excursions which were arranged for the Thursday. In this respect next year's meeting at Edinburgh will afford a much larger scope for the lovers of the picturesque. B.

Resolutions of the General Committee

Applications for Reports and Researches not involving Grants of Money

That Prof. R. B. Clifton, Mr. Glaisher, Mr. Huggins, Dr. Matthiessen, Prof. W. Hallows Miller, Dr. Balfour Stewart, Mr. G. Johnstone Stoney, Lieut.-Col. Strange, and Sir J. Whitworth, Bart., be a Committee for the purpose of reporting on Metric Standards, in reference to the communication from Prof. Jacobi, appended hereto:—

"The Academy of Sciences of St. Petersburg, observing that the Standard Metric Weights and Measures of the various countries of Europe and of the United States, differ by sensible, though small, quantities from one another, express the opinion that the continuance of these errors would be highly prejudicial to science. They believe that the injurious effects could not be guarded against by private labours, however meritorious, and they have therefore recommended that an international commission be appointed by the countries interested to deal with this matter. They have decided to bring the subject before the Russian Government, and have appointed a Committee of their own body, who have drawn up a careful Report containing valuable suggestions; and they have deputed Prof. Jacobi to lay this Report before the British Association, and to request the Association to take action in reference to it."

That Dr. Anton Dohrn, Prof. Rolleston, and Mr. P. L. Sclater be a committee for the purpose of promoting the foundation of zoological stations in different parts of the world, recognising the foundation of a zoological station at Naples as a decided step in this direction; that Dr. Anton Dohrn be the Secretary.

That the committee of Section D be requested to draw up a statement of their views upon Physiological Experiments in their various bearings, and that this document be circulated among the members of the Association.

That the said committee be further requested to consider from time to time whether any steps can be taken by them or by the Association, which will tend to reduce to its minimum the suffering entailed by legitimate physiological inquiries, or any which will have the effect of employing the influence of this Association in the discouragement of experiments which are not clearly legitimate on live animals.

Resolution passed by the Committee of Section D (Biology):

"That the following gentlemen be appointed a Committee for the purpose of carrying out the suggestion on the question of Physiological Experiments made by the General Committee:—Professor Rolleston, Professor Lawson, Professor Balfour, Dr. Gamgee, Professor M. Foster, Professor Humphry, Professor W. H. Flower, Professor Sanderson, Professor Macalister, and Professor Redfern; that Professor Rolleston be the Secretary, and that they be requested to report to the Committee."

Involving Application to Government

That Sir R. I. Murchison, Bart., Sir Charles Lyell, Bart., Mr. Findlay, and Admiral Sir John D. Hay be a committee for the purpose of bringing to the notice of the Commissioners of the Admiralty the importance of revising the survey of the west coast of South America, with a view to ascertaining what changes have taken place in the levels since the recent great earthquakes on that coast; that Mr. Clements Markham be the secretary.

That Prof. Jevons, Mr. R. Dudley Baxter, Sir John Bowring, Mr. J. T. Danson, Mr. James Heywood, Dr. W. B. Hodgson, and Prof. Waley be a committee for the purpose of urging upon her Majesty's Government the expediency of arranging and tabulating the results of the approaching census in the three several parts of the United Kingdom in such a manner as to admit of ready and effective comparison; that Mr. Edmund Macrory be the secretary.

SYNOPSIS OF GRANTS OF MONEY appropriated to Scientific Purposes by the General Committee at the Liverpool Meeting in September 1870. The names of the members who would be entitled to call on the General Treasurer for the respective Grants are prefixed:

	£	s.	d.
Kew Observatory			
The Council.—Maintaining the Establishment of Kew Observatory	600	0	0
Mathematics and Physics			
*Brooke, Mr.—British Rainfall	50	0	0
*Thomson, Professor Sir W.—Underground Temperature	150	0	0

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE

Abstract of an Investigation of the Mathematical Theory of Combined Streams.—Professor W. J. M. Rankine, F.R.S. The object of the investigation of which this is an abstract is to extend to combinations of any number of streams of fluid, whether liquid, vaporous, or gaseous, the principles which have been applied to combinations of two streams by previous authors, and especially by Professor Zeuner, in his treatise entitled "das Locomotiven-Blasrohr" (Zürich, 1863). Several component streams of fluid, each coming through its own supply-tube and nozzle, are led in directions parallel to each other, into one end of a cylindrical space called the junction-chamber, in which they mingle so as to form a resultant stream; and that resultant stream escapes from the other end of the junction chamber through an orifice called the throat. The dynamical principle upon which the motion depends is that of the equality of impulse and momentum. The aggregate momentum per second of the component streams is found by multiplying the mass of fluid which comes from each nozzle in a second by its velocity, and adding together the products. The momentum of the resultant stream is the product of the mass of fluid discharged from the throat in a second, into the velocity at the throat. The difference of these two momenta is equal to the impulse per second exerted in the junction-chamber, which impulse is found by multiplying the area of the throat by the difference between the intensities of the pressure at the nozzle end and at the throat end of the chamber respectively. If there be a gain of momentum, the pressure at the throat is less than at the nozzles; if there be a loss of momentum, the pressure at the throat is greater than at the nozzles.

There is always a loss of energy, which is expended in producing eddies; unless the velocities of the component and resultant streams are all equal to each other. The amount of that loss can be calculated in any given case, by the help of the principle already stated; and that principle being expressed in the form of an equation, and taken together with another equation expressing the equality of the mass discharged at the throat to the sum of the masses which come through the nozzles, affords the means of solving various problems as to combined streams.

Abstract of a Paper on the Thermo-dynamic Acceleration and Retardation of Streams.—Professor W. J. M. Rankine, F.R.S.* The object of this paper is to state in a more general and comprehensive form than has hitherto been done to my knowledge, a thermo-dynamic and hydro-dynamic principle of which many particular cases are well known and understood. That principle may be stated as follows:—

In a steady stream of any fluid, the abstraction of heat at and near places of minimum pressure, and the addition of heat at and near places of maximum pressure, tend to produce acceleration; the addition of heat at and near places of minimum pressure, and the abstraction of heat at and near places of maximum pressure, tend to produce retardation; in a circulating stream, the quantity of energy of flow gained or lost in each complete circuit is equal to the quantity of energy lost or gained in the form of heat; and in the absence of friction, the ratios borne by that quantity to the heat added and the heat abstracted (of which it is the difference) are regulated by the absolute temperatures at which heat is added and abstracted, agreeably to the second law of thermo-dynamics.

Amongst particular cases of the thermo-dynamic acceleration and retardation of streams, the following may be specified:—

Acceleration by the addition of heat at and near a place of maximum pressure; the draught of a furnace; and the production of disturbances in the atmosphere in regions where the ground is hotter than the air.

Retardation by the abstraction of heat at and near a place of maximum pressure; the dying away of atmospheric disturbances in regions where the ground is colder than the air.

Acceleration by the abstraction of heat at and near a place of minimum pressure; the injector for feeding boilers, in which a jet of stream, being liquefied by the abstraction of heat, is enabled not only to force its way back into the boiler, but to sweep a current of additional water along with it; also, to a certain extent, the ejector-condenser.

The conduction of heat from the parts of a stream where the pressure and temperature are highest, to the parts of the same stream where the pressure and temperature are lowest, produces, according to the foregoing principles, a gradual and permanent retardation of the stream, independently of the agency of friction; and this is accompanied by the production of heat to an amount equivalent to the lost energy of flow.

* Printed in full in the "Philosophical Magazine" for October, 1870.

SECTION B.—CHEMICAL SCIENCE

On the Weldon Process for the Manufacture of Chlorine.—Mr. W. Weldon, F.C.S., the author, said the process was one for the manufacture of chlorine by means of a perpetually-regenerated reagent consisting mainly of a compound containing the elements of peroxide of manganese and lime, and which was previously unknown. He had described the process last year at the Exeter meeting, when it was in operation at only two works. It is now either in operation or on the point of being adopted at almost all the works in this country, and at a number of works in France and Germany. In consideration of the fact that the production of chlorine will probably be completely revolutionised by the Weldon process, and considering, likewise, that chlorine is largely prepared in the neighbourhood of Liverpool and in other parts of Lancashire, the author had agreed to the request of Prof. Roscoe that he should submit to the section a brief account of the practical results, which the process had been found to yield under more extended experience, and of the development which it had undergone during the year. The author first described the apparatus employed, and exhibited a small model of it, and then proceeded to state that the chloride of manganese, which results in the ordinary preparation of chlorine, and which is generally acid, is neutralised by adding to the liquor finely divided carbonate of lime. The liquor then consists of a neutral mixed solution of chloride of manganese and chloride of calcium, and contains, in suspension, a large quantity of sulphate of lime and smaller quantities of oxide of iron and alumina. The clear solution, after settling, is oxidised by passing into it a blast of atmospheric air from a blowing engine, and heated, if necessary, by a current of steam. Milk of lime is then run into the oxidiser until the liquid ceases to give a manganese reaction with solution of bleaching powder. A further quantity of milk of lime is added, and ultimately from eighty to eighty-five per cent. of the manganese is converted into peroxide. The mixture is allowed to settle, the chloride of calcium solution forming the supernatant liquid is run off, and the residual black mud containing the manganese peroxide is used in the stills where hydrochloric acid is decomposed and chlorine gas produced. A residual liquor such as was commenced with, results, and the round of operations is begun again; and so on, time after time indefinitely. After giving an outline of his mode of treating still liquor, Mr. Weldon described at considerable length the details of the process, both as to quantities of materials employed and obtained, and the nature of the chemical compounds formed at different stages of the process. As explained by Prof. Roscoe, the principle upon which the process depends is that, although when alone, the lower oxides of manganese cannot be oxidised by air and steam under the ordinary pressure to the state of dioxide, yet this is possible when one molecule of lime is present to each molecule of oxide of manganese. The manganous oxide is precipitated from the still liquors with the above excess of lime, and by the action of steam and air on this, a black powder, consisting of manganese dioxide and lime, or calcium manganite (MnO_2 Ca O), is formed. This compound is again capable of generating chlorine from hydrochloric acid, and thus the chlorine process is made continuous with a working loss of only 2⅜ per cent. of manganese.

A short discussion followed the reading of the paper, in the course of which Mr. Gossage stated that his experiments on the improvement of the chlorine process had extended over thirty-five years, and he was glad Mr. Weldon's efforts had been attended with such a large measure of success.

Air Pollution from Chemical Works.—Mr. Alfred E. Fletcher, F.C.S., one of the inspectors under the Alkali Act. The author remarked that during the progress of many manufacturing processes gases or vapours were given off, which passing into the surrounding air, polluted it and rendered it more or less unfit for animal or vegetable life. If all noxious vapours were to be suppressed by the summary stoppage of the manufacturing processes causing them, we must dispense with the use of a variety of useful substances; indeed, it might be said that every manufacture was accompanied at its birth by some offensive smell or smoke. Still, the public were right in requiring that noxious vapours should be reduced to a minimum. Those who were not acquainted with manufactures would be surprised at the large amount of noxious vapours discharged from works. He then referred to the direction which he thought future legislation should take, his opinion being, he said, guided by the observations of Dr. Angus Smith, in his reports as chief inspector under the Alkali Act. In places where complaints were made against manufacturers by farmers, as to damage to their crops by corrosive smoke, let the district be called "a manufacturing district," upon the requisition of a certain number of inhabitants. To such district an inspector should then be appointed, who should have power at any time to ascertain the nature and amount of gases escaping from the various works. At the end of each month, or a longer period, the inspector should publish a list of all the works in his district, with a number indicating the average amount of acid vapour he had found upon his visits. There the inspector's duties should terminate, as he should be neither prosecutor nor judge, but merely publish the facts ascertained, which the farmer himself could never have gathered. He contended that such a plan would be beneficial in its operation. It would be universal in its application, and would embrace every description of manufacturing works. Hitherto legislation had been partial. There was an Alkali Act, but it regulated the alkali manufacture only.

In the discussion it was strongly urged that over-legislation on this question should be avoided, and that the crops do not suffer to the extent which was sometimes imagined. The Alkali Act had been so far beneficial as to call the attention of manufacturers to the subject of air pollution, and they had been induced to employ improved apparatus at their works.

On the Phenomena of the Crystallisation of a Double Salt.—Mr. J. Berger Spence. Mr. Spence said that hitherto many scientific chemists had doubted the possibility of producing soda alum; but the results of upwards of fifty experiments which he had made conclusively showed that this salt can be produced under certain circumstances. The principal point of interest in Mr. Spence's paper consisted in the discovery, made by him, that the crystals are produced from an amorphous mass, which is formed when the solution is prepared at high densities. The immediate result of this discovery may be that the large quantity of ammonia which is now used in the production of alum will be displaced in favour of soda, and that the valuable fertiliser, ammonia, which has no intrinsic value in alum, will be given to the soil, which, in an economic point of view, will be of considerable advantage to the country.

SECTION C.—GEOLOGY

Report on British Fossil Corals.—Prof. P. M. Duncan. The distinction between the palæozoic and later coral faunas was shown to be not so exact as was supposed, and that the aporose and perforate corals existed in the palæozoic rocks, as well as rugose and tabulate forms, which latter had closely allied recent analogues. The report contained a new classification of the Tabulata, and entered into the Alcyonarian characters of the *Chætetinæ* and the Hydrozoan characteristics of the *Milleporidæ*.

On the Fossil Elephants from Malta.—Dr. Leith Adams. After referring to his former reports, communicated to the Association in 1865 and 1866, in which the situation and nature of the Maltese ossiferous caves were described, Dr. Leith Adams now submitted further observations on the elephantine remains which has been collected by him in enormous quantities in those localities, and pointed out the important results that might be expected to flow from the comparison of these materials with those which had been brought by Captain Spratt from Zebbug, in which the late Dr. Falconer, in the year 1862, had discerned the existence of a dwarf or pigmy species, together with that of a larger form. Subsequently, Mr. Busk, on proceeding to work out Captain Spratt's collection in detail, found reason to discriminate three distinct forms, one of the average dimensions of the existing African and Asiatic species, and two others, differing from each other not only in size, but, as it would appear, in other osteological characters, but both of comparatively small or dwarf stature. The Zebbug collection, however, afforded but very scanty evidence with respect to the largest form, whilst that made by Dr. Leith Adams abounds with its remains, and will consequently allow of the correct determination of the true relations of that form with the two smaller forms found in association with it, as well as with other existing and extinct species, and especially with *E. antiquus*, whose relations up to the present time have remained obscure. Mr. Busk, by whom the paper was communicated, exhibited specimens selected from Dr. Adams' collection, proving the existence of the three forms above adverted to.

Report on the Exploration of Kent's Cavern.—Mr. W. Pengelly. During the past year the committee had investigated the only portions of the eastern division of the cave which had remained unexplored. Those portions had been called by the Rev. J. McEnery, the North and South Sally Ports in the belief that they led to external openings. The South Sally Port has a south-east direction into the hill, and away from the hill-side; it occupies a space of 80 feet by 40 feet. It was filled with, first, a red cave-earth from 12 to 20 inches thick; second, a stalagmitic floor from 1 to 24 inches thick; and third, a cave-earth of unknown depth, but exceeding 5 feet. The diggings yielded a large number of bones—including several birds and a few fish—portions of antlers, and about 1,400 fragmentary and perfect teeth, some of them still attached to the jaw-bones. The teeth belonged to the following animals:—Horse, hyena, rhinoceros, bear, sheep, badger, fox, rabbit, elephant, deer, lion, ox, hare, and pig. Agglutinated lumps of wings and elitra of beetles. Besides these, twenty-one flint implements and flakes were found. The North Sally Port covers an area of 86 feet by 84 feet, and passes out to an opening in the eastern slope of the hill. The three layers described in the South Sally Port are found in this opening also, and the remains obtained in the excavations were the same as and in like proportions to those found in the South Sally Port. Smerdon's Passage was determined to be the entrance to the North Sally Port, and also to a previously unsuspected passage. Numerous remains were found in this passage.

SECTION D.—BIOLOGICAL SCIENCE

Professor Rolleston's Inaugural Address. (Continued from p. 427.)

Pathology has made a return to Physiology for much service she has received, and this in the following directions. Dr. W. Ogle has thrown much light on the physiology of the cervical sympathetic nervous system by his record of a pathological history to be found in the recently issued volume (vol. lii.) of the "Medico-Chirurgical Transactions." The rough and cruel experimentation of war has had its vivisections utilised for the elucidation of the physiology of nerves, and especially of their trophic function, by the valuable volume issued by the American Sanitary Commission, under the editorship of Dr. Austin Flint. Dr. Broadbent has done something towards elucidating the question of the localisation of functions in particular parts of the cerebral convolutions which was so extensively and so very exhaustively discussed at Norwich by his paper in our most useful and comprehensive Cambridge "Journal of Anatomy and Physiology," May 1870, "On the Cerebral Convolutions of a Deaf and Dumb Woman."

I take this opportunity of mentioning two valuable papers on the very practical question of the influence of the vagus upon the heart's action. One of these is a German paper by a gentleman who is a zoologist and comparative anatomist as well as a physiologist, Dr. A. B. Meyer, "Das Hemmungsnervenssystem des Herzen" is the title of his memoir, a separate publication as I think; the other is an abstract of a paper [I have not seen the paper published *in extenso* as yet] by Dr. Rutherford, "On the Influence of the Vagus upon the Vascular System," published in the Cambridge journal just referred to. Especially do I think Dr. Rutherford's view as to the vagus acting centrifugally as regards the stomach, and carrying stimulus, not thither but thence, to the medulla oblongata, which stimulus is then radiated downwards by a route formed distally by the splanchnic nerve, so as to produce inhibitory vascular dilatation in the neighbourhood of the pepetic cells, as worthy of attention.* A considerable number of the papers which will be read before this Section, indeed a considerable part of the Section itself, will be devoted to the Natural History of Man. Nothing, I apprehend, is more distinctive of the present phase of that "proper study of mankind" than the now accomplished formation of a close alliance between the students of archæology strict and proper and the biologist with the express purpose of jointly occupying and cultivating that vast territory. Literature and art and the products of the arts furnish each their data to the ethnologist and anthropologist in addition to those which it is the business of the anatomist, the physiologist, the palæontologist, and the physical geographer, to be acquainted with; nor can any conclusion attained to by filling up any single one of those lines of investigation be considered as definitely absolved from the condition of the provisional until it has been shown that it can never be put into opposition with any conclusion legitimately arrived at along any other of the routes specified. In political alliances the shortcomings of one party necessarily hamper and check the advance of the other; a failure in the means or in the perseverance of one party may bring the joint enterprise to a premature close; mutual forbearance, not to dwell longer upon extreme cases, may finally be as effectual in slackening progress as even mutual jealousies. No such disadvantages attach themselves to the alliance of literature with science, as the German "Archiv für Anthropologie," issued to the world under the joint management of Ecker the biologist and Lindenschmidt the antiquarian, will show any one who consults its pages, replete with many-sided but not superficial, multifarious but never inaccurate, information.

The antiquary is a little prone, if he will allow me to say so, when left alone, to make himself but a connoisseur; the historian, whilst striving to avoid the Scylla of judicial dulness, slides into the Charybdis of political partizanship; and the biologist not rarely shows himslf a little cold to matters of moral and social interest, whilst absorbed in the enthusiasm of speciality. The combination of minds varying in bent is found efficacious in correcting these aberrations, and by this combination we obtain that white and dry light which is so comforting to the eye of the truth-loving student, to say nothing as to its being so much stronger than the coloured rays which the work of one isolated student has sometimes cast upon it from the work of another. It would be invidious to speculate, and I have forborne from suggesting whether the literary contingent in the conquering though composite army has learnt more from observation of the methods and evolutions of the scientific contingent, or the scientific man from the observation of the literary; it is, however, neither invidious nor superfluous to congratulate the general public upon the necessity which these, like other allies, have been reduced to, of adopting one common code of signals, and discarding the exclusive use of their several and distinctive technicalities. Subjects of an universal interest have thus come to be treated, and that by persons now amongst us, in a language universally understanded of the people. I have been careful to include the Palæontologist amongst the scientific specialists whose peculiar researches have cast a helpful and indeed an indispensable light upon the history of the fates and fortunes of our species. But it is not organic science only which anthropology impresses into its service, and it would be the sheerest ingratitude to forget the help which the Mineralogist gives us in assigning the source whence the jade celt has come or could come, or to omit an acknowledgment of the toil of the analytical chemist, who has given the percentage of the tin in the bronze celt, or in the so-called "leaden" and therefore Roman coffin.

I am very well aware that many persons who have honoured me by listening to the last few sentences, have been thinking that it is at least premature to attempt to harmonise the two classes of evidence in question; and that the best advice that can be given to the two sets of workers severally is, that they should work independently of each other. Craniography is said, and by irrefragable authority, to be a most deceptive guide; works and articles on ethnology tell us stories of skulls being labelled, even in museums of the first order of merit, with such Janus-like tickets as "Etruscan Tyrol *or* Inca Peruvian;" and one of the most celebrated anthropotomists of the day, has been so impressed with the fact that Peruvian as well as Javanese and Ethiopian skulls may be found on living shoulders within the precincts of a single German university town, that he has busied himself with forming a pseudo-typical ethnological series from the source and area just indicated. Great has been the scandal thence accruing to craniography, and the collector of skulls has thence come to be looked upon as a dilettante with singular ghoul-like propensities, which are pardonable only because they relate only to savage races of modern days, or to cemeteries several hundred years old, but which are not to be regarded as being seriously scientific. Now to me the existence of such a way of estimating such a work appears to argue a sad amount of ignorance of the laws of the logic of practical life, or, indeed, of the chapters on "approximate generalisations," which any man, however unpractical, can read in a treatise on logic. A man's features and physiognomy are instinctively and intuitively, or, if you prefer so to put it, as a result of the accumulated social experiences of generations of men, taken as a more or less valuable and trustworthy indication of his character; were this not so, photographers would not, as I apprehend, and hope they do; make fortunes, yet the face is at least as often fallacious as an index of the mind as the skull is fallacious as an index of race. The story of the misconception by a physiognomist of the character of Socrates is familiar to us, as I think, from Lemprière's Dictionary; and it may serve to parallel the story which Blumenbach and Tilesius tell us of the exact correspondence of the proportions of a skull from Nukahiva with those of the Apollo Belvidere. The living faces in a gaol again, to put the same argument upon other grounds, are as dangerous to judge from as are the skulls in the museum; yet every detective is something like a professor of physiognomy, and most of them could

* Since writing as above I have seen, but have not read, a paper by Dr. Coats in Ludwig's "Arbeiten aus der Physiologischen Anstalt zu Leipzig" for the present year. The Wurtzburg Physiological Laboratory Reports for 1867-1868, contain, as is well known, a series of papers on this subject.

write a good commentary on Lavater. The true state of the case may, perhaps, be represented thus:—A person who has had a large series of crania through his hands, of the authenticity of which, as to place and data, he has himself had evidence, might express himself, perhaps, somewhat to the following effect if he were asked whether he had gathered from his examination of such a series any confidence as to his power of referring to, or excluding from, any such series, any skull which he had not seen before. He might say, "the human, like other highly-organised types of life, admits of great variety, aberrant forms arise, even in our own species, under conditions of the greatest uniformity possible to humanity; amongst savages great variety exists (see Bates, 'Naturalist on the Amazons,' ii. p. 129), even though they all of them may live the same 'dull grey life,' and die the same 'apathetic end;' and consequently it may never, except in the case of Australian or Esquimaux, and perhaps a few other crania, be quite safe to pledge oneself as to the nationality of a single skull. Still there is such a thing as craniographical type, and if half-a-dozen sets, consisting of ten crania apiece, each assortment having been taken from the cemeteries of some well-marked nationality, were set before me, I would venture to say, after consultation and comparison, especially with such assistance as that which an assembly such as this might furnish me with, that it might be possible to show that unassisted cranioscopy, if not invariably right, even under such favourable circumstances, was nevertheless not wrong in a very large number of cases." If it is true on the one hand that *in generalibus latet error*, it is true on the other that security is given us by the examination of large numbers for the accuracy and reliability of our averages, a principle which, Gratiolet informs us, is thoroughly recognised in Chinese metaphysics, and which he has formulated in the following words:—"L'invariabilité dans le milieu s'applique à tout. La verité n'est point dans un seul fait mais dans tous les faits; elle est dans les moyennes, c'est-à-dire dans une suite d'obstructions formalées après le plus grand nombre d'observations possibles." (Mémoire sur les Plis cérébraux, p. 93). The natural history sciences do not usually admit of the strictness which says that an exception, so far from proving a rule, proves it to be a bad one; rather are we wise in saying that in them at least the universality of assertion is in an inverse ratio to that of knowledge, and that the sweeping statements dear, as Aristotle long ago remarked (Rhetoric, ii. 21. 9 & 10.; ii. 22. 1.), to a class which he contrasts with the educated, are abhorrent to the mind of organic nature. It is true enough, as is sometimes said, that when opinions and assertions are always hooped in by qualifications, the style becomes embarrassed, and the meaning occasionally hard to be understood; but this difficulty is one which lies in the very nature of the case, and the real excellence of style does not consist in its lulling the attention and relieving the memory by throwing an alliterative ring on to the ear, but in the furnishing a closely fitting dress to thought, and an accurate representation of actual fact.

If we are told that the attempt to harmonise the results, not merely of cranioscopy, but of any and all natural science investigation, with the results of literary and linguistic research, is needless and even futile, this is simply equivalent to saying that one or other of these methods is worthless. For as Truth is one, if two routes, purporting both alike to lead to it, do not sooner or later converge and harmonise, this can only be because one or other of them fails to impinge upon the goal. It is true that by certain lines of investigation light is thrown upon a problem, but at a single point, and that all further prosecution of investigation along that line will but lead us off at a tangent. Still the throwing of even a single ray upon a dark surface is an achievement with a value of its own; and it is a cardinal rule in our sciences never to ignore the existence of seemingly contradictory data, in whatsoever quarter they may show themselves. For what would be said of an investigator of a subject such as physical geography, who should declare that he would pay no attention but to a single set of data, when he was discussing whether a particular archipelago had been formed by upheaval, or should be held to be the fragments and remnants of a disrupted continent; and that if geological evidence was in crying discord with his interpretation of the facts of the distribution of species, it was not his business to reconcile them. He would be held to have neglected his business, as you may see by a reference to Mr. Bentham's Address to the Linnean Society, May, 24, 1869. (Linn. Soc. Proc. for 1869, p. xcii.*)

The argument from identity of customs and practices to identity of race is liable to much the same objections and to much the same fallacies as is the argument from identity of cranial conformation. The case may be found admirably stated in Mr. Tylor's work on the "Early History of Mankind," p. 276, ed. 2, and I may say that the means of bringing the problem home to oneself may be found by a visit to any collection of flint implements. In such a collection as Mr. Tylor has pointed out, p. 205, we are very soon impressed with the marked uniformity which characterises these implements, whether modern or thousands of years old, whether found on this side of the world or the other. For example, a flint arrowhead which came into my hands a short time back, through the kindness of Lord Antrim, after having done duty in these iron times as a charm at the bottom of a water-tub for cattle in Ireland, was pointed out or at to me by a very distinguished Canadian naturalist, who was visiting Oxford the other day, as being closely similar to the weapons manufactured by the Canadian Indians. Now after such an experience one may do well to ask in Mr. Tylor's words ("Early History," p. 206):—

"How, then, is this remarkable uniformity to be explained? The principle that man does the same thing under the same circumstances will account for much, but it is very doubtful whether it can be stretched far enough to account for even the greater proportion of the facts in question. The other side of the argument is, of course, that resemblance is due to connection, and the truth is made up of the two, though in what proportions we do not know. It may be that, though the problem is too obscure to be worked out alone, the uniformity of development in different regions of the Stone age, may some day be successfully brought in with other lines of argument, based on deep-lying agreements in culture which tend to centralise the early history of races of very unlike appearances, and living in widely distant ages and countries."

If the psychological identity of our species may explain the identity of certain customs, its physiological identity may explain certain others. Some of this latter class are of a curious kind, and relate not to matters of social or family, but to matters of purely personal and individual interest, concerning as they do the sensibility, and with it, all the other functions of the living body. Such customs are the wearing of labrets, or lip-rings, nose-rings, and if I may add it without offence, of certain other rings, inserted in the wide region supplied by the fifth or tri-facial nerve. A physiological explanation may lie at the base of these practices, which appear to put at the disposal of the persons who adopt them a perennial means for setting up an irritation, whence reflex consequences in the course of reflex nutrition and reflex secretion, as of gastric juice, may flow. A curious book was written, or at least published, on the subject of these practices, and others akin to them, in 1653, by Dr. John Bulwer, a benevolent doctor, who paid attention to the care of the deaf and dumb previously, I think it is stated, to Dr. Wallis, and who consequently, with proper pride, if this precedence really belongs to him, signs himself "J. B. cognomento Chirosophus." The title of the book is "Anthropometamorphosis; Man Transformed, or the Artificial Changeling." I was made acquainted with its existence by my friend, Mr. Tomlinson, of Worcester College, from the library of which Society I procured a copy for consultation; the book is not rare I think; but I think it is little known, it contains much that is curious, and it is, inasmuch as it was written more than 200 years ago, ὅτ' ακήρατος ἦν ἔτι λείμων, from some, though not from all points of view, the more valuable. It is, I apprehend, to some of these customs, as well as to others, that Zimmerman—not the author of the work on Solitude, but Zimmerman the zoologist—alludes in a rather amusing passage, which may be found in the third volume of his larger work on the Distribution of Species, and on Zoology (see p. 257). I speak of the passage as amusing, it is more than that, or I would not quote it; indeed you will not see that it is particularly amusing unless I tell you that volumes ii. and iii. are of date 1783, and are dedicated to his own father, whilst volume i., of date 1778, is dedicated to "His Most Serene Highness and Lord, Ferdinand Duke of Brunswick, my Most Gracious Lord." Its quality of amusingness depends upon these dates, and the speculations they set us to make as to how the Duke had offended the man of science in the interval between 1778 and 1783. It may be a warning to Serene Dukes how they

* The following references to passages of the kind referred to above as to the unreliability of craniographical evidence may be useful:—Geographisches Jahrbuch, 1866, p. 481. Hyrtl, Topograph. Anatomie, i. p. 13. Henle, System. Anat. i. 198. Krause, Archiv für Anthropologie, ii. 1. Holder, *ibid.* See also His and Rütimeyer, and Eckers in their systematic works severally, the Crania Helvetica, and the Crania Germaniæ meridionalis.

treat men of science. It runs thus :—"If you argue from similarity of customs and ceremonies to identity of origin of two tribes under comparison, you must first show that these customs are not such as would naturally tend to the amelioration of the conditions of the inhabitants in the two countries under consideration, and would probably therefore, or can naturally suggest themselves to each of the races in question. Or there may be customs founded on innate folly and stupidity, and thus, for your argument to be valid, you must show that of two peoples widely separated, each cannot by any chance come into its own country to adopt the like foolish and stupid customs. For whilst two wise heads are to make out, each independently of the other and contemporaneously, a wise discovery or invention, it is much more likely in the calculation of chances, and considering the much greater number of fools and blockheads ('Thoren und Dummköpfen') that in two countries widely apart, closely similar follies should be simultaneously invented. And then, if the inventing fool happens to be a man of influence and consideration, *which is, by the way, an exceedingly frequent coincidence*, both the nations are likely to adopt the same foolish practice, and the historian and antiquarian after the lapse of some centuries, is likely to draw from this coincidence the conclusion that the two nations both sprang from the same stock." Judge and speculate for yourselves how the spirit which breathes in this passage was excited, but note its scientific value too. We must not forget that it is possible, in thought, at least, to dissociate the psychological unity of man from his specific identity even; and that as regards identity of race, it is only reasonable to expect that when similar needs are pressing, similar means for meeting them are not unlikely to be devised independently by members of two tribes who have for ages been separated from their original stocks. The question to be asked is, does the contrivance about which we are speculating, combine or does it not combine in itself so large a number of converging adaptations, as to render it upon the calculation of chances, unlikely that it should have been independently invented? Yet this very obvious principle has been neglected, or Lindenschmidt would not have found it necessary to say, that by laying too much stress upon certain points of national identity in the stones used for the formation of cromlechs or dolmens, the Hünenvolk might be made out to have chosen to settle only in those parts of Germany where erratic blocks of granite or other such large stones could be found! (Archiv für Anthropologie, iii. p. 115, 1868.)

Sir John Lubbock's recently published work on "The Origin of Civilisation," may, I anticipate, cause the history and genealogy of manners and customs to enter largely into the composition of our lists of papers. There is no need for me, as the author of the book is here himself to speak, as announced, for himself, to occupy your time in recommending his work; but I may be allowed to say that the utility of such pursuits as those which Sir John Lubbock's book treats of, receives some little illustration from the fact that, as we learn from him and from Mr. Tylor, the human mind blunders and errs and deceives itself in these subjects in just the same way as it does in the kindred, though more immediately arising, pressing and important matters of social and political life. In these latter spheres of observation we are apt occasionally to mistake one of those intermittent reactions of opinion, produced as eddies are produced in a river, by the deposit of sand and mud at angles in its onward course, for a deliberate giving up of the principles upon which all previous progress has been dependent. The straws which float upon the surface of a backwater may be taken as proofs that the river is about to flow upwards, and a feeble oarsman in a light boat may be deceived for some moments by the backward drifting of his small craft. Now an analogous blunder is often made in matters of purely historical interest; and we may do well to learn from the experience thus cheaply earned. "The history of the human race has," says Sir J. Lubbock, p. 322, *l. c.*, "I feel satisfied, on the whole been one of progress; I do not of course mean to say that every race is necessarily advancing; on the contrary, most of the lower are almost stationary," but Sir John regards these as exceptional instances, and points out that if the past history of man had been one of deterioration, we have but a groundless expectation of future improvement, whilst on the other, if the past has been one of progress, we may fairly hope that the future will be so also.

Mr. Tylor's words are equally to the purpose, though as forming the end of a chapter merely, and that at the end of the book, they are less enthusiastic in tone. (P. 193, Tylor, "Early History of Mankind.") They run thus—

"To judge from experience, it would seem that the world, when it has once got a firmer grasp of new knowledge or a new art, is very loath to lose it altogether, especially when it relates to matters important to man in general, for the conduct of his daily life, and the satisfaction of his daily wants, things that come home to men's 'business and bosoms.' An inspection of the geographical distribution of art and knowledge among mankind seems to give some grounds for the belief that the history of the lower races, as of the higher, is not the history of a course of degeneration or even of equal oscillations to and fro, but of a movement, which, in spite of frequent stops and relapses, has on the whole been forward; that there has been from age to age a growth in man's power over nature, which no degrading influences have been able permanently to check."

I must not trespass into the province of the Botanist, but I should be glad to say that no easier method of learning how the natural history sciences can be made to bear upon the history of man, as a whole, can be devised than that furnished by the perusal of such memoirs as those of Unger's upon the plants used for food by man. The very heading and title of the paper I am specially referring to appears to me to have an ambiguity about it which, in itself, is not a little instructive. In that title, "Botanische Streifzüge auf dem Gebiete der Cultur-Geschichte," the latter word may be taken, I imagine, etymologically at least, to refer either to culture proper or to agriculture. At any rate, the paper itself may be read in the Sitzungsberichte of the Vienna Academy for 1857; it has, I suppose, superseded the interesting chapters in Link's "Urwelt und Alterthum," of date 1821; and it is not unlikely, I apprehend, to be itself, in its turn, superseded also.

Coming, in the third place, to Zoology, I suppose I shall be justified in saying that the largest issue which has been raised in the current year, an issue for the examination of the data for deciding which the two months of July and August which are just past, may have furnished persons now present with opportunities, is the question of the kinship of the Ascidians to the Vertebrata. There is or was nothing better established till the appearance of Kowalewsky's paper, now about four years ago, than the existence of a wide gulph between the two great divisions of the animal kingdom, the Vertebrata and the Invertebrata; nothing could be more revolutionary than the views which would obviously rise out of his facts, and within the present year these facts have been abundantly confirmed by Prof. Kupfer, whose very clearly written and beautifully illustrated paper has just appeared in the current number of Schultze's "Archiv für Microscopische Anatomie." Kupfer's researches have been carried on upon *Ascidia canina*, but they more than confirm the accuracy of what Kowalewsky had stated to take place in *Ascidia mammillata*, and which may be summed up briefly thus: In the larval Ascidian we have in its caudal appendages an axis skeleton clearly analogous, if not essentiallly homologous, to the chorda dorsalis of the vertebrate embryo, as consisting like it of rows of internally-placed cells, and giving insertion by its sheath to muscles. We have further the nervous system and the digestive taking up in such embryos much the same positions relatively to each other, and to this molluscan chorda dorsalis, that are taken up by the confessedly homologous system in the Vertebrata; we have the nervous system originating in the same fashion and closing up like the vertebrate myelen cephalon out of the early form of a lamellar furrow into that of a closed tube; we have finally the respiratory and digestive inlets holding the vertebrate relationship of continuity with, instead of the invertebrate of dislocation and separation from each other. Such are the facts; but I am not convinced that they will bear the interpretation that has been put upon them; though I must say the possession of this chorda dorsalis by the active locomotor larva of the Ascidian which one day settles down into such immobility, lends not a little probability to Mr. Herbert Spencer's view of the genesis of the segmented vertebral column in animals undoubtedly vertebrate. But on this view I should not be inconsistent with myself, inasmuch as, to waive other considerations, the chorda dorsalis in each case would be considered as an adaptive or teleological modification, not a sign of morphological kinship. Much perplexity may or must arise here, and whilst entertaining these views, I felt myself bound to examine myself strictly to find whether in not taking them up, I might not be giving way to that reactionary reluctance to accept new ideas which advancing years so frequently bring with them; but a recent paper, by Lacaze Duthiers, published in the *Comptes Rendus* for May 30, 1870, and translated in the Annals and Magazine of Natural History for July, 1870, would justify me, I think, in calling that reluctance by another name. For in that paper the renowned malacologist just mentioned has brought to light the fact that there is another sessile and solitary Ascidian, the *Molgula tubulosa*, which goes through no such tadpole-like stage, as had been supposed to be gone through by all Ascidians except the Salpæ, which is never active and never puts out the activity which is so remarkable in the other Ascidians, but settles down and remains sedentary immediately after it is set free from the egg capsula, neither enjoying a Wanderjahr *nor possessing a chorda dorsalis*. We are not surprised after this that M. Lacaze Duthiers observes that "although embryology may and must furnish valuable information by itself, it may also, in some cases, lead us into the gravest errors." Mr. Hancock, of Newcastle-upon-Tyne, has sent us a paper upon this subject, which will be read duly, and duly noted by us.

Leaving Malacology, which has not in the United Kingdom obtained the same hold as yet upon the public mind that it has on the Continent, where, like Entomology, there and here, it has a periodical or two devoted to the recording of the discoveries of its votaries, I have much pleasure in directing attention to two short papers by Siebold in the *Zeitschrift für wissenschaftliche Zoologie* (xx. 2, 1870), on Parthenogenesis in *Polistes gallica v. Diadema*, and on Pædogenesis in the *Strepsiptera*. In each of these short papers Siebold informs us that adequate room and time could not be given them in the Innsbruck meeting held just a year ago, or in the report of the meeting. It is to me a matter of difficulty to think what there could have been of greater value than those papers in a section of Wissenschaftliche Zoologie; it will be to all present a matter of congratulation to learn from the venerable professor's papers that he will shortly favour us with a new work on the subject of Parthenogenesis. A fresh instance of Parthenogenesis in Dipten, in *Chironomus*, has just been put upon record in the St. Petersburg Imperial Academy's memoirs (xv. 8, Jan. 13, 1870).

The subject of the Geographical Distribution of the various forms of vegetable and animal life over the surface of the globe, and in the various media, air, earth, water, fresh and salt, whether deep or shallow, has always been, and will always remain, one of the most interesting subsections of biology. It was the contemplation of a simple case of geographical distribution in the Galapagos Archipelago which brought the author of the "Origin of Species" face to face with the problem which the title of his work embodies; and it is impossible that sets of analogous and of more complicated facts,—many of which, be it recollected, such as the combination now being effected between our own Fauna and Flora and those of Australia and New Zealand, are patent to the observations of the least observing,—should not, since the appearance of that book, force the serious consideration of the explanation it offers upon the thoughts of all who think at all. The wonders of the Deep Sea Fauna will, I apprehend, form one, the Commensalism of Professor Van Beneden another, subject of discussion, and furnish an opportunity for receiving instruction to all of us. The one set of observations is a striking exemplification of the way in which organisms have become suited to inorganic environments, the other is an all but equally striking exemplification of the way in which organisms can fit and adapt themselves to each other. The current journals have,* as was their duty, made us acquainted with what has been done in both of these directions, and I am happy to say that in the case of the Deep Sea Explorations as in that of Parthenogenesis and Spontaneous Generation, a new work, giving a connected and general view of the entire subject, is announced for publication.

One instance of the large proportions of the questions which the facts of geographical distribution bear upon, is furnished to us in the address recently delivered before the Geological Society by its president, who is also our president, aud who may have forgotten to refer to his own work (see NATURE, No. 24, 1870). Another may be found in the demonstration which Dr. Günther, contrary to our ordinarily taught doctrines, has given us (Zool. Soc. Trans. Vol. vi., pt. 7, 1868, p. 307) of the partial identity of the fish-faunas of the Atlantic and Pacific coasts of Central America; a third is furnished to us by Mr. Wallace's works *passim*.

It would be superfluous, after introducing even thus hurriedly to your notice so large a series of interesting and important subjects as being subjects with which we shall forthwith begin to deal in this Section, to say anything at length as to the advantages to be expected reasonably from the study of Biology. I may put its claims before you in a rough way by saying that I should be rejoiced indeed if when money comes to be granted by the Association for the following up the various lines of biological research upon which certain of its members are engaged, we could hope to obtain a one-hundredth, or I might say a thousandth part of the amount of money which has in the past year been lost to the State and to individuals through ignorance or disregard of biological laws now well established. I need say nothing of the suffering or death which anti-sanitary conditions entail, as surely as, though less palpably and rapidly than, a fire or a battle; and I might, if there were time for it, take my stand simply upon what is measurable by money. This I will not do, as it is less pleasant to speak of what has been lost than of that which has been or may be gained. And of this latter let me speak in a few words, and under two heads—the intellectual and the moral gains accruing from a study of the Natural History Sciences. As to the intellectual gains, the real psychologist and the true logician know very well that the discourse on method which comes from a man who is an actual investigator is worthy, even though it be but short and packed away in an Introduction or an Appendix, or though it cover but a couple of pages, like the "Regulæ Philosophandi" of Newton, more than whole columns of the "Sophistical Dialectic" of the ancient Schoolman and his modern followers. "If you wish your son to become a logician," said Johnson, "let him study Chillingworth"—meaning thereby that real vital knowledge of the arts and sciences can arise only out of the practice of reasoning; and as to the value of actual experimentation as a qualification for writing about method, Claude Bernard and Berthelot are, and I trust will long remain, living examples of what Descartes and Pascal, their fellow-countrymen, are illustrious departed examples. (See Janet, Revue de deux Mondes, tome lxii. p. 910, 1866.)

I pass on now to say a word on the working of natural science studies upon the faculty of attention, the faculty which has very often and very truly been spoken of as forming the connecting link between the intellectual and the moral elements of our immaterial nature. I am able to illustrate their beneficial working in producing carefulness and in enforcing perseverance, by a strong turning upon the use of, or rather upon the need for, a word. Von Baer, now the Nestor of biologists, after a long argumentation (Mem. Acad. Imp. Sci., St. Petersburg, 1859, p. 340) of the value which characterises his argumentations as to the affinities of certain Oceanic races, proceeds to consider how it is that certain of his predecessors in that sphere, or rather, in that hemisphere, as Mr. Wallace has taught us Oceania is very nearly, had so lamentably failed in attaining or coming anywhere near to the truth. This failure is ascribed to something which he calls "Ungenirtheit," a word which you will not find in a German dictionary, the thing itself not being, Von Baer says, German either. I am happy not to be able to find an exact equivalent for this word in any single English vocable, the opposite quality shows itself in facing conscientiously "the drudgery of details, without which drudgery," Dr. Temple tells us (Nine Schools Commission Report, vol. ii., p. 311), "nothing worth doing was ever yet done." Mr. Mill, I would add, speaks to the same effect, and even more appositely, as far as our purpose and our vocations are concerned, in his wise Inaugural Address at St. Andrews, p. 50. For the utter incompatibility of an ἀταλαίπωρος ζήτησις,—those two words give a Thucydidean rendering of "*Ungenirtheit*,"—with the successful investigation of natural problems, I would refer any man of thought, even though he be not a biologist, to a consideration of the way in which problems, as simple at first sight as the question of the feeding or non-feeding of the salmon in fresh water (see Dr. McIntosh, Linn. Soc. Proc., vii., p. 148), or that of the agencies whereby certain molluscs and annelids bore their way into wood, clay, or rocks must be investigated. It is easy to gather from such a consideration how severe are the requirements made by natural science investigations upon the liveliness and continuousness of our faculty of attention.

I shall speak of but one of the many purely moral benefits which may be reasonably regarded either as the fruit of a devotion to or as a preliminary to success in natural science. Of this I will speak in the words of Helmholtz, taking those words from a report of them as spoken at the meeting of the German Association for the Advancement of Science, which was held last year at Innsbruck. There Professor Helmholtz, in speaking of the distinctive characteristics of German scientific men, and of their truthfulness in particular, is reported to have used the following words:—

* See NATURE, No. 39, July 28, 1870, and "Royal Society's Proceedings," Aug. 1870, for Deep Sea Explorations, and *Academy*, Sept. 10, 1870, for Commensalism.

"Es hat diesen Vorzug auch wesentlich zu verdanken der *Sittenstrenge* und *der uneigennutzige Begeisterung* welche die Männer der Wissenschaft beherrscht und beseelt hat, und welche sie nicht gekehrt hat an aussere Vortheile und gesellschaftliche Meinungen." These words are, I think, to the effect that the characteristics in question are in reality to be ascribed to the *severe simplicity of manners* and *to the absence of a spirit of self-seeking*, which form the guiding and inspiring principles of their men of science, and prevent them from giving themselves up to the pursuit of mere worldly advantages, and from paying undue homage to the prejudices of society. I think *Sittenstrenge* may be considered as more or less adequately rendered by the words *severe simplicity of manners*; at any rate, as things are known by their opposites, let me say that it is the exact contradictory of that "*profound idleness and luxuriousness*" which, we are told by an excellent authority (the Rev. Mark Pattison, "Suggestions on Academic Organisation," p. 241),—for whose accuracy I would vouch in this matter were there any need so to do,—"*have corrupted the nature*" of a large class of young men amongst ourselves, whilst *the absence of a spirit of self-seeking* is, in its turn, the contradictory of a certain character which Mr. Mill (*l.c.*, p. 90), has said to be one of the commonest amongst us adults, and to which Mr. Matthew Arnold has assigned the very convenient epithet of "Philistine." Investigation as to whether these undesirable tendencies are really becoming more rife amongst us, might be carried on with advantage in a place such as this, in the way of inquiries addressed to colonists returning home after a successful sojourn abroad. Such persons are able to note differences without prejudice, and, *ex hypothesi*, with unjaundiced eyes, which we are apt to overlook, as they may have grown up gradually and slowly. But, perhaps, researches of this kind are not quite precisely the particular kind of investigation with which we should busy ourselves; neither would the leaders of fashion, the persons with whom all the responsibility for this illimitable mischief rests, be very likely to listen to any statistics of ours, their ears being filled with very different sounds from any that, as I hope, will ever come from Section D. Whether men of science in England are more or less amenable to blame in this matter than the rest of their countrymen, it does not become us to say; but it does become and concern us to recollect that we have particular and special reasons, and those not far to seek, nor dependent on authority alone, for believing and acting upon the belief that real success in our course of life is incompatible with a spirit of self-seeking and with habits of even refined self-indulgence.

Department of Ethnology and Anthropology.—John Evans, F.R.S., in the chair.

Before commencing the business of the department, Mr. Evans offered a few remarks as to the subjects that properly came within the province of the department—the present condition of knowledge of those subjects, and the methods at command for increasing that knowledge. The subjects which may with propriety be brought under the consideration of the Department may approximately be defined as:—(1) all that relates to the antiquity of man, or the origin of the various races of mankind; (2) all that illustrates the progress and development of human civilisation; and (3) all that concerns the condition of the less civilised portions of the human race, even if not immediately connected with any general question of its origin or progress. The President then proceeded to show what an enormous field these subjects embrace, how much there is still to learn in the means of investigating them, notwithstanding the efforts of the numerous labourers, who have now for many years been employed in this field of research, and concluded a very interesting address by expressing his confidence that nothing would be said calculated to injure the feelings of any who, like ourselves, are in pursuit of truth, and that all will bear in mind how difficult it is to take in the whole of any single truth at one view, and how, of its many sides, two contending parties may each be seeing one only, and that possibly not the most important.

On the Principal Geological Changes which have occurred in Europe since the Appearance of Man.—Professor P. Martin Duncan, F.R.S., F.G.S., &c.

This short communication does not pretend to offer any new facts or opinions; but I trust that it will be found to be a truthful representation of the results of the more important labours of men who have laboured so sedulously and conscientiously on the subject of the antiquity of man. As such, I hope the paper will be of interest to the associates of the Section, although I cannot anticipate that it will yield any satisfaction to my more learned colleagues.

Most of the geological changes which have occurred since man first appeared in Europe are estimated and asserted in consequence of the results of direct observation upon the succession of phenomena which belong to the debatable ground between what is usually termed physical geography and geology. Some, however, are dependent upon the arguments which are brought forward by naturalists respecting the limitation and separation of parts of great natural history provinces.

For instance, if the remains of man or his early works are found in sediments high up on the sides of valleys, the sediments having been produced by the river when it flowed far above its present level, the vertical distance between the remains and the existing water-level affords evidence of geological or physico-geographical changes. And if a vast number of bones belonging to extinct and existing species of large animals, such as elephants and rhinocerides, hyænæ and lions, are found upon islands the area of which could not possibly have sustained and nourished the mammalia during life, the separation of the areas from the nearest continent is inferred, especially if the species are still existing there, or if their remains abound there.

It is necessary to premise that no trace of man has been found associated with any deposits which are formed during the Glacial Period in Northern Europe. The very nature of them would prevent such a discovery.

The loftiest mountains of Europe, such as the Alps, Pyrenees, Ardennes, and Vosges, underwent a great grinding down during the Glacial Period; and when it was over the results of this wear and tear were scattered far and wide all around them in the form of wash-down, gravel, and more or less angular stones. In a general view, this gravel, the result of the first glacialisation, is of the same geological age as the drift gravel of England north of the Thames, and of Northern Germany, which is called glacial drift, and which, as I have just observed, is older than the earliest traces of man in Europe. The earliest remains of man and his works, and of the beasts associated with him and hunted by him, rest upon these deposits, and are therefore later in time.

It would appear that man followed up the retreating ice of the north of Europe, for the remains of his works are found high up in many British valleys, which must then have begun to be formed by the natural drainage out of the deposits of the Glacial Period.

Now, after a time, there was another period of mountain glacialisation; and the glaciers of the Alps and Pyrenees, especially, extended far into the districts below them.

The grinding down of the mountain sides during this second glacialisation produced enormous quantities of mud and gravel; and when the glaciers retreated this detritus was washed far and wide over the plains. This deposit is constantly found to cover the remains of man and his works, and is therefore later in time.

The second glacialisation, and the dispersal of the wash-down, appears to form a rude line of separation between the Palæolithic Period, when man used rude stone weapons, and the Neolithic Period, when smooth or polished implements were made by him; and they also, in a general sense, mark the time when the great mammalia, the early prey of man, disappeared from the northern and western parts of Europe.

The following are the principal geological changes which occurred after the appearance of man in Europe:—

1. The subsidence of an area of land which connected Sicily with Crete and Northern Africa north of the Sahara.

2. The formation of a volcanic tufa on the hills bordering the present valleys of the Tiber and its tributaries; the excavation of those valleys by the river and its streams; the last eruption of the volcanoes of Latium, and their permanent extinction. The space included in the Roman territory has received its contour, and vast tracts near the coast have been worn away.

3. The formation of valleys in the Alpine detritus, which covered up large tracts of Northern Italy, and the re-excavation of old valleys, which had been more or less filled with the detritus. This great gravel was the wash-down of the wear and tear of the first extension of the south Alpine glaciers, and was, in a general sense, contemporaneous with the upper glacial drift of Northern Europe. It was deposited before man, as traced by his relics and works, lived in South Europe.

The dispersal of vast depths of silt and gravel over the plains into the valleys and far up the hill sides of the Sardinian States and Lombardo-Venetia, south, and to a certain extent south-east, of the Alps; the result of the wash-down of the wear and tear of the second extension of the Alpine glaciers; the formation of valleys in this gravel or silt, and the production of such heights as those which bound such plateaux as Rivoli.

4. Considerable local alterations in the relative level of land and sea along the west Neapolitan coast.

5. The formation of the straits of Gibraltar.

6. The excavation of such valleys as that of the Manganores in Central Spain, the formation of gravels containing flint implements and mammalian bones near Madrid, and therefore far beyond the influence of marine action.

7. The wearing down of many of the valleys to the north of the Pyrenees below the level of such lower mammaliferous caves as those in the neighbourhood of Tarascon; the dispersion of the results of the wear and tear of the second extension of the Pyrenean glaciers, and the filling up of the old valleys with it; the re-excavation of the valleys, and the carrying down of their silt or loess to the plains; the formation of streams and water-courses through this deposit.

8. The formation of certain valleys in the Perigord by streams to a certain extent, but principally by the gradual effects of rain, heat, frost, and other meteorological actions.

9. The excavation of the valleys of North and Eastern France, and the denudation and retrogression of their watersheds.

10. The dispersion of Alpine rocks, gravels, and rocks to the north of the Alps, produced by the wear and tear of the great glacialisation, which was, in a general sense, contemporaneous with the first extension of the glaciers south of the Alps, and the first extension of the Pyrenean glaciers, occurred before man appeared in Europe. After his first wanderings and huntings he left his remains above this old Alpine detritus. Then the valleys in the carboniferous limestone of Belgium were worn down ninety yards or more by rain and rivers, and the bones of the extinct mammalia and rude stone implements and bones of man were washed into caves with the gravel.

After the retirement of the glaciers, subsequent to this second extension, the wash-down of the Alps, Vosges, and Ardennes was spread over the older gravel. It filled up the valleys, and extended with a thickness varying from a few yards to a thousand feet and more, all down and over what is now the valley of the Rhine, Holland, and Belgium. The loess thus formed was then washed out of the valleys, was cut into by rivers, and has been worn down ever since.

11. The separation of the coasts of France and England about Dover and Calais.

12. The excavation of nearly all the valleys in the district east of a line drawn from King's Lynn to Portland, the denudation of their watersheds, and retrogression of the river sources.

13. The denudation of the valley of the Weald of Kent.

14. The separation of the Isle of Wight from the main land.

15. The formation of a great part of the Bristol Channel.

16. The upheaval of many sea beaches, and the general destruction of forest land on the south and west of England; the formation of many peats.

17. Enormous destruction of the sea coast.

18. A sufficient upheaval of the Scandinavian peninsula and Denmark, to produce such a restriction of the outlet as has determined a change in the marine fauna of the Baltic.

19. A slow upheaval of large areas appears to have accompanied the excavation of the valleys upon them, and a subsidence of equally large districts appears to have accompanied the recession of the second glaciers; probably another upheaval followed.

20. The uprise of the Desert of Sahara in Africa after the second extension of the Alpine glaciers.

SECTION E.—GEOGRAPHICAL SCIENCE

On Atmospheric Currents.—Mr. J. K. Laughton. In examining into the geographical distribution of winds, we must bear in mind that well-attested and careful observation is the only satisfactory basis, and that descriptions founded on theoretical opinions are of no value whatever. If we refer Hadley's Theory of the Trade Winds to this test, we find, *in the first place*, that the effect of heat in producing wind is not quite such as has been represented. Experimentally, heat does not produce a blast, unless the space between the heat and cold air be very confined, as is roughly shown by holding a newspaper before the fire. Geographically, heat does not cause a wind towards any of the principal areas of greatest temperature; either towards the Great African Desert, the Desert of Arabia, or of Australia, towards the Red Sea or the Persian Gulf, or even, when carefully traced, towards the Great Prairie of North America. *In the second place*, we find that the effect attributed to the rotation of the earth is not consistent with numerous observed facts, such as the S.E. wind in the Gulf of Mexico, the N.W. wind on the coast of North Africa, the N.W. gales in the North Atlantic, the S.W. wind on the south coast of Australia, and very many others; and, indeed, the idea appears to have originated in a temporary forgetfulness of the power of friction, which in the case of air and all fluids is very intense.

Winds, which, in accordance with Hadley's theory, have been very generally divided into *polar* and *equatorial*, seem more naturally to divide themselves into *easterly* and *westerly*; and it is this division which has, from the days of Columbus, been adopted by really practical men, to whom the winds were matters of fact, not of mere theory; but the trade-winds—having attracted early notice by their very great steadiness and regularity—have always been considered as the direct manifestations of the first cause, whatever it might be, of the great atmospheric movements; the westerly winds, which were not discovered till much later, having been considered as secondary and comparatively of little importance. But, as our experience grows larger, we learn that the westerly winds have an extent and a strength and a rude vigour incompatible with the idea of their secondary nature. Whether in the northern or southern hemisphere, they are exceedingly violent and boisterous; and, without considering the Arctic and Antarctic regions, concerning which we have not sufficient evidence, they extend from 60° N. to 60° S., interrupted only by the trade-winds, which blow over an area large indeed, but small *in comparison* with that on which they intrude. The trade-winds are also of very limited height, whilst above them the westerly winds blow as strongly as they do in the temperate zones, where they reach into the upper strata of the atmosphere as far as we have any knowledge. We are thus led towards the conclusion that the westerly winds are really the primary winds, far extending and boisterous; whilst the quiet equable trade-winds—of very limited volume—are reflex streams of air caused by the impact of the great westerly winds on the continental barriers, whether against mountain ranges or the more sluggish air which lies over the land. The Atlantic Ocean affords us the most familiar illustrations of this; where we see the main westerly stream dividing on about the parallel of 45° N., and turning north, as a south-westerly wind on our coasts, and the coast of Norway; or south, as a north-west and northerly wind on the coast of Portugal, and a north-easterly on the coast of Africa; whilst the rest of it forces its way onward, a westerly wind over Northern Europe and Asia, or a northerly deflection in the several basins of the Mediterranean. On the other hand, on the extreme west, the westerly wind continually dragging away the air from the eastern side of the Rocky Mountains, causes such a tendency towards a vacuum, that the air from the south and north is induced towards it, and the wind over Western America rules from the south or north, according as the season throws the axial line of the temperate zone to the north or south of its mean position. Examining at great length into the various local winds and irregularities in the different parts of the world, we arrive at the conclusion that the whole atmosphere has a continued tendency to move from west to east, and does so more when it is not interrupted. The interruptions are of two kinds: one occasional and irregular, being caused by fluctuations in the hydrostatic condition of the air, the other permanent or seasonal and regular, caused by the pressure of lines of coast and mountain ranges.

It is impossible to say definitely why the atmosphere should have this prevailing motion; but if the cause is neither heat nor the influence of the earth's rotation, nor any agency which we can detect at work on the earth, we are driven almost insensibly to the belief that it must be the result of celestial attraction; and the fact that the barometer shows no trace of any noteworthy rise or fall, as of an atmospheric tide, suggests that the atmospheric currents, which must necessarily be formed by the action of such an intense disturbing force, do not in any way clash, but flow uninterruptedly onwards in one certain direction, either towards the east or towards the west. All observation shows us that there is not a permanent current towards the west, but that there is one towards the east; and although we are unable at present to master all the details of the manner of the motion, the evidence of geographical fact, combined with that of astronomical possibility, justifies us in inclining towards the belief that the motive force for which we are seeking is really the disturbing force of the attraction of the heavenly bodies.

SECTION G.—*Mechanical Science.*—President, Mr. Charles B. Vignoles, F.R.S., Pres. C.E.

In his introductory address, bearing chiefly on railway development and the defence of the country, the President remarked that that day, the 15th of September, was the anniversary of an event in which Liverpool played a most important part forty years ago. The opening of the Liverpool and Manchester Railway was entirely owing to the high public spirit shown by the merchants of Liverpool. At that time the ways and means of communication were so completely crippled that the trade of Liverpool would have become paralysed, had not better, speedier, and cheaper means of communication been created, and especially by the opening of the railway connecting Liverpool and Manchester. In this great work Liverpool took the lead; and it was particularly owing to the zeal of one of Liverpool's most distinguished citizens, the late Mr. Henry Booth, who was the original secretary of the railway company, and to the energy and scientific knowledge which he brought to bear upon the question of railways, that attention was paid to the improvements of the steam-engine, which was now performing such wonders both at home and abroad. He (the President) thought the people of Liverpool had not shown themselves sufficiently grateful to the memory of Mr. Henry Booth in allowing his name to lapse, as it were, from public recollection; but he was glad to have been invited to a meeting held in Liverpool a short time ago, at which a subscription was inaugurated for the raising of a statue to that eminent man and successful worker in mechanical science. The subscription list needed only a little addition to complete this most desirable object. Liverpool was peculiarly appropriate for this meeting of the British Association, for that Association and the railway system might be said to have had their birth in the same year, both having originated just forty years ago. He had himself taken part in laying down the Liverpool and Manchester Railway, and felt a special interest in this anniversary. The President then went on to mention the principal subjects which would be discussed in that Section. He next referred to the position of this country in regard to the means and preparedness for military defence, and as to the military service of England. He might, perhaps, be disabusing the minds of many persons who had supposed that the Government of this country was not prepared or was not alive to the necessity of creating the best means of internal communication, in the event of war or invasion of the country, when he mentioned to them that for several years past the military authorities had been in constant communication with the chief engineers of the country, and had formed deliberate arrangements, by which, in the event of such a casualty as a military invasion of England, within forty-eight hours the military forces of the whole country, say 100,000 men, might be brought down upon any given point that might be attacked. Therefore they might feel reassured as to the position of England in case of an invasion. As an old soldier himself, he had, at the request of the Government, treated this question, and had shown completely that within twelve hours of the alarm of invasion at any given point, the rolling stock of the railways of the country could be applied for concentrating all the military resources of the country upon the point threatened. He had stated in Liverpool forty-one years ago that the institution of railways would have this very result; and it had been practically exemplified in the war that was raging on the Continent. On Tuesday, he might mention, papers would be read upon the construction and stability of ships by some of the most distinguished men in the country, bearing upon the most unfortunate accident that had occurred to the ironclad steamship *Captain*, to the causes of which the attention of the whole scientific world was now being directed.

REPORT OF THE COMMITTEE ON BOILER EXPLOSIONS

Mr. Lavington E. Fletcher, C.E., reporter. The other members of the Committee were Sir William Fairbairn, Bart., C.E., F.R.S., LL.D., &c.; Sir Joseph Whitworth, Bart., C.E., F.R.S.; John Penn, C.E., F.R.S.; Frederick J. Bramwell, C.E.; Hugh Mason, Samuel Rigby, Thomas Schofield, Charles F. Beyer, C.E.; and Thomas Webster, Q.C., F.R.S.

In concluding their report, the committee stated that they decidedly incline to the plan of enforcing inspection directly by law rather than indirectly by penalty. They are not without apprehensions that, however ingeniously the principle of joint-stock insurance might be surrounded with a series of checks and counterchecks, yet that it would lead to inspection being cut down to the lowest possible point. On the other hand, were the inspection enforced by law, and nationally administered either by a central steam board or by a series of district ones, they consider that a far more generous system would be secured. The steam boards, uninfluenced either by private or local interests, or by the desire to accumulate profits, would take altogether higher ground, and inspect, not simply in their own interests, and just sufficiently to narrowly escape explosion, but with a view to assist steam users, disseminate practical information on the making and management of boilers, and promote progress. These objects would be altogether foreign to competing joint-stock insurance companies. The committee hold the view that, had coroners' verdicts been as satisfactory as they might have been, boiler explosions would not have been as numerous as they now are. With the additional experience of another year they feel compelled to take one other step in advance, and they have come to the conclusion that the time has arrived when the Government should enforce the periodical inspection of all steam boilers. They are convinced that explosions might be, and ought to be, prevented; that competent inspection is adequate for this purpose, and that any well-organised system of inspection extended throughout the entire country would practically extinguish boiler explosions, and save the greater part of the seventy-five lives now annually sacrificed thereby.

A paper on the same subject was read by Mr. E. B. Marten, C.E., and the discussion was taken upon both communications. The speakers were Sir William Fairbairn, Mr. Siemens, Sir Joseph Whitworth, Messrs. Hawksley, Bramwell, Rigby, Longridge, Gray, Mallet, Sir William Armstrong, and the President. In summing up, the President remarked that many accidents were attributable to the dishonest construction of boilers. English habits seemed to kick against anything like Government interference, but such accidents as had arisen from boiler explosions should be put an end to as forcibly as possible—like stamping out the smallpox or the cattle plague, notwithstanding vulgar prejudices—if necessary, by an iron hand. The Government should pass a law making the inspection of boilers compulsory.

On Mechanical Stoking.—Messrs. James Smith and J. and T. Vicars, Liverpool. The paper is too long to reproduce here, but we may mention, in reference to the method described in it, that Mr. L. E. Fletcher, C.E., of the Steam Users' Association, remarked that he had witnessed some very carefully-conducted trials with the apparatus as against very careful hand-firing, and that he could testify that the furnace was perfectly smokeless, and in every respect attained good results.

THURSDAY, OCTOBER 6, 1870

SCIENTIFIC ADMINISTRATION

NO reflecting Englishman can contemplate the great events of the present time without desiring to extract from them such warnings and instruction as may be serviceable to his country in case she should be drawn into war. Accordingly the press teems with discussions on every branch of the military art. We leave these to others. In what respects the constitution, the discipline, the training, and the arming of one army are superior to those of the other, it is scarcely the function of this journal to point out. Taking the broad fact that the Prussian army has, up to the present point, proved itself superior on the whole to that of France, and indeed to any army that has ever existed—a fact that no unprejudiced person will deny—let us ascertain, if we can, whether there may not be recognised some one broad cause to account for so broad a fact.

In this inquiry we have been almost forestalled by the Chancellor of the Exchequer at Elgin. Mr. Lowe recited the lessons which he considered we have to learn from the Prussians. He spoke of their "intelligence," their "organisation and docility," their "extraordinary knowledge, forecast, and diligence." He enumerated nearly all the qualities that command success. But there was one word which that profuse enumeration did not contain—a word which Mr. Lowe no doubt felt unable to utter, and that word is—Science. A Government which refuses aid to astronomers anxious to observe so rare a phenomenon as a total solar eclipse, cannot be expected to vaunt the prowess of science. Mr. Lowe's statement of the causes of Prussian success was therefore incomplete; it was a mere reckoning of the bricks of the building, without a word of its architecture and design.

The Prussians, whatever their other qualities, are emphatically a scientific people, and to that predominating characteristic first and foremost are their recent military triumphs due. We do not mean that because they are great chemists, astronomers, and physicists, therefore are they necessarily great soldiers; so narrow a proposition would hardly be tenable. What we mean is that the spirit of science possesses the entire nation, and shows itself, not only by the encouragement given throughout Germany to physical research, but above all by the scientific method conspicuous in all their arrangements. What does the word Science, used in its wider sense, imply? Simply the employment of means adequate to the attainment of a desired end. Whether that end be the constitution of a government, the organisation of an army or navy, the spread of learning, or the repression of crime, if the means adopted have attained the object, then science has been at work. The method is the same, to whatever purpose applied. The same method is necessary to raise, organise, and equip a battalion, as to perform a chemical experiment. It is this great truth that the Germans, above all other nations, if not alone amongst nations, have thoroughly realised and applied. In all the vast combinations and enterprises with which they have astounded the world, no one has been able to point to a single deficiency in any one essential element. Every post has been adequately filled and every want provided for; from the monarch, the statesman, and the strategist, to the lowest grade in the army—each department complete, each arm of the service, whether cavalry, infantry, or artillery, trained to its own special duties, and efficiently equipped for their performance. This is the method of science, literally the same method which teaches the chemist to prepare his retort, his furnace, and his re-agents, before commencing his experiment.

This, we maintain, is the great lesson, of a material kind, which the war should teach us. Where is our science? At the Admiralty and the War Office, partisan placemen preside over technical administrations. Is that science? Under pressure of the newspapers or of private influence, a ship of war is built by an amateur in spite of the demonstration of our professional adviser that she must be unsafe, and she goes accordingly to the bottom with 500 souls in the first gale of wind. Is that science? One-half of the forces on which we reckon for the defence of the nation is composed of patriotic volunteers, with whom training is optional, and to whom efficient officers and arms are denied. Is that science? The government of London, the greatest metropolis in the world, is parcelled out to scattered knots of ignorant, sordid tradesmen, on whom no ingenuity has ever been able to fix a shadow of responsibility. Is that science? Have we before us the crudest outline of the strategical and military operations with which it is proposed that an invasion of this country should be repelled? Coming political policies always, in England, cast their shadows long before. Have we any indications of a coming military policy? Have we the means of calling together, in a short space of time, properly provided with the necessaries of a campaign, the forces requisite for carrying out a given military policy? Do we know, for instance, how our volunteers, who are reckoned on, man for man, as equivalent to regular troops, are to be employed?

We fear it is a terrible truth that absence of scientific method is as conspicuous with us as its presence is with the Germans. As a nation, we have never realised the necessity for system and completeness in utilising our material resources. The use for the scientifically trained mind has, in our idea, been limited to chemicals and the like.

In courage, energy, intelligence, and wealth, natural and acquired, England need shrink from no comparisons with other nations, but she has yet to awake to the want of that something in her arrangements that shall enable her to turn her enormous advantages to the best account. Science, using the word in its sense of the method applied to things, not to the things themselves, is that something.

OWENS COLLEGE, MANCHESTER

OCCASIONS may sometimes arise, and in fact have already arisen, when it becomes a necessity for a journal like ourselves, devoted exclusively to scientific matters, to direct some attention to what is going on around it in the general world. One of these lately occurred, and caused us to make the remarks we did recently on the apathy displayed by the Government towards scientific research. This week, in a similar manner, we desire to call the attention of our readers to some proceedings which took place on the 23rd ult. in Manchester. This we do because of the great interest these proceedings have to all scientific men, both on account of the ultimate benefit science generally will attain through them, and also on account of some one or two very remarkable speeches made on the occasion.

The laying of the foundation-stone of the new Owens College building by the Duke of Devonshire, its newly elected president, is an event of national importance. For in it we see clearly—and such is the view held by all the professors and governors of that institution—the beginning of the great Scientific University of the North of England. Owens College was founded some twenty years ago by the munificent bequest of Mr. John Owens, a Manchester merchant of the old school, who left his money to found an endowment for the promotion of learning in his native town of Manchester. He was wise enough to stipulate that his money should not be employed for any building purposes, but solely towards educational purposes, leaving it to his fellow-townsmen to provide the house accommodation. This was done at first on a small scale, but Owens College has been from that time gradually increasing in numbers year by year, until a few years ago it was found absolutely necessary that new buildings should be obtained to meet the constantly augmenting number of students. Subscriptions were immediately set on foot, and in a short time something like 130,000*l.* was raised. With this the present buildings have been undertaken. On Friday week the foundation-stone was laid by the Duke of Devonshire, in the presence of the Bishop of Manchester, Professor Huxley, Professor Tyndall, and all the professors and governors, and the chief notabilities of Manchester. In the address presented to the Duke of Devonshire, it is stated that the projected buildings will provide for 600 day students, and a much larger number of evening students, and will include both chemical and physical laboratories. The architect, Mr. Waterhouse, has provided for the permanent accommodation of the Natural History and Geological Museums, presented by the late Manchester Natural History Society and the Manchester Geological Society, and also for the large library and various lecture and examination rooms.

The Duke of Devonshire, in laying the stone, remarked that he looked upon this day as one very celebrated in the annals of Manchester, and one destined to make Manchester more and more renowned at no distant date, as possessing a college second to none in England, and one which would become the centre of the scientific culture of the north of England. No year passes without some considerable benefactions being made to the college, and as fast as funds accumulate, new professorships in all branches of science are being founded, and the college has already become one of quite national importance.

Professor Huxley and Professor Tyndall also spoke, the former congratulating the town on the great results it has attained without any State aid, this State aid having been refused, and showing the great benefits which could not fail to attend the increased college accommodation in the great manufacturing and mining district all round Manchester; and the latter showing that the past work achieved by the eminent and able professors of the college was a sure guarantee of the work which would be done in the future.

The proceedings wound up with a luncheon in the Town Hall, at which the most remarkable speech of the day was delivered by the Bishop of Manchester, Dr. Frazer. In replying to the toast of the Bishop of Manchester and the clergy of all denominations, he said he had no hesitation in replying to this toast, as Owens College had been founded for educational purposes, without any reference to special religious bodies, and he continued—

"I take a very large, broad, and comprehensive view of what is meant by Truth. I believe that everybody who earnestly seeks to propagate the truth, to preach the truth in the largest sense of the word, is doing good to his fellow men. I never believed that true Science is contrary to true Religion, or that true Religion ought to be afraid of any legitimate consequences of true Science. I know well, and the knowledge makes me speak with some tremulousness, that I am in the presence of those who are considered to be, and who have established their right to be considered to be, the ablest interpreters of the laws and phenomena of the physical and material world. I cordially welcome those gentlemen as teachers and propounders of the truth. If scientific men will only believe that we, the clergy of this kingdom, are not sceptics in disguise, or charlatans trying to palm off upon the world something that has been found to fail; if they will only believe that we want to tread calmly, step after step, where we find our remedies have succeeded, I think they will allow that we are searching after truth, the only truth I care to find—practical truth—truth that will elevate man in the scale of being—and I think they will admit that we are trying to follow out truth by strictly scientific methods. I do not care from what source it comes; I will welcome every means which is calculated to settle the disputed boundaries between Religion and Science, and show that both alike, in their legitimate province, minister to, and help to bind up the great temple of Truth."

The fearlessness with which the Bishop thought it his duty to speak out, would, if followed throughout the whole of England, serve to overthrow that unfortunate antagonism there is at present between Religion and Science, founded on an entire misconception of the aims and the value of the latter as compared to the former.

The further proceedings on this interesting occasion were the delivery of some very instructive speeches by Profs. Huxley and Tyndall, and also by Prof. Henry, of the Smithsonian Institution, Washington, which, however, our space prevents us from further noticing. Certain it is, however, that the proceedings of the opening day are such as every scientific man throughout the kingdom will welcome with pleasure, and we cannot doubt that a report of them will be interesting to our readers. We hope that this occasion will inaugurate a new era for science, and will serve to bind together in the strongest bands those untiring workers in the pursuit of truth, whether they be scientific men or the clergy of all denominations.

The present Government has so far entirely refused to assist Owens College by any grant of money similar to that which a few years ago fell to the share of Glasgow University. The Government alleges that since the Manchester merchants have done so much for the college they can easily do more, and so complete the good work they have so well commenced. A stranger and more disheartening reason it would be hard to imagine. Our rulers appear to have yet to learn that there is such a thing as principle in the application of public money to the promotion of the real progress of the nation. We look forward to the report of the Science Commission to define the principles on which these grants should rest; and we trust we may then have a Government both capable of understanding what these principles are, and of firmness in carrying them out into practice.

J. P. E.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Aurora Borealis

THE Aurora Borealis noticed in the *Times* was observed here on Saturday the 24th inst. between 9 and 11 P.M. Another was observed on Sunday the 25th between 2.30 and 3.15 A.M.; and again another on the same day about 8.30 P.M.

I did not see the first, but I did see the two last, and the Aurora of Sunday morning appears to have been the most vivid of the three.

About 2.30 A.M. a strong red glare as of blood appeared above a thick black cloud about 40° eastward of north and 30° elevation. As this faded, the red glare appeared westward of north at the same elevation. The clouds did not extend to the horizon, which was pretty clear, and in half an hour they had passed away.

At 3.15 the sky was clear, and vivid yellowish rays extended nearly to the polar star. The rays had a gradual motion to the eastward. This was well observed by the rays passing in front of the stars of the tail of the Great Bear, which were at that time nearly parallel to the rays. I ceased observing about 3.30.

The Aurora observed at 8.30 P.M. appeared to me very faint in comparison to that at 3.20 A.M. I would hardly have noticed it if a friend had not pointed it out to me.

This same person had observed the Aurora of the 24th, and it was from his observation that I inferred that the Aurora of the morning of the 25th was also much brighter than that of the evening of the 24th.

Louvain, Sept. 30

Fuel of the Sun

I AM not mathematician enough to form any opinion on the merits of the controversy as to the "fuel of the sun;" that is to say, I am not able to decide whether it is consistent with the conditions of the equilibrium of the solar system that the sun's heat should have been kept up through the ages of geological time by the falling in of meteors. But I wish to state some evidence which proves that meteors are constantly falling in, though it does not touch the question whether this source is sufficient to account for the whole or any large part of the total supply of heat radiated away by the sun.

In the first place, the meteors have been seen. On Sept. 1, 1859, Mr. Carrington and another observer simultaneously observed two meteor-like bodies, of such brightness as to be bright against the sun's disc, suddenly appear, move rapidly across the sun from west to east, and disappear.

The fact that their motion was from west to east is important. If the supply of meteors to the sun is constant and tolerably regular, it is scarcely possible to doubt that the meteors, like the entire solar system, move round the sun from west to east, and occupy a space of the form of a very oblate spheroid, having its equator nearly coincident with the sun's equator.

If this is the case, the meteors ought to fall in greater numbers near the sun's equator than near his poles, making the equator hotter than the poles. Such is the fact. Secchi, without having any theory to support, has ascertained that the sun's equator is sensibly hotter than his poles. The instrument used was an electric thermo-multiplier, and the indications show, not the ratio, but the difference of the heat from the two sources compared.

It can scarcely be doubted that the meteors must enter the sun's atmosphere with a velocity not much less than that of a planet, revolving at the distance at which they enter. We know that the sun's rotatory motion is incomparably less than this, and consequently the meteors, revolving from west to east, ought to make the sun's atmosphere move round his body in the same direction, and with greater velocity in the equatorial regions, where most meteors fall in. This is what is observed. Mr. Carrington, also without any theory to support, has shown that the motion of the solar spots from west to east is most rapid in the latitudes nearest the equator. We cannot compare the motion of the spots with that of the sun's body, as we do not see his body. But the fact that the motion from west to east is most rapid in the equatorial latitudes proves that these motions are not due to any cause like that which produces trade-winds and "counter-trades" of our planet; for, supposing the sun or any planet to rotate from west to east, in any circulation that could be produced in its atmosphere by unequal heating at different latitudes, the relative motions of the atmospheric currents in high and low latitudes would be similar to that of the trade-winds and "counter-trades," and opposite to that which the motions of the spots indicate in the atmosphere of the sun. This will be true at all depths in the atmosphere.

JOSEPH JOHN MURPHY

Suggestions for the Improvement of Meteorological Investigation

THE position of Great Britain at the head of a vast empire encircling the globe, and soon to be at the centre of a network of telegraphs that will feel all the pulses of the world, imposes upon British naturalists and the British Government the duty of leading the way in the important work of meteorological investigation. In the hope of aiding the progress of this work, I venture, through your columns, to call public attention to the following suggestions:—

First:—The increase of the number of meteorological stations on and near the equator is very desirable. For instance, an increase of weather reports from the West Indies and the Atlantic States of North America, especially about latitudes 30° to 32°, would be highly valuable to the people of Great Britain and other portions of Western Europe.

Second:—In meteorological reports, we should recognise both the unity of the atmosphere and its division into areas corresponding with the great divisions of the earth's surface into land and water. As storms are generally confined within these areas, they may be called storm areas, or sections of the atmosphere in which disturbances are very closely connected. For instance, the area within which the greater storms that visit Great Britain begin and end, or circulate with destructive force, is bounded by the equator on the south, and the Rocky Mountains on the west. The northern and eastern boundaries are not yet determined. On September 7, 1869, the first "Northers" of the season visited New Orleans; on September 8th, storms passed over the Northern States; and between September 9th and 23rd, storms passed over Great Britain and Western Europe. Again, on October 1st, 1869, the barometer at Havana indicated the approach of bad weather; on October 2nd, 3rd, and 4th, there were heavy gales and rains at New York; on the night of October 4th, occurred one of the most destructive storms that has ever visited Maine and New Brunswick; on October 6th, there was a heavy gale in England. The destructive gale in England, on October 16th, was preceded by a hurricane in New England on October 11th. These two last-mentioned storms appear to have been closely connected not only with each other, but also with the extraordinary heat which prevailed in England on October 8th, 9th, and 10th, and in France on October 11th. All the storms mentioned, however, are only specimens of the many annual disturbances of the same kind whose connection with the Atlantic Ocean as a centre has been, or may easily be traced. They are referred to here, merely to show that about an eighth of the whole atmosphere constitutes, and may be named, the Atlantic storm area. To make a weather report of much practical value in Great Britain and Western Europe, it should cover the whole of this area. The number of places, however, from which reports are published, need not be so large as at present.

Third:—The records of the atmospheric conditions and changes should be arranged with reference to the latitude and longitude of each station. At present there is no system in tabulating meteorological observations. The weather tables now published in the daily papers are of comparatively little value to the general public, owing to their want of arrangement. A weather-table, to be of any great practical value in the northern hemisphere, should contain—first, a record of observations made at points south of the place for which the table is designed, and if possible on or near the equator and the 30th to the 32nd parallel; next, a record of observations made at western points within the limit of what I have ventured to call the storm area; next, a record of observations at northern stations about latitude 60°; and next, at eastern stations within the storm area. This statement is not to be understood as implying that all storms begin at the equator or at any one point of the compass, or that they are in all cases confined within one section of the atmosphere, or move in one direction.

Fourth:—It is very important to obtain correct and copious data regarding the atmospheric currents between (say) 5,000 feet and five miles above the level of the sea, and especially at various points on and near the equator, and at about 30° to 32° North and South latitudes. Within these limits the rain-bearing currents of the atmosphere move. If self-registering meteorological instruments were placed permanently upon several of the leading mountain ranges of the world, and their records copied at stated intervals, we should obtain valuable data for determining the direction, velocity, and magnitude of the controlling atmospheric currents of the globe. More valuable still would be data obtained by the use of self-registering and self-regulating machines that would ascend to any desired height within the limit mentioned above, remain up for a time determined by clock-work, and then descend, bringing with them complete records of temperature, moisture, direction and velocity of currents, &c. Additional facts regarding the great atmospheric currents within the limits named are required to enable us to interpret correctly the oscillations of barometers near the surface of the sea. G.

New York

Colour Blindness

I HOPE your readers will bear with a few more observations from me on the foregoing subject. It is an undoubted fact that modes of nervous action which have once coexisted tend to excite each other afterwards. This the phenomenon known as Association of Ideas sufficiently proves. It is to this cause that I should be disposed to attribute the phenomenon of accidental or complementary colours. I do not, of course, mean that this latter fact can be resolved into Association of ideas, but that it and association depend on the same organic law. It is probable that in addition to this, however, the mutual excitation of vibrations comes in. Judging from the determination of wave-lengths by diffraction, the ratio of the wave-length of any given ray to that of the complementary one is not very far from 2 to 3 or 3 to 2; and, as the colours excited do not seem to be exactly complementary, it is probable that the vibration referred to is that chiefly excited. For an accurate determination of this question we should require to determine the wave-lengths for each colour in the liquid which surrounds the eye, or rather, perhaps, in the retinal substance. Such are the two causes to which I should be disposed to ascribe the phenomenon of accidental colours. From the former it would follow that the more completely the eye had been accustomed to white light, the more likely the person would be to become colour blind; and that colour-blindness might be remedied, or at least altered in character, by accustoming the eye to look at everything through coloured glasses.

There are, however, subjective causes which determine the eye to exhibit various colours in particular instances. Of these, jaundice, which makes the object appear yellow, is one. Derangement of the stomach, I believe, often invests objects in the dark with a blue tint. Colours of this description constantly mingle with our ordinary perceptions without being noticed, but when a finer distinction is needed it becomes necessary to avoid them. Thus, in some of the delicate optical experiments to which I referred in my last, the experimentalist must not operate after a long fast or a hearty meal, or after taking any alcoholic drink. He sometimes finds, also, that his two eyes differ in their appreciation of colours. Two instances of this subjective colouring recently came under my notice. In one case an old lady for some time saw everything red, which she attributed to looking very much at a red flower (which she greatly admired) in her sitting-room. She was advised to look a good deal at the green fields opposite her window, and soon recovered. In the other case a friend of mine, reading a note-book which he had marked with a blue pencil, was surprised to find that the marks appeared green. He showed me the book, and the marks were quite unaltered to my eye. He was reading hard, and somewhat nervous, but otherwise in good health. In most of the cases I have referred to, the subjective colouring was only temporary; but I have little doubt that there frequently exists a permanent subjective colouring which modifies all the phenomena of vision, and leads to effects, in some respects, similar to those of ordinary colour-blindness.

Some time ago the question was suggested to me whether a blind man (whose retina was not destroyed) could have a perception of extension by sight, or whether, in the uniform darkness which was supposed to surround him, he could distinguish extension at all? I tried the experiment by shutting my eyes, but finding that when the light was good a very perceptible amount made its way through the eyelids, I placed bandages over them in addition. I could never, however, obtain uniform darkness. Points over the field always appeared less dark than the surrounding ones, and the positions of these points were easily distinguishable. On making the experiment for the third or fourth time, I was rather surprised to see part of the visible surface covered by a faint blue. Subsequent observation confirmed this, and I now believe that it was only from habitual inattention to colours when the eye was shut (as well as the difference between colours on a dark and on a bright ground), that I failed to observe it on the first occasion. These colours are by no means confined to blue. In fact, I think I have seen every tint in the spectrum, and I never can close my eyes for three minutes without seeing some of them more or less distinctly. They generally only cover a patch which, however, is not fixed, and the colour first visible sometimes disappears altogether. I may, perhaps, add to this that I often see a collection of small, bright, round moving spots about the centre of the field of vision. These spots I can likewise see in the dusk with my eyes open. This affords a proof of subjective colours in my own eyes, but from their variability, I do not think my eyes have a predilection for any particular tint. I often see more than one of these colours at the same time. If the eye had a predisposition for any particular colour, it could probably be discovered in this way. The observations are worth repeating. A close attention to the sensations is required on account of their faintness.

I have mentioned the expedient of looking through coloured glasses. Professor Wartmann succeeded in this way in making colour-blind persons distinguish colours which they confounded with the naked eye—a fact quite explicable on my principles; but he found it impossible to predict what effect a glass of any given colour would produce. But might we not by repeated experiments hit upon the particular tint which would suit the eye of any particular patient? If, for example, we tried his eye with a solar spectrum, and interposed one or more coloured glasses of different tints, and in this tentative manner at last succeeded in making him see seven colours, each confined within the same limits that they are to the ordinary eye, it is pretty evident that these glasses would enable him to distinguish the colours of all objects in the daylight.

Not having read much on the subject, I cannot say how far these views are original. The subject is at least one which requires further investigation, and if I can induce some of the eminent contributors to your columns to take up the matter, my letters will not have been vain though the result may be to overthrow all that I have advocated. W. H. S. MONCK

Trinity College, Dublin

The Effect of Tannin on Cotton

IN your last number you mention the fact that cotton fabrics are rendered more durable by treatment with tannin, as if it was a new discovery, and state that "it is believed the change cannot be great, since it has escaped the notice of practical tanners."

In our neighbourhood (the coast of Northumberland) the fishermen have, for many years past, been in the habit of tanning their nets and sails with oak-bark or catechu.

At the tanyard with which I am connected, we tan a large number yearly, including many cotton nets. Not only does it render them more durable, but in some cases, where wet nets have heated and become tender, their toughness has been restored by tanning. I cannot attempt to explain the chemical action which takes place, and, indeed, the still more important ones by which leather is produced are very imperfectly understood.

HENRY R. PROCTER

North Shields, Sept. 26

The Intended Engineering College

IN my letter on the above subject, I alluded to Mr. Mason's magnificent foundation of an educational institution in Birmingham, and by a queer inadvertence wrote the Christian name "Oliver"; and shall be much obliged if you will insert this correction of my mistake. It is Mr. *Josiah* Mason, the well-known pen manufacturer and founder of the orphanage and almshouses at Erdington, who is so liberally and judiciously enriching the Midland metropolis

W. MATTIEU WILLIAMS

The Haze Accompanying Auroral Displays

I DOUBT if the haze, seen before and during Aurora, has received sufficient attention. The beautiful displays which we in Canada have so frequently seen of late, have been well adapted to lead us to inquire into their cause; and I think in making observations, the beauty of the luminous portion has led us to overlook other things which are equally important.

On the night of April 15, 1869, we had a grand exhibition of Aurora at Toronto. It spread itself all over the heavens, forming a glorious canopy, filling the south as well as the north.

Previous to any auroral display, however, the atmosphere became thick and hazy; I was viewing the setting moon through a telescope, and though there were no clouds, I found the definition become extremely bad; I thought my breath must have got on the eye-piece, but soon found this was not the case. I then went outside, and on looking round, found the whole atmosphere full of haze. It had not the appearance of fog, but the whole air seemed thick and turbid, and shortly auroral columns commenced forming. This haze was visible for hours. Referring to this feature, Prof. Kingston says (*American Journal of Science*, July 1869, p. 65):—"Throughout the night, a generally diffused luminosity prevailed, such as is commonly seen with a full moon and hazy sky. This was evidently not occasioned by the moon, which was scarcely four days old, and was low in the horizon, but was part of the aurora itself, the brilliancy of whose more active features it greatly impaired." This haze is seldom seen spread in this way all around us; but it is usually seen as a bank in the north, and is surmounted by the auroral arch; stars can be seen through it, but it greatly dims their lustre. Prof. Loomis says:—"The slaty appearance of the sky, which is a common feature of great auroral exhibitions, arises from the condensation of the vapour of the air, and this condensed vapour probably exists in the form of minute spiculæ of ice or flakes of snow. Fine flakes of snow have been repeatedly observed to fall during the exhibition of auroras, and this snow only slightly impairs the transparency of the atmosphere without presenting the appearance of clouds. It produces a turbid appearance of the atmosphere, and causes that dark bank which in the United States rests on the northern horizon. This turbidness is more noticeable near the horizon than it is at great elevations, because near the horizon the line of vision traverses a greater extent of this hazy atmosphere. When the aurora covers the whole heavens, the entire atmosphere is filled with this haze, and a dark segment may be observed resting on the southern horizon."

Whilst approving of the professor's description, I must dissent from his explanation of the cause. This haziness is seen during our hot summer nights, as well as our cold ones; and I have seen it when snow-flakes would be out of the question in such a temperature. Many reasons leads me to regard this haze as cosmical, falling on our earth from without; but at present, I will call attention to the appearance only, reserving my explanation for a future time.

A. ELVINS

NOTES

IT is with very great regret that we have to announce the death, at the age of fifty-two, of Dr. William Allen Miller, Professor of Chemistry in King's College, London, and treasurer and vice-president of the Royal Society. Professor Miller's writings have earned for him a position in the literature of chemistry, from which he will be very greatly missed.

WE understand that Professor Allman has resigned the Chair of Natural History in the University of Edinburgh. It has long been felt that the subjects of Geology and Mineralogy which have hitherto been taught from this Chair are of such vast and growing importance and extent, that they can no longer be properly included in it when a successor is appointed. It gives us the greatest pleasure to state that Sir Roderick Murchison, who has already done so much for the geology of his native country, has munificently come forward with the offer of 6,000*l.* towards the endowment of a separate Chair of Geology and Mineralogy, on the understanding that on this, as on former occasions, the Government will supplement the private grant by an equal sum. Here then we have an admirable occasion for the Government to show itself alive to the importance of fostering the cultivation of those sciences on which especially the future welfare of the country must largely depend.

THE new Faculty of Science in University College, London, was opened on Tuesday last, by an inaugural address by Prof. A. W. Williamson, F.R.S. The discourse was devoted to an exposition of the importance of scientific method, and of the value of a scientific training, as an introduction even to the life of an ordinary man of business.

IN addition to his discourse to the Social Science Congress at Newcastle, Dr. Lyon Playfair delivered, on Thursday evening last, the inaugural address on opening the session of the Birmingham and Midland Institute. The subject of the lecture was announced as "The Inosculation of the Arts and Sciences;" and in its course the lecturer discussed the intimate union between science and labour. It is not science which creates labour or the industries flowing from it. On the contrary, science is the progeny of the industrial arts on the one side, and on the other of the experiences and perceptions which gradually attach themselves to these arts, so that the evolution of science from the arts is the first circumstance of human progress, which, however, quickly receives development and impulse from the science thus evolved. Industrial labour, then, is one of the parents, and science the child; but, as often happens in the world, the son becomes richer than the father, and raises his position. Apologising for the apparently pedantic form of the word, Dr. Playfair said he proposed to treat of the "inosculation" of arts and sciences, their junction with open mouths, as when two arteries join and mingle their contents. It will be seen that science does not depend upon facts alone, but upon the increase of mental conceptions which can be brought to bear upon them; these conceptions increase as slowly as the common knowledge derived from experience—they both descend by inheritance from one generation to another, until science in its progress becomes a prevision of new knowledge by light reflected from the accumulated common knowledge of the past. In the progress of time common knowledge passes into scientific knowledge. The amazing changes which have taken place since 1838 are due to our better conceptions of forces and their mutual relations and conversions. Formerly heat, light, electricity, magnetism, and chemical affinities, were thought to be separate and independent existences, not even related to each other. Now we know that forces are convertible and interchangeable. This knowledge has already given great stimulus to their application, and will do so more in the future. Further, we know that the primary source of nearly all the power on the earth is the sun above.

THE publishing trade shows indications of its usual activity at this time of the year. Among the announcements of forthcoming works from the leading houses bearing more or less directly on science, we note the following. From Messrs. Longmans and Co. :—The Life of Isambard Kingdom Brunel, Civil Engineer, by Isambard Brunel, B.C.L. ; A System of Logic and History of Logical Doctrines, by Dr. F. Ueberweg, 1 vol. ; The Sun : Ruler, Light, Fire, and Life of the Planetary System, by Richard A. Proctor, B.A. ; Spectrum Analysis in its Application to Terrestrial Substances and the Physical Constitution of the Heavenly Bodies, familiarly explained by Dr. H. Schellen, Director der Realschule I. O. Cologne, translated from the German by Jane and Caroline Lassell, edited, with notes, by William Huggins, LL.D., D.C.L., F.R.S , 1 vol. crown 8vo., with coloured plates and other illustrations ; Select Methods in Chemical Analysis and Laboratory Manipulations, by William Crookes, F.R.S., &c., editor of the *Chemical News ;* A Handbook of Dyeing and Calico Printing, by William Crookes, F.R.S., &c., illustrated with numerous specimens of textile fabrics ; Text-Books of Science, a new series of elementary works on Mechanical and Physical Science, forming a series of Text-Books of Science adapted for the use of artisans and of students in public and other schools, in small 8vo., each volume containing about 300 pages. From Messrs. Macmillan and Co. :—The Sun, by Balfour Stewart, LL.D., F.R.S., and J. Norman Lockyer, F.R.S. ; The Beginnings of Life, including an Account of the present State of the Spontaneous Generation Controversy, by H. C. Bastian, M.D., F.R.S.; An Introduction to the Osteology of the Mammalia, by W. H. Flower, F.R.S. ; A Treatise on Magnetism, designed for the use of Students at the University, by G. B. Airy, Astronomer Royal ; New Volumes of the School Class Book Series—Elementary Lessons in Logic, Deductive and Inductive, by Prof. Jevons, and Elementary Lessons in Physics, by Balfour Stewart, LL.D., F.R.S. From Messrs. Rivingtons :—Exercises adapted to Algebra, Part. 1, by J. Hamblin Smith ; A Manual of Logic, or, A Statement and Explanation of the Laws of Formal Thought, by Henry J. Turrell. From Messrs. Blackie and Son :—A translation, by Prof. Everett, of Prof. Deschanel's Elementary Treatise on Natural Philosophy, Part 1—Mechanics, Hydrostatics, and Pneumatics, illustrated with a coloured plate and many woodcuts. From Messrs. Asher and Co :—Man in the Past, Present, and Future, from the German of Dr. L. Buchner, translated by W. S. Dallas, F.L.S. From Messrs. Churchill :—A Manual of Botany, by Robert Bentley, Professor of Botany, King's College, London, and to the Pharmaceutical Society (second edition) ; A Laboratory Text-Book of Practical Chemistry, or Introduction to Qualitative Analysis, a guide to the course of practical instruction given in the laboratories of the Royal College of Chemistry, by W. G. Valentin, F.C.S. ; Handbook of Volumetric Analysis, or the Quantitative Estimation of Chemical Substances by Measure, by Francis Sutton, F.C.S., Norwich (second edition, much enlarged).

THE early publication is announced of "The Year-Book of Pharmacy," containing the proceedings at the yearly meeting of the British Pharmaceutical Conference, and a Report on the Progress of Pharmacy, which will include notices of all Pharmaceutical papers, new processes, preparations, and formulæ published throughout the world. It will be edited by Mr. J. C. Brough.

THE Professor of Chemistry to the University of Cambridge will begin a course of lectures on the Experimental Laws of Heat on Monday the 17th of October. He will also give instruction in Chemical Manipulation on Mondays, Wednesdays, and Fridays, at 1 P.M., beginning on the 10th of October, at the University Laboratory, which will be open daily from 10 till 6 for the use of students.

THE prospectus of the South London Working Men's College for the coming session includes classes in the following departments of Natural Science :—Chemistry, Physics, Animal Physiology, Geology, Metallurgy, and Applied Mechanics, as well as in Political Economy. The presence on the Council of the names of Professors Huxley, Fawcett, and Tyndall, Sir John Lubbock, and Dr. Cobbold, are a sufficient guarantee of the quality of the instruction given.

PROFESSOR DUNCAN, F.R.S., will commence a course of evening lectures on Geology, at King's College, London, on Monday, October 10th.

THE first meeting for the session of the Royal Microscopical Society will be held at King's College, London, on Wednesday, the 12th inst., at 8 o'clock, when the following papers will be read by Dr. G. W. Royston Pigott, M.A. :—"On Aplanatic Illumination," and "On Aplanatic Definition, with Optical Illustrations."

A MEETING of the Leeds Field Naturalists' Society will be held on Tuesday, October 11th, at 8 o'clock, at the Young Men's Christian Association, South Parade, to consider the advisability of holding weekly meetings during the winter session.

OWENS COLLEGE, Manchester, has lately received a very valuable donation to its large geological collection, in the shape of a collection of fossil Marsupials from Australia. This collection was to have been presented to the British Museum, but the donor ultimately decided to bestow it on Manchester instead.

THE Jesuit College at Manilla, in the Philippine Islands, has established a meteorological observatory, with self-recording instruments, where records of earthquakes are made in that region so fertile of them.

A MAGNIFICENT refracting telescope, with an object-glass of 25 inches diameter, is being constructed at the manufactory of Messrs. Clarke and Sons, Cambridgeport, Massachussetts, for the National Observatory at Washington. The money for this valuable instrument was voted by Congress last session, and amounts to 50,000 dollars, about 10,000*l*. It is believed that this telescope, when completed, will be one of the largest in the world ; meanwhile, it will take four years to finish it completely.

THE closing of Paris deprives us of the communication of meteorological observations and the Registrar-General of the records of births and deaths. The next international congress should provide for the requirements of science.

THE recent great summer-heat in America has been attracting great attention there. According to the records of Yale College, it has been the hottest summer for the last 92 years. "From July 10, to Aug. 15, 1870, the mean daily temperature was, at New Haven, 85°, and no season since 1778 has shown so many consecutive hot days. Our highest temperature this summer was (July 17) noted at 98°, and this has only been exceeded four times during the period above indicated at New Haven, the thermometer rising to 100° one day each year in 1784, 1800, and 1845, whilst in 1798 it reached 101°." This will be very interesting to compare with the temperatures ascertained this year in England.

IN the aquarium of the Dublin Zoological Gardens there are several specimens of the blind fish (*Amblyopsis spelæus*) lately brought from the Kentucky caves by Prof. Mapother. The small specimens, being very transparent, show the vertebral column, the heart, and the optic bulbs very distinctly. In the largest there are dark red spots over the optic bulbs, probably due to their having been kept in an iron vessel, which may have given colour for a rudimentary pigment membrane.

In the last part of the *Zeitschrift für Biologie* is an interesting paper by Dr. Camerer, on the locality of the sense of taste, or, as he expresses it, "On the dependence of the sense of taste on the part of the oral cavity irritated." His experiments have been conducted on himself, his wife, a lady friend, and six peasant girls. He employed solution of common salt, quinine, sugar, and sulphuric acid as the exciting agents, and localised their action by pouring a drop or two into a small open tube that was pressed on different parts of the tongue, the determination of the test fluid being required without the subject of the experiment being made acquainted with the nature of the solution used. It is well known that there are three kinds of papillæ on the tongue—the conical, the fungiform, and the circumvallate. Dr. Camerer finds that the sensibility of different parts of the tongue depends essentially on the presence and on the number of the fungiform papillæ. The fungiform papillæ, he finds, are most abundant near the apex of the tongue, they are less numerous at the edges of the tongue, and disappear near the root. There are no papillæ on the under surface of the tongue. The latter part he finds to be destitute of gustatory sensibility, whilst the sensibility is most acute when the papillæ are most closely aggregated together. He states also that when a strong solution has been tasted of any of the above substances, the delicacy of the sensibility is impaired for twenty-four hours. Other direct and carefully conducted experiments showed that the gustatory sensibility resided in the fungiform papillæ themselves and not in the parts adjoining.

According to the *Food Journal*, in Belgium the butchers use laurel-oil on the door-posts and window-frames for the purpose of keeping away flies, with great success. So simple a contrivance would be a great boon to the *habitués* of our eating-houses and confectioners, and would be useful to every housekeeper. The emanation from minced laurel leaves is rapidly fatal to all small insects.

With a view further to promote the cultivation of the Rhea fibre, the Viceroy of India has sanctioned an expenditure temporarily of 8*l*. per month, at Shaharunpore and at Dehra Dhoon, a hill station.

There are now in London specimens of iron manufactured for the first time in Peru by the Peruvian Government Commission from magnetic iron ore, found within twenty miles of Lima, and from fair anthracite taken from a seam sixty feet thick at sixty miles from Lima. The Government is awaiting the development of the railways now in progress. Renewed efforts are being made to enlist English capital in the restoration of the silver mines.

Mr. Adams, the Secretary of our Legation in Japan, has been rendering good service in doing all he can to protect the silkworm in those countries by his influence and advice, which are willingly received. At the last advices he had returned from a lengthened tour in the interior, on which he will report. In Japanese are some illustrated works on silk culture.

*ON CERTAIN PRINCIPLES TO BE OBSERVED IN THE ESTABLISHMENT OF A NATIONAL MUSEUM OF NATURAL HISTORY**

It having been now finally determined that the Natural History collections of the British Museum shall be removed from their present site to South Kensington, to form the nucleus of a National Museum of Natural History,† it appears to me that the principles upon which the proposed new institution are to be established and conducted, are well worthy of the special and most serious attention of the British Association for the Advancement of Science. The inauguration of a National Museum of Natural History by one of the nations that have contributed most largely to the advancement of the natural sciences, is an event that is not likely to recur very often. If the opportunity thus presented be properly taken advantage of, and the new institution started upon sound principles of administration and arrangement, there can be no doubt that a most material impetus will be given to the progress of natural science in this country.

Under these circumstances I think I need hardly apologise for troubling the section with a few remarks upon certain points which appear to me to be most essential to be observed in the establishment of a National Museum of Natural History. These, I trust, will at all events provoke discussion, and induce some of the many distinguished naturalists present at this meeting to turn their attention to this most important subject.*

The energies of our rulers, especially in these troubled times, are too fully occupied with ordinary politics to allow them to bestow much care on such a matter, and unless it be forced on their attention by the British Association, or in some other authoritative manner, the result will be, I fear, that the system of administration now followed in the British Museum as regards the Natural History collections, will be transplanted along with the collections themselves, and the excellent opportunity of a grand reform, which may never again present itself, will be utterly wasted.†

The remarks which I propose to offer to the section on this subject may be divided into three heads. First, I will say a few words concerning what appears to me to be the best mode of government of the proposed National Museum of Natural History. Secondly, I will speak of the form of building which in my opinion ought to be adopted; and lastly, of the arrangement of the collections within that building.

I. *Of the form of Government of the National Museum of Natural History.*

On this part of my subject I shall make but few remarks, having regard to the fact that, in common with many other of my fellow naturalists, I strongly committed myself on this point some years ago, and have in nowise changed my views since that period. In the memorial, of which I hold a copy in my hands, and which was presented to the Chancellor of the Exchequer in 1866 having been signed by 25 leading members of the Royal, Linnean, Geological, and Zoological Societies, it will be found to be stated that in our opinion the chief administration of the National Museum of Natural History should be entrusted to one officer, who shall be immediately responsible to some member of the Government. Those who are acquainted with the present mode of administration of the Natural History collections in the British Museum will, I am sure, readily agree to this proposed reform. It will be recollected that the government of the British Museum is vested by Act of Parliament in a body of fifty trustees, consisting principally of great officers of state, and of nominees of certain families whose ancestors have contributed to the heterogeneous contents of that building. Amongst these fifty trustees there are but two or three that are in any wise interested in Natural History. Their secretary and

* Read before Section D at the meeting of the British Association at Liverpool, on September 16, 1870.

† On the 3rd of August last a vote of 6,000*l*. was proposed in the House of Commons by the Chancellor of the Exchequer to clear the ground "for the erection of a Natural History Museum" on the site of the International Exhibition at South Kensington, and carried, after a division.

* For account of this discussion see p. 465.

† In the "bill to enable the Trustees of the British Museum to remove portions of their collections," prepared and brought in by the Chancellor of the Exchequer in 1862, it was proposed to be enacted that the trustees might remove the natural history collections to South Kensington and certain pictures to the National Gallery. But, in a subsequent clause, it was proposed to be added that "*except in so far as was therein before expressed, nothing therein contained should affect the rights, powers, duties, or obligations of the trustees of the British Museum.*" At that time, therefore, it was clearly intended to continue the rule of the trustees over the natural history collections when removed to South Kensington.

chief executive officer is the present principal librarian, with whose great literary qualifications for his position every one is well acquainted, but who would not, I am sure, claim for himself in any sense the name of a naturalist. It will thus be seen that the actual government of our Natural History collections is at present vested in persons who have no special qualifications for the task. But, it may be said, there is the Superintendent of the Natural History collections, and the keepers of the various departments into which they are divided—have they nothing to do with the administration? To this I reply, very little indeed, unless their advice is asked, or unless they choose to offer it. And, in the latter case, they can only address the trustees through the secretary, who is the only official present at the meetings of the trustees, and in whose hands, therefore, the administration of the Natural History collections is practically vested. This objectionable form of government, we think, ought to be replaced by appointing a director of the proposed new institution, "immediately responsible to one of the Queen's Ministers." This simple form of administration has been most successful in other scientific institutions, such as the Kew Gardens and Herbarium, and the Royal Observatory, and we believe it would be the best in the present case. It might, however, be advisable to give the Director of the National Museum of Natural History a board of advice, composed of the heads of the principal departments into which the Museum is divided. Or another mode of softening the despotism would be to appoint a board of visitors, consisting of distinguished naturalists. These might be delegates from the principal scientific societies of the country, each of whom would be specially bound to see that the particular branch of science, to the advancement of which his society is devoted, received its fair share of attention.

As regards the subordinate appointments in the Natural Museum of Natural History, these ought to be made, if not on the nomination of the director, at least not without his full sanction and approval. The director, being held responsible for the well-doing of the whole establishment, should certainly be allowed to select his own officers more or less directly. It is well known that some of the appointments made by the trustees in the departments of Natural History in the British Museum have been, to say the least of them, in no wise felicitous, and that in one case at least great public scandal has been caused by the notorious incompetence of the person nominated. It is in vain to address remonstrances to a body of irresponsible trustees, but if the director is required to sanction every nomination, we shall know to whom to apply in case of any appointment not being up to the mark.

II. *Of the form of Building of the National Museum of Natural History.*

In discussing the form of building best adapted for a great National Museum of Natural History, let us begin by considering the principal classes of persons for whose accommodation it is or ought to be constructed. These are—

1. The public at large, who go there to get a more or less general notion of the structure of natural objects and of their arrangement in the *Systema Naturæ*.

2. The students who use the Museum for scientific purposes.

3. The officers of the institution, whose business it is to amass and arrange the collections.

In the opinion of most members of parliament apparently especially of those who represent metropolitan constituencies, the first of these three classes is that whose accommodation ought to be first considered in the present case. In my opinion, and probably in that of most of those here present, the National Museum of Natural History ought to be constructed primarily for the accommodation of the third of the three classes. For, unless the officers of the institution have ample space and opportunity to examine and arrange the collection, it is obvious that neither the public nor the special student can be benefited thereby. At the same time I do not think that the public ought to be utterly excluded from their Museum four days in every week, as is now the case, and I therefore put it forward as an axiom that some system of construction of the New Museum should be adopted whereby the public can be admitted all day and every day to view the collections without interfering with the scientific work of the establishment or with the special examination of objects by students. There is, so far as I know, only one plan by which this object can be carried out—namely, by arranging the exhibited objects in large wall-cases, to which access is obtainable from the back by doors opening into work-rooms adjoining the exhibition room. In this way any ordinary object can be removed out of the series into the adjoining work-room, and returned to its place without disturbing the public in front of the cases, just as any article can be taken out of the shop-windows in Regent Street without interfering with those who are looking into them from the pavement outside. This system of exhibition would be attended by the further very great advantage that the glass cases may be hermetically sealed on the side towards the public, and the ingress of dirt and dust thus prevented. Those who are acquainted with the filthy state of the specimens in the public galleries of the British Museum, in spite of frequent cleansings inflicted upon them, will readily appreciate the merit of this plan.*

This collocation of the exhibition galleries and corresponding working-rooms being insisted upon as of primary importance, the general form of the building must depend somewhat upon the site on which it is to be placed. My own belief, however, is that a hollow square, or something nearly approaching that form, will in many ways be most convenient for a National Museum of Natural History, and the sketches which I now exhibit, which have been prepared for me by my accomplished friend Mr. Osbert Salvin, will serve to show the general plan of arrangement which I propose. The building might be of three or four stories, since, in the system of exhibition which I advocate, it would not be necessary to have top-lights. The basement, which might be partly below the surface, would be dedicated to taxidermy and to rooms for unpacking, storage, and mechanical work of all sorts. In the outer galleries running round the whole length of the ground story, I should propose to arrange the entire series of vertebrates from the highest mammal to the lowest fish. The specimens, according to the system already spoken of, would be placed in hermetically sealed glass cases along the inner walls of the galleries. The inner series of rooms surrounding the interior of the hollow square would be the working-rooms for the officers of the museum and the students of natural history, and would communicate with the glass cases on the inner side of the outer galleries. Each set of working-rooms would, of course, be in immediate apposition to the glass cases containing the corresponding series of exhibited objects. The lights to these working-rooms would be furnished from the inner sides of the hollow square.

In the first story of the building I should propose to arrange the series of invertebrate animals in exactly the same way, with the rooms for officers and students immediately adjoining them on the inner side.

The third story might contain the botanical and mineralogical collections, and perhaps certain others which it might not be possible to introduce into the general series, unless room could be found for these collections in the second story.

* In an admirable article on this subject in NATURE, for May 26, 1870, Prof. Flower has attributed the original invention of this mode of exhibition to myself, I having first brought it under his notice. It appears, however, from a subsequent communication to NATURE by Prof. Flower (June 2, 1870), that the same plan had been already proposed by Dr. Hooker in the *Gardener's Chronicle* for 1858, p. 749. I can only, therefore, claim to be *an* (not *the*) original inventor of this method of arrangement.

In a circular building, the centre of the hollow square, I should propose to place the library above and lecture-theatre below. The library might be connected by light iron galleries with the different working-rooms, so that the students of every department would have equally ready access to it.

Such is a slight outline of the kind of building I would propose for a National Museum of Natural History. It is, of course, a mere sketch, and there would be, no doubt, many difficulties in the details to be surmounted, but none, I think, such as an experienced architect would not be able to overcome. The advantages of this plan would be :—

1. The museum might be opened to the public every day without interfering with the scientific work of the establishment or of the students. Under the present arrangement, the collections are only open two or three days in the week, during which scientific work is suspended, as regards all objects in the public galleries.

2. The exhibited specimens would be much better protected from dirt and dust than they are in cases opening in front.

3. The exhibition of the whole series of organic beings in one continuous range of galleries would be much more instructive to the public than any system in which (as in the British Museum) they are dispersed about in different rooms.

4. The library being in the centre, would be equally accessible from any one of the working-rooms surrounding the interior of the hollow square.*

III. *Of the Arrangement of the Collections in the National Museum of Natural History.*

The remarks which I have already made under the previous head will have served to show the section that I am an advocate of what has been called the "typical," but what it would be better, perhaps, to call the "representative" system of arrangement of the Natural History collections. Nor am I able to understand how any reasonable person can seriously maintain that every object in a National Museum of Natural History ought to be exhibited to the indiscriminating public. In accordance with the views of the memorialists of 1858,† who may be considered as having inaugurated the reform in our Natural History collections which I hope to see shortly carried out, the collections should be primarily separated into three series : (*a*), objects for public exhibition ; (*b*), objects for private study. The class *a*, which is to be arranged in the public galleries behind the hermetically sealed glass cases, should embrace a very full and well-selected series of representatives of the principal forms of every class. In some cases it may be necessary to place in this category examples of every species of a group, in others only a selection of each genus or of each family. Every specimen exhibiting the external form in this series should be carefully prepared and mounted in a natural attitude. The representative species of the group having been selected, specimens of both sexes and of all ages should be placed in the series, as likewise examples of variation, if any such are known. The skeleton and other preparations of the internal structure should be added, as also the eggs and nests in the case of birds, and examples of corresponding structures in other classes. In short, the utmost endeavours should be made to illustrate, by preparations, models, and drawings, the life-history of the selected "representative," in as complete a manner as possible. To every exhibited specimen should be attached a printed label, giving its scientific and popular name, locality, and origin, and some short explanation regarding its chief peculiarities and most noticeable points of interest. There can, I think, be no doubt whatever that a small but well-selected series of any branch of the kingdom of nature, arranged after this method, would be of much greater interest and much more instructive to the public at large, than ten times the number of objects arranged according to the present fashion of the British Museum.

On the other hand, the great mass of the collections (*b*) intended only for the private examination of experts should be treated after a very different fashion. In this division of the collections, the object is to arrange specimens in as small a space as possible, and, at the same time, in the most convenient manner for easy examination. The work-rooms immediately adjoining the part of the public galleries appropriated to division *a* of any class, will, of course, be devoted to the reception of division *b* of the same class, so that the whole *a* and *b*, being separated only by the partition-wall at the back of the glazed cases, which will be pierced by frequent doors, will practically form but one collection. In these work-rooms, moreover, should be assembled together the whole of the specimens relating to the particular class to which they are devoted. In the British Museum, according to the present system, the mounted specimens are in one room, the skins in a second, the skeletons in a third, and the spirit-preparations in a fourth. So that, in order to make a complete examination of a small mammal, for instance, it may be necessary to go to four or five different parts of the building, ranging from the galleries to the cellars, and from the extreme north-east corner of the former to the furthest south-west corner of the latter. In the new National Museum of Natural History, it is to be hoped, this inconvenience will be remedied by the entire amalgamation of the various collections of skins, mounted specimens, spirit-specimens, and skeletons, into one uniform series. Besides the greater convenience of this mode of arrangement, another obvious advantage will be that the future student will be induced to devote his attention rather to the whole structure of the organism than to confine it to one particular part. If bird-cabinets were accompanied by skeletons and corresponding specimens in spirits, there can be no doubt that a much more perfect system of ornithology than any that we have yet attained to would be quickly arrived at. Our new national museum must take the lead in this great reform, and set an example to other collections. In the same way, as every naturalist will allow, our conchological brethren will lose nothing by having the soft bodies of the mollusca close at hand to aid them in their investigations on the form of the external shell. There may be, of course, some exceptional cases in which it will be practically impossible to adopt this course, but, as a general rule, the principle should be insisted upon that every specimen, of whatever nature it may be, should be located in the rooms devoted to the reception of the class to which it belongs, and should be placed as nearly as possible in immediate apposition to its nearest natural allies.

To carry out these principles to their legitimate issue, I do not hesitate to support the view put forward by Prof. Flower * and other naturalists, that the palæontological department of the British Museum, as at present constituted, ought to be totally abolished, and its contents distributed amongst the zoological and botanical collections, so that extinct forms may be studied in association with their nearest living representatives. The arguments in favour of this plan are, I think, unassailable, and although some little difficulties may be met with in carrying it out, there are none, in my opinion, that may not be overcome by judicious treatment. There is no doubt, I believe, that the progress of palæontology and palæophy-

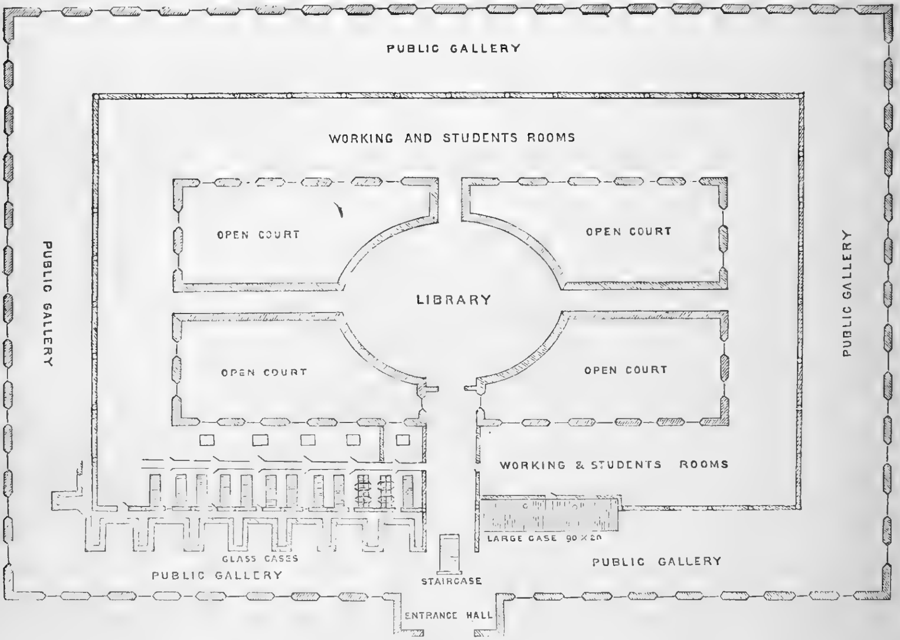
* A great deal has been said by those who have advocated the retention of the Natural History collections in their present site, about the importance of keeping up their conjunction with the National Library. It is, of course, obvious that their removal will necessitate the acquisition of a special Library of Natural History for the new museum. I believe, however, that a library of the kind, sufficiently comprehensive for all practical purposes, can be got together without much difficulty and at a comparatively small cost, and that when formed, it will be of much greater use for those working at the collections than the present overgrown establishment at the British Museum. It must be also recollected that the library of the British Museum is only available for the use of the officers. The books cannot be brought to the specimens nor the specimens to the books by ordinary students.

† See this memorial, as reprinted in NATURE for June 9, 1870.

* See NATURE for May 28, 1870.

tology has been much retarded by the neglect of the students of the extinct forms of animal and vegetable life to make themselves sufficiently acquainted with the structure of the corresponding forms now in existence. So long as fossils were looked upon as the products of numerous successive and independent creations, there might have been some excuse for this mode of dealing with them. But now that we regard animated nature, past, present, and future, as one and indivisible; now that we acknowledge the stream of life, since its first appearance on this planet, to have been unbroken and continuous, let us exhibit its products, whether existing or extinct, in one continuous and unbroken series. The structure of an extinct organism can only be correctly understood after study of the nearest allies at present in existence. The best palæontologist must be he that has deduced his knowledge of extinct beings from comparison of their remains with the corresponding parts of those now alive. Those who appreciate these truths will not fail to allow that the proposed amalgamation of the palæontological collection in the general series in the new Museum of Natural History, will be a decided step in advance, and one imperatively called for in the present state of natural science.

I have now, I think, touched upon some of the principal points on which changes are required in our present system of treatment of the collections of natural history belonging to the nation. It would be easy to go into further particulars in which reforms are needed. Especially I might call attention to the inadequacy in point of numbers of the present staff of officers in some of the Natural History departments of the British Museum, the insufficiency of the yearly sum allowed for acquisitions, the vexatious regulations concerning the examination of specimens, and the miserably insufficient accommodation for private study. But all these things we may well hope to see altered in a new institution, and I will not



take up time by enlarging upon them. In conclusion, however, I will recapitulate the principal topics touched on in the following propositions, which I trust the members of the British Association will agree with me in putting forward as the "platform" of reforming naturalists.

1. The administration of the New Museum of Natural History should be vested in a director, who should be immediately responsible to one of the Queen's Ministers.

2. The collections should be primarily divided into two series: *(a)* those intended for public exhibition; *(b)* those reserved for private study.

3. The collections *a* (for public exhibition) should be arranged in their natural order, in one continuous series of galleries, so as to give the best possible general idea of the principal forms of life, and of their arrangement according to the natural system.

4. The collections *b* (for private study) should be arranged in rooms immediately adjacent to the public galleries, in such a manner that the corresponding portions of *a* and *b* should practically form but one series, and that the private student should have access at all times to objects in the public galleries.

5. A complete Library of Natural History should be furnished for the special use of the institution, and be placed in some central portion of the building, equally accessible to all departments.

6. The collection of osteology, the spirit-preparations, the skins in store, the series of British animals, the collection of "nests and nidamertal structures," and all other subordinate collections, should be amalgamated in the general series.

7. The collections of the Palæontological Department should likewise be amalgamated with the general series.

P. L. SCLATER

SOCIAL SCIENCE CONGRESS, NEWCASTLE

DR. PLAYFAIR'S OPENING ADDRESS TO THE EDUCATIONAL SECTION

In the address delivered by Dr. Lyon Playfair before the National Association for the Promotion of Social Science, he began by referring to the lamentable position of English education at present. Speaking of the Act of last session, he pointed out that it deals with the quantity of education, and not with its quality; and insisted on the absolute necessity of introducing instruction in Science into our primary schools. The following are some of the more important passages of the address on this point:—

The educational principle of continental nations is to link on primary schools to secondary improvement schools. The links are always composed of higher subjects, the three R's being in all cases the mere basis of instruction. Elementary science, and even some of its applications, is uniformly encouraged and generally enforced. I shall not detain you with examples, as they are to be found in any work treating of continental schools. But as we have no schools corresponding to the secondary improvement schools for the working classes, we suppose that we can do without the higher subjects used as links. With what result? Our primary schools, on the whole, do not teach higher instruction than a child of eight years of age may learn. In our class of life, our children acquire such knowledge as a beginning; with the working classes, they get it as an end. What an equipment for the battle of life! No armour-plate of knowledge is given to our future artisan, but a mere thin veneer of the three R's, so thin as to rub off completely in three or four years' wear and tear of life. I am speaking on official record, for we are assured by inspectors, that nothing under Standard IV. suffices for permanent use, and yet the Committee of Council ell us that four-fifths of the children of ages at which they leave school pass only in lower standards. Recently, under Mr. Corry's minute, inducements have been given for subjects higher than the three R's, but for some reason it produces scarcely any result. So, under our present system of elementary teaching, no knowledge whatever bearing on the life-work of the people reaches them by our system of State education. The air they breathe, the water they drink, the tools they use, the plants they grow, the mines they excavate, might all be made subjects of surpassing interest and importance to them during their whole life; and yet of these they learn not one fact. Yet we are surprised at the consequences of their ignorance. A thousand men perish yearly in our coal-mines, but no schoolmaster tells the poor miner the nature of the explosive gas which scorches him, or of the after-damp which chokes him. Boilers of steam-engines blow up so continually that a committee of the House of Commons is now engaged in trying to diminish their alarming frequency; but the poor stokers who are scalded to death or blown to pieces, were never instructed in the nature and properties of steam. In Great Britain alone more than one hundred thousand people perish annually, and at least five times as many sicken grievously, out of pure ignorance of the laws of health, which are never imparted to them at school; they have no chance of learning them afterwards, as they possess no secondary schools. The mere tools of education are put into the hands of children during their school time without any effort being made to teach them how to use the tools for any profitable purpose whatever; so they get rusty or are thrown away altogether. And we fancy that we have educated the people! Our pauperism, our crime, and the misery which hovers on the brink of both, increase terribly, and our panacea for their cure is teaching the three R's up to Standard III. The age of miracles has passed by, and our large faith in our little doings will not remove mountains. It is best to be frank. Our low quality of education is impoverishing the land. It is disgracefully behind the age in which we live, and of the civilisation of which we boast; and until we are convinced of that we cannot be roused to the exertions required for its amendment. In censuring the low condition of knowledge in our primary schools, as represented by the results of the Revised Code, I do not aim to restore them to the position which many of them had before it. That code was, in fact, rendered necessary because their aggregate teaching was not sufficiently large and diffused to justify the increasing expenditure. In imitation of our classical schools, verbalism and memory-cramming had grown up as tares and choked the growth of the wheat. Words had taken the place of conceptions. A child could tell you about the geography of the wanderings of the children of Israel, but had no conception whatever of the ordinary phenomena around it. It was hopeless to put to them the commonest scientific questions. Whence comes the water that fills the Thames? What is the origin of hail, snow, rain, or dew? Why does the sun rise in the east, or set in the west? What produces night and day, summer and winter? In history they could rattle out to you the names and dates of kings and queens, perhaps even the names and ages of all Queen Anne's children as they died in childhood; but, as a true historical conception, apart from memory cramming of words and dry facts, to be vomited forth upon the examiner, it required a very good school under the old system to find it. Words, instead of ideas, were worshipped. Inspection, under the old system, did something to correct this tendency to verbalism and cram; under the new system they had no time, and, if they had, would find fewer of the higher subjects taught in any way. The teaching of science, if properly done, is the reverse of all this, and will go far to remedy its defects. Books in this case ought only to be accessories, not principals. The pupil must be brought in face of the facts through experiment and demonstration. He should pull the plant to pieces and see how it is constructed. He must vex the electric cylinder till it yields him its sparks. He must apply with his own hand the magnet to the needle He must see water broken up into its constituent parts, and witness the violence with which its elements unite. Unless he is brought into actual contact with the facts and taught to observe and bring them into relation with the science evolved from them, it were better that instruction in science should be left alone. For one of the first lessons he must learn from science is not to trust in authority, but to demand proof for each asseveration. All this is true education, for it draws out faculties of observation, connects observed facts with the conceptions deduced from them in the course of ages, gives discipline and courage to thought, and teaches a knowledge of scientific method which will serve a lifetime. Nor can such education be begun too early. The whole yearnings of a child are for the natural phenomena around, until they are smothered by the ignorance of the parent. He is a young Linnæus roaming over the fields in search of flowers. He is a young conchologist or mineralogist gathering shells or pebbles on the sea shore. He is an ornithologist and goes bird-nesting; an ichthyologist and catches fish. Glorious education in nature, all this, if the teacher knew how to direct and utilise it. But as soon as the child comes into the school-room, all natural God-born instincts are to be crushed out of him; he is to be trained out of all natural sympathies and affections. You prune and trim, cramp and bind the young intellect, as gardeners in olden times did trees and shrubs, till they assumed monstrous and grotesque forms, altogether different from the wide-spreading foliage and clustering buds which God himself gave to them, and which man is idiot enough to think he can improve. Do not suppose that I wish the primary school to be a lecture theatre for all or any of the "ologies." All the science which would be necessary to give a boy a taste of the principles involved in his calling, and an incitement to pursue them in his future life, might be given in illustration of other subjects. Instead of mere descriptive geography drearily taught and drearily learned, you might make it illustrative of history, and illustrated by physical geography, which, in the hands of a real master, might be made to embrace most of what we desire to teach. The properties of air and water, illustrations of natural history, varieties of the human race, the properties of the atmosphere as a whole—its life-giving virtues when pure, and its death dealings when fouled by man's impurities—the natural products of different climes, these and such like teachings are what you could introduce with telling and useful effect. Far better this than overlading geography with dry details of sources and mouths of rivers, of isothermal lines, latitudes and longitudes, tracks of ocean currents, and other tendencies towards the old verbalism and memory-cramming. If I have explained myself with clearness, you will see that while I advocate the introduction of higher subjects into our schools, I wish them to be of immediate interest and applicability to the working classes. The main difficulty in education is getting them to stay long enough at school. Teach them, while you have them, subjects of interest and utility. The short time will thus be made productive, and inducement will be offered for its extension. Six months spent in teaching future labourers the geography of the wanderings of the children of Israel, is sheer waste of time, either for their eternal or temporal interests. Think of the few precious hours as the training for a whole lifetime, and let us use them by giving living and intelligent learning, not obsolete and parrot instruction. Those who are believers in the teaching of the great secondary schools of this country will deem my aspirations for the improvement of primary education, low and utilitarian. Frankly I admit the latter. Such a style of education will never realise Lord Brougham's hope that the time may come when every working man in England will read Bacon; but it might contribute to the fulfilment of Cobbett's desire, that the time might come when every man in England could eat bacon. I deny, however, that the utilitarian view of primary education is ignoble. The present system is truly ignoble, for it sends the working man into the world in gross ignorance of everything that he is to do in it. The utilitarian system is noble, in so far as it treats him as an intelligent being, who ought to understand the nature of his occupation, and the principles involved in it. The great advantage of directing education towards the pursuits and occupations of the people, instead of wasting it on dismal verbalism, is that, while it elevates the individual, it at the same time gives security for the future prosperity of the nation. In the industrial battles of peoples, we are content to leave our working classes armed with the old Brown Bess of warfare, while men of other countries are arming themselves with modern weapons of precision. In the competition of nations, the two factors of industry—raw material and intellect, applied to its conversion into utilities—are altering their values. The first is rapidly decreasing, the second quickly augmenting in value. We anchor our hopes on the sand, which the advancing tide of knowledge is washing away, while other nations throw out their anchors on firm ground accumulating around, and enabling their vessels to ride in safety. There are instances of nations, rich in the natural resources of industry, yet poor from want of knowledge how to apply them; and there are opposite examples of nations utterly devoid of industrial advantages, but constituted of an educated people who use their science as a compensation for their lack of raw material. Spain is an example of the first class, and Holland of the second. Having pointed out at some length the contrast between these two countries, in consequence of the difference of their culture, Dr. Playfair proceeded to show the necessity of good physical training, to argue in favour of a compulsory educational system, and of graded education, and to define the true position and qualifications of teachers in primary schools.

THE BRITISH ASSOCIATION

LECTURE ON STREAM LINES IN CONNECTION WITH NAVAL ARCHITECTURE, BY PROF. RANKINE

THE lecturer stated that his object was to give a brief summary of the results of some application of the mathematical theory of hydrodynamics to questions regarding the designing of the forms of ships, and the mutual actions between a ship and the water in which she floats. The art of designing the figures of ships had been gradually developed by processes resembling those called "natural selection," and the "struggle for existence" in the course of thousands of years, and had arrived in skilful hands at a perfection which left little more to be desired, when the object was to design a ship that should answer purposes and fulfil conditions which had previously been accomplished and fulfilled in the course of practical experience. But cases now frequently arose in which new conditions were to be fulfilled; and purposes accomplished beyond the limits of the performance of previous vessels, and in such cases the process of gradual development by practical trials made without the help of science was too slow and too costly, and it became necessary to acquire and to apply scientific knowledge of the laws that regulate the actions of the vessel on the water and of the water on the vessel. Amongst the questions thus arising were the following: What ought to be the form of the immersed surface or skin of a ship in order that the particles of water may glide smoothly over it? And, the form of such a surface being given, how will it affect the motion of particles in its neighbourhood, and what mutual forces will be exerted between the particle of water and that surface? Practical experience, unaided by science, answers the first question by saying that the surface ought to belong to a class called "fair surfaces" (that is, surfaces free from sudden changes of direction and of curvature) of which various forms have in the course of ages been ascertained by trial, and are known to skilful ship-builders. That answer is satisfactory so far as it goes; but in order to solve problems involving the mutual actions of the ship and the water, something more is wanted, and it becomes necessary to be able to construct fair surfaces by geometrical rules based on the laws of the motion of fluids, and to express their forms by algebraic equations. There were many very early attempts to do this, but through not being based on the laws of hydrodynamics, they resulted merely in the finding of empirical rules for reproducing when required forms which had previously been found to answer in practice, and did not lead to any knowledge of the motions of the particles of water or of the forces exerted by and upon them; and they had little or no advantage over the old process of modelling by the eye and hand, and of "fairing" the lines with the help of an elastic rod called a "batten." As regards this process, indeed, the mathematical methods about to be referred to are to be regarded, not as a substitute for it in designing the form of a ship, but as a means of arriving at a knowledge of the mutual actions between her and the water, which the old process is incapable of affording. The earliest method of constructing the figures of ships by mathematical rules, based on hydrodynamical principles, was that proposed by Mr. Scott Russell about twenty-five years ago, and since extensively practised. It consisted in adopting for the longitudinal lines of a ship curves imitated from the outlines of waves in water. The motions which surfaces formed upon this model impress on the water were known to a certain degree of approximations. These "wave-lines," however, although they were fair curves in the sense already mentioned, were by no means the only fair curves, but were only one class out of innumerable classes of curves having the property of gliding smoothly through the water; and it was well known in practice that vessels had proved successful whose lines differed very widely from wave-lines. It was therefore desirable that methods should be devised of constructing by mathematical rules based on the laws of the motions of fluids, a greater variety of curves possessing the requisite property of fairness, and not limited to the wave-line shape. Such had been the object of a series of researches that had been communicated to the Royal Society at different dates since 1862. They related to the construction of what it has been proposed to call stream-lines. A stream-line is the track or path traced by a particle of water in a smoothly and steadily flowing current. If, when a ship is gliding ahead through the water with a certain speed, we imagine the ship to be stationary, and the water to be flowing astern past the ship in a smooth and steady current with an equal average speed, the motions of the ship and of the particles of water relatively to each other are not altered by that supposition; and it becomes evident that if the form of surface of the skin of the ship has the property of fairness, all the tracks of the particles of water, as they glide over that surface, are stream-lines, and the surface itself is one containing an indefinite number of stream-lines, or, as it has been called, a stream-line surface. It is also to be observed, that when we have deduced from the laws of the motion of fluids the relations which exist between the form of the stream-lines in different parts of a current, and between those forms and the velocities of the particles as they glide along different parts of those lines, we know the relations between the form and speed of a ship whose surface coincides with a certain set of these stream-lines, and the motions of the particles of water in various positions in the neighbourhood of that ship. The lecturer then proceeded to explain, and to illustrate by diagrams, the methods of constructing stream-lines. These methods were based upon the application to stream-lines in a current of fluid of a mathematical process which had previously been applied by Mr. Clerk Maxwell to lines of electric and magnetic force. A current of fluid is represented on paper by drawing a set of stream-lines so distributed that between each pair of them there lies an elementary stream of a given constant volume of flow. Thus, while the direction of flow is indicated in any given part of the current by the direction of the stream-lines, the velocity of flow is indicated by their comparative closeness and wideness apart, being evidently greatest where these lines lie closest together, and least where they are most widely spread. If, upon the same sheet of paper, we draw two different sets of stream-lines, these will represent the currents produced in one and the same mass of fluid by two different sets of forces. The two sets of lines form a network, and, if through the angles of the meshes of that network we draw a third set of stream-lines, it can be proved from the principle of the composition of motions, that this third set of lines will represent the current produced in the same mass of fluid by the combination of the forces, which, acting separately, would produce the current represented by the first two sets of stream-lines respectively. The third set may be called the resultant stream-lines. Suppose, now, that a third set of component stream-lines are drawn representing the current produced by a third set of forces : this will form a network with the previously drawn resultant stream-lines, and a set of lines drawn through the angles of the meshes of this new network will represent the resultant current produced by the combination of the three sets of forces ; and so on to combinations of any degree of complexity that may be required. In order to draw a system of stream-lines suited for the longitudinal lines of a ship, three sets at least of component stream-lines must be combined. One of these is a set of parallel straight lines, representing a uniform current, running astern with a speed equal to the actual speed of the vessel. A second set consists of straight lines radiating from a point called a focus in the forepart of the vessel, and they represent the diverging motion that is produced by the ship displacing the water near her bows. The third set of component stream-lines consists of straight lines converging towards a second focus in the afterpart of the vessel; and they represent the motion of the water closing in astern of the ship. The resultant stream-lines thus produced present a great variety of forms, all resembling those of actual ships having all proportions of length to breadth, and all degrees of bluffness and fineness at the ends, ranging from the absolute bluffness of a sort of oval to a bow and stern of any degree of sharpness that may be required. It has been proposed to call stream-lines of this sort Oögenous Neoïds ; that is, ship-like lines generated from an oval, because any given set of them can be generated by the flow of a current of water past an oval solid of suitable dimensions. The properties of these curves were investigated in 1869. They have, however, this defect, that the absolutely bluff ovals are the only curves of the kind that are of finite extent; all the fixed curves extend indefinitely in both directions, ahead and astern ; and in order to imitate the longitudinal lines of a fine-ended vessel, a part only of some indefinitely extended curve must be taken. In 1870 an improvement in the construction of such curves was introduced, by which that defect was overcome ; it consisted in the introduction of one or more additional pairs of foci, involving the combination of at least five sets of component stream-lines. By this device it is possible to imitate longitudinal lines of actual vessels by means of complete closed curves, without rising portions of indefinitely extended curves ; and thus the motion of the particles of water, as shown by the stream-lines that lie outside the closed lines representing the form of the vessel, becomes more definite and accurate. The lecturer mentioned that the idea of employing four foci and upwards had been suggested to him by the experiments of Mr. Froude on the resistance of boats modelled so as to resemble the form of a swimming bird ; for which purpose stream-lines with four foci are specially adapted. It has been proposed to call such lines Cycnogenous Neoïds—that is, ship-like curves of shapes like that of a swan. In such curves the outer foci—that is, the foremost and aftermost—are situated in or near the stem and sternpost of the vessel, which are represented in plan by small horse-shoe curves, as if they were rounded off at the corners instead of being squared, as in ordinary practice. The inner foci are situated respectively in the fore and after body. When the foci of the longitudinal lines of a vessel have been determined, the proportion borne by the aggregate energy of the motion impressed on the particles of water to that of the motion of the vessel herself can be approximately determined. The lecturer next proceeded to explain the bearing of some of the mechanical properties of waves upon the designing of vessels, especially when these properties are taken in combination with those of stream-lines. It had long been known that ships, in moving through the water, were accompanied by trains of waves, whose dimensions and position depended on the speed of the vessel ; but the first discovery of precise and definite laws respecting such waves was due to Mr. Scott Russell, who published it about twenty-five years ago. The lecturer now described in a general way the motions of the particles of water in a series of waves, and illustrated them by means of a machine designed for that purpose. He showed how, while the shape of the wave advances, each individual particle of water describes an orbit of limited extent in a vertical plane. The periodic time of a wave, its length, the depth to which a disturbance bearing a given ratio to the disturbance at the surface of the water extends, and its speed of advance, are all related to each other by laws which the lecturer explained. He then stated that Mr. Scott Russell had shown that when the vessel moved no faster than the natural speed of advance of the waves that she raised, these waves were of moderate height, and added little or nothing to her resistance ; but when that limit of speed was exceeded, the waves and the resistance caused by them increased rapidly in magnitude with increase of speed. His own (Professor Rankine's) opinion regarding these phenomena was, that when the speed of the vessel was less than or equal to the natural speed of the waves raised by her, the resistance of the vessel consisted wholly, or almost wholly, of that arising from the friction of the water gliding over her skin ; and he considered that this opinion was confirmed by the results of practical experience of the performance of vessels. The wave motion, being impressed once for all on the water during the starting of the vessel, was propagated onward like the swell of the ocean, from one mass of water to another, requiring little or no sensible expenditure of power to keep it up. But when the ship was driven at a speed exceeding the natural speed of the waves that she raised, these waves, in order to accompany the ship, were compelled to spread outwards instead of travelling directly ahead ; and it became necessary for the vessel, at the expense of her motive power, to keep continually originating wave-motion afresh in previously undisturbed masses of water ; and hence the waste of power found by experience to occur when a ship was driven at a speed beyond the limit suited to her length. This divergence or spreading sideways of the train of waves had a modifying effect on the stream-lines representing the motions of the particles of water. It caused them, in the first place, to assume a sinuous or serpentine form ; and then, instead of closing in behind the ship to the same distances from her course at which they had been situated when ahead of her, they remained permanently spread outwards. In other words, the particles of water did not return to their original distances from the longitudinal midship plane of the vessel, but were shifted laterally and left there, much as the sods of earth are permanently shifted sideways by the plough. The place of the water which thus fails to close in completely astern of the vessels is supplied by water which rises up from below and forms a mass of eddies rolling in the wake of the ship. This was illustrated by a diagram. Lastly, the lecturer explained the principles according to which the steadiness of a ship at sea is affected by storm-waves, and the difference between the properties of steadiness and stiffness. The mathematical theory of the stability of ships had been known and applied with useful results for nearly a century ; but in the course of the last ten years it had received some important additions, due especially to the researches of Mr. Froude on the manner in which the motions of the waves affect the rolling of the vessel. A stiff ship is one that tends strongly to keep and to recover her position of uprightness to the surface of the water. A steady ship is one that tends to keep a position of absolute uprightness. In smooth water these properties are the same ; and a stiff ship is also a steady ship. Amongst waves, on the other hand, the properties of stiffness and steadiness are often opposed to each other. A stiff ship tends as she rolls, to follow the motions of the waves as they roll. She is a dry ship ; but she may be what is called uneasy, through excessive rolling along with the waves. The property of stiffness is possessed in the highest degree by a raft, and by a ship which, like a raft, is broad and shallow, and whose natural period of rolling in smooth water is very short compared with the periodic time of the waves. In order that a ship may be steady among waves, her natural period of rolling should be considerably longer than that of the waves ; and in order that this property may be obtained without making the vessel crank, the masses on board of her should be spread out sideways as far as practicable from her centre of gravity ; this is called "winging out the weights." A vessel whose natural period of rolling in smooth water is only a little shorter or a little longer than that of the waves, has neither the advantages of stiffness nor those of steadiness, for she rolls to an angle greater than that of the slope of the waves ; and her condition is specially unsafe if her natural period of rolling is a little greater than that of the waves, for then she tends to heel over towards the nearest wave-crest, to the danger of its breaking over her deck. This is called "rolling against the waves." The most dangerous condition is that of a vessel whose period of rolling in smooth water is equal to that of the waves that she encounters, for then every successive wave makes her roll through a greater angle ; and under these circumstances no ship can be safe, how great soever her statical stability. All these principles have been known for some years through Mr. Froude's researches. The lecturer exhibited a machine he had contrived for illustrating them, in which the dynamical conditions of vessels of different degrees of stiffness and steadiness were approximately imitated by means of a peculiarly-constructed pendulum hanging from a pin, whose motions imitate those of a particle of water disturbed by waves.

SECTIONAL PROCEEDINGS

Section A.—Mathematical and Physical Science

On the Mode of Action of Lightning on Telegraphs, and on a New Method of Constructing Telegraph Coils.—Mr. S. Alfred Varley. He remarked that when lightning storms occur in the neighbourhood of telegraph wires, although the wires may not be actually struck, powerful currents are induced in them which may be sufficiently strong to fuse the coils, but which more frequently simply demagnetise, and as often reverse the magnetism of the magnetic needles situated in the coils of needle telegraph instruments. Thus, not only is a considerable amount of damage done annually to telegraph instruments, but telegraphic communication is very liable to serious interruption. Mr. Varley mentioned a number of observations going to prove that an interval of dust separating two metallic conductors opposes practically a decreasing resistance to an increasing electrical tension, and that incandescent particles of carbon oppose about $\frac{1}{60}$th part of the resistance opposed by a needle telegraph coil. Reasoning upon these data, he has constructed an instrument, the main feature of which is what he terms a "lightning bridge." Two thick metal conductors, terminating in points, are inserted usually in a piece of wood. These points approach one another within about $\frac{1}{16}$th of an inch in a chamber cut in the middle of the wood. This bridge is placed in the electric circuit in the most direct course which the lightning can take, and the space separating the two points is filled loosely with powder, which is placed in the chamber, and surrounds and covers the extremities of the pointed conductors. The powder employed consists of carbon (a conductor) and a non-conducting substance in a minute state of division. When this instrument is used, therefore, lightning which strikes a circuit finds in its direct path not a space of air but a bridge of powder, consisting of particles of conducting matter in close proximity to one another. These the lightning connects under the influence of the discharge, and the particles are thrown into a highly incandescent state. The secondary current, developed by the demagnetisation, finds an easier passage across this heated matter than through the coils. These lightning bridges have been in use since January 1866, and at the present moment there are upwards of 1,000 doing duty in this country alone. Yet not a single case has occurred of a coil being fused when protected by them. The reason why a powder consisting entirely or chiefly of conducting matter cannot be safely employed is, that although it can oppose a practically infinite resistance to the passage of electricity of the tension of ordinary working currents, when a high tension discharge occurs, the particles under the influence of the discharge generally arrange themselves so closely as to make a conducting connection between the two points of the lightning bridge. In the course of his exposition, Mr. Varley endeavoured to prove that when telegraphic circuits protected by ordinary protectors are struck by lightning, it is to the secondary current and not to the main discharge that the fusion must be attributed. He also pointed out the defects of the protector, which consists of two silk wires wound side by side upon a bobbin.

Mr. Varley also read a second paper containing *A Description of the Electric Time Signal, at Port Elizabeth, Cape of Good Hope.* After an elaborate account of the Liverpool time ball, he proceeded to say that in the year 1859, Sir Thomas Maclear, the Astronomer Royal of the Cape of Good Hope, inspected the electrical time signals in this country, with a view to erecting time balls in connection with the Royal Observatory at Cape Town. Sir T. Maclear remarked the greater rapidity of action of the Liverpool trigger, and this led to Mr. Varley's afterwards designing and constructing at different times two triggers for use in the Cape. Both these triggers discharged more rapidly than the Liverpool trigger. In September 1864, he was requested to construct a trigger for discharging a time ball to be erected at Port Elizabeth. He considered the intervention of any relay or secondary apparatus to be objectionable. He therefore determined if possible to construct the trigger sensitive enough to be discharged by the batteries in the Cape Town Observatory, and in its construction he adopted a modification of a principle first introduced by Professor Hughes in his printing telegraph (described at the Newcastle meeting).

The trigger was constructed with a soft iron armature, rendered magnetic by induction from a compound bar magnet, and which strongly attracted the soft iron cores of an electro-magnet, but which was prevented from actually touching the poles of the electro-magnet.

A spiral spring attached to this armature was so adjusted that it nearly overcame the magnetic attraction induced by the bar magnets.

The time current polarised the electro-magnet in the opposite direction to that induced by the bar magnets, and as the attraction between the armature and the soft iron cores was already almost overcome by the spiral spring, a very small amount of polarisation in the opposite direction was necessary to release the armature, which was rapidly pulled away by the spiral spring, and the trigger discharged.

There were some other alterations made in the general mechanical construction of this trigger, but they may be regarded as matters of detail.

The rapidity of discharge was very great, $\frac{1}{20}$th part of a second only elapsed between the arrival of the time current and the falling of the ball.

From a report in the Port Elizabeth paper of August 29, 1865, giving an account of the inauguration of this time signal, and forwarded to Mr. Varley by Sir Thomas Maclear, it appears that the time elapsing between the time current leaving the Observatory at Cape Town and the receipt at Cape Town of the signal announcing the falling of the ball, is only $\frac{1}{15}$th of a second.

The time which elapsed between the Greenwich current reaching London and the falling of the ball at Liverpool was $\frac{11}{20}$th of a second. In other words, the Algoa ball is discharged from a distance of 500 miles in less than $\frac{1}{7}$th of the time of that of the Liverpool ball.

What is being daily done in the Cape can, however, be best summed up by a short quotation from a letter received from Sir Thomas Maclear, giving an account of the successful inauguration of this time signal. After detailing the general arrangements, Sir Thomas Maclear goes on to state: "A few tentative signals having proved satisfactory, the 'preface' was issued from the Observatory at ten minutes before one o'clock, and at the instant of one o'clock, the Observatory time-ball clock closed the circuit discharging the Observatory ball, the Simon's Town ball, twenty-four miles distant; the Cape Town time gun, three miles distant; and the Port Elizabeth ball, distant 500 miles."

On the present State of the Question relative to Lunar Activity or Quiescence.—W. R. Birt, F.R.A.S. From the time of Schröter, the question of change on the moon's surface has been more or less agitated. The *Selenotopographische Fragmente* contains numerous instances of what he considered to be changes of a temporary character, and a few of a more permanent nature, as the formation of new craters. It is, however, notorious that he failed to establish the fact of a decided change in any one instance; nor is this to be wondered at when we consider the paucity of the materials he had at his command. Notwithstanding the comparative neglect into which the observations recorded in the "Fragments" have fallen, and the judgments passed upon them by some of the best known selenographers, there can be no question that they embody the results of zealous and persevering attention to the moon's surface, and ought not to be passed over in the examination of any given spot, the history of which we are desirous of becoming acquainted with *during the earliest period of descriptive observational selenography.*

The labours of Schröter's successors, Lohrmann, and Beer and Mädler, have added greatly to the number of objects, either as delineated on their maps or referred to in their letter-press. Lohrmann appears to have carefully studied Schröter's results, as we find him quoting the measures obtained by Schröter in several instances. On examining the results of the two greatest selenographical works of the present century, and comparing the one with the other, we find precisely the same kind of phenomena presenting themselves which in a great measure perplexed Schröter; but as Lohrmann and Mädler worked independently of each other, and Mädler evidently had a very low idea of the value of the preceding labours of Schröter, these phenomena passed unnoticed at the time. Upon consulting the three works for elucidating the history of any given object, such results as these are frequently obtained. An object is found in Schröter designated by a Greek or other character, and its appearance described in his text. This object may be altogether omitted by Lohrmann, but given on Beer and Mädler's map, and objects are by no means rare which may be found on Lohrmann, but omitted by Beer and Mädler, and *vice versa*.

Were the results of the labours of Julius Schmidt during a period of nearly thirty years given to the public, there can be no doubt that our knowledge of selenography would be greatly advanced. His chart must contain a large proportion of the objects previously recorded by Schröter, Lohrmann, and Beer and Mädler; and judging from the instances already alluded to, of *apparent omissions* by one or other of the above-named observers, it is highly probable that the number of such instances would be much increased. The value of his measures (4,000) of the altitudes of lunar mountains for comparison with or addition to those of Schröter and Mädler, cannot admit of a doubt. His published catalogue of rills is very valuable in this respect. It is to Schmidt that we are indebted for one of the most important announcements bearing on the subject of lunar activity, that of a change in the crater *Linné*, "which," says Mädler (Reports British Association, 1868, p. 517) "has hitherto offered the only authentic example of an admitted change." He had previously said (same report): "What has lately been observed in the crater *Linné* proves, at all events, that *there* real changes have taken place, and that, too, under circumstances even visible to us." Further on, however, the great selenographer remarks that on the 10th of May, 1867, his eye having undergone an operation for cataract, he attempted an observation of *Linné* in the heliometer of the Observatory at Bonn, and found it shaped exactly, and with the same throw of shadow as he remembered to have seen it in 1831. "The event," he says, "of whatever nature it might have been, must have passed away without leaving any trace observable by me." The doubt still hanging over this object is well known, and it may be regarded as furnishing, at least, one of the instances of the present state of the question of activity. The uncertainty attaching to the question of change in this particular instance mainly arises from the difficulty of deciding upon the accuracy or otherwise of the delineations of Lohrmann and Beer and Mädler, although both describe it as showing a diameter of five or six English miles. Generally speaking, the observations between October 1866 and July 1870, all agree in its present appearance, differing greatly from that which it must have presented according to the delineations and descriptions of the two selenographers just named, also that no change of a physical character has taken place in it during the 3½ years it has been under observation. It has been supposed that photography would solve all such difficulties, and that photograms of the lunar surface taken under similar angles of illumination and visual ray would agree with each other; but here again precisely the same difficulties present themselves which perplexed Schröter, and which have been met with in comparing Lohrmann's and Beer and Mädler's works. Objects figured by the earlier selenographers occur on some photograms, but not on others, of about the same phase of illumination. There appears to be an agency capable of affecting the visibility of objects, rendering them indistinct or invisible on some occasions; while, on others, they are distinctly seen on the photograms. Whatever operations may have taken place in the crater *Linné*, producing phenomena the recurrence of which is *rare*, in all the examples above mentioned, from Schröter's time to the present, we have phenomena of a different character, exceedingly difficult of explanation, and constituting an important element in the solution of the question of present activity or quiescence; for unless it be fully proved that *all* these instances depend upon changes of visual and illuminating angles, a strong suspicion will exist of their being more immediately connected with the moon itself. To effect such a proof, however, is a matter of no small difficulty. Mädler alludes to the performance of calculations of the most varied kind as necessary for the delineation of lunar forms, and in the case before us the calculation of several elements for *each separate observation*, and they are very numerous, is absolutely essential for the purpose of referring the phenomena observed to changes of illumination and visual ray. Calculations of this kind have not been made to any great extent, and the consequence is, that the entire question remains involved in doubt. During the last seventeen months, as many as 1,227 observations of the spots on *Plato* alone have been made, and although the varying state of the earth's atmosphere affects in no slight degree the visibility of such delicate objects, phenomena are presenting themselves which call for a much more rigorous treatment than has yet been accorded to them. The affirmation of change on, or quiescence of, the moon's surface, must depend, not upon the accumulation of desultory and undiscussed observations, but upon such as are undertaken on a well-arranged system, and discussed with reference to every known agency capable of affecting them. The present state of the question is therefore one of *doubt*, one that calls for observation of the most vigorous character, and discussion of the most rigorous nature to settle it. Observation of late has been tending towards a registration of minute detail detected on the moon's surface, but discussion in various ways is behind the requirements of selenography, and until it can keep pace with observation the doubt alluded to above must remain.

Section B.—Chemical Science

On Artificial Alizarine.—Mr. W. H. Perkin, F.R.S. In introducing Mr. Perkin the President said that that gentleman might be regarded as the representative in England of artificial colouring matters, and that the subject to be treated of was one of great importance, both theoretically and in its practical aspects. The author referred to the use of madder and its preparation called garancine, in the production of Turkey red dye, and then traced the history of the investigations of chemist regarding the chemical nature of the colouring matters contained in madder-root. About thirty-nine years ago those investigations commenced, and ever since that time they have been continued by many eminent chemists, among others by Graebe, Liebermann, Schunck, Strecker, Laurent, Anderson, and others, as also those of the author himself. Two colouring compounds had been obtained from madder known as alizarine and purpurine. The exact composition of alizarine had been the subject of much discussion among chemists. From that compound a hydrocarbon derivative had been obtained which is called anthracene, and then from anthracene, as an ingredient of coal-tar and mineral pitch, alizarine had been produced by the action of various chemical agents. Alizarine, thus artificially produced, yields with mordants the same colours on cotton goods as the natural alizarine from madder-root. Mr. Perkin performed a great variety of experiments in order to demonstrate the chemical identity of the artificial and natural alizarine when absolutely pure. He had also, during upwards of twelve months, been engaged in studying the properties of anthracene and its compounds, all of which are very markedly fluorescent. There were many difficulties in the way of obtaining artificial alizarine in large quantities, but they were gradually disappearing. In the discussion which followed, Dr. Schunck, F.R.S., referred to the alleged differences between the natural and the artificial alizarine, and said he had no doubt whatever that the two were identical, and he thought the confusion had arisen from persons examining impure products. The artificial product was generally supplied impure, but the impurities could be separated. He was quite satisfied as to the importance of alizarine, and that it was the only essential dye product of madder. Some years ago he had shown that the finest madder pinks contained nothing but alizarine.

Section C.—Geology

On the Extension of the Coal-fields beneath the newer Formations of England.—Mr. Edward Hull. Having referred to the paper by Sir R. I. Murchison, on the parts of England and Wales in which coal may or may not be looked for, the author expressed his gratification that his own views coincided in the main with those of his chief, especially as regarded the absence of coal in the eastern and portions of the midland counties, now overspread by mesozoic formations. The author showed that there was evidence for believing that the coal measures were originally deposited in two continuous sheets, one to the north, and the other to the south of a ridge of old land formed of Silurian rocks which stretched eastward from Shropshire to the south of the Dudley coal-field. This ridge, or barrier, had never been altogether submerged beneath the waters in which the coal measures were deposited. Towards the north, the boundaries of the coal formation were formed by the Cambro-Silurian rocks of North Wales, the Lake District, and portions of the southern uplands of Scotland. Over the region north of the barrier, the coal measures were deposited in greatest thickness towards the north-west; while over that south of the barrier they were deposited in greatest force in a westerly direction.

At the close of the coal period, disturbances of the strata, resulting from lateral pressure acting in north or south directions, took place over the whole carboniferous area of the north of England, whereby the strata were thrown into a series of folds, the axis of which ranged along approximately east and west lines. These disturbances were accompanied and followed by enormous denudation, by which the coal measures were swept away over large tracts of the north of England, and the northern limits of the Lancashire and Yorkshire coal-fields were determined. As regards the tract south of the central barrier, it was inferred, on the ground of parallelism of direction with the east and west flexures of the north of England, that the northern and southern limits of the South Wales coal-field, the axis of the Mendip Hills, and the easterly bend of the culm-measures of Devonshire, were all referable to the same geological period, *i.e.*, that which intervened between the deposition of the carboniferous and the Permian rocks.

After the deposition of the Permian beds over the inclined and denuded surfaces of the carboniferous rocks, disturbances (accompanied by denundations) occurred along lines nearly at right angles to those of the preceding period, *i.e.*, along north and south lines (approximately). To this epoch the axis of the Permian chain, and all north and south trendings of the strata, were probably to be referred. Some of the results brought about by these movements were the disseverance of the Lancashire and Cheshire from the Yorkshire and Derbyshire coal-fields, the determination of the western limits of the Flintshire and Denbighshire coal-field, the disseverance of the Forest of Dean coal-field from that of South Wales, and the uptilting of the lower carboniferous rocks along the eastern margin of the Somersetshire coal-field beneath the Jurassic formations.

From these considerations it seemed clear to the author that to the intersection of these two systems of disturbances (*i.e.*, the E. & W. with the N. & S.) and the concomitant denudation, the basin-shaped form of nearly all the British coal-fields (sometimes partially concealed by newer formations) might be attributed.

The author then proceeded to show that over these carboniferous basins, the Permian and Triassic rocks were distributed according to a well-defined plan, the Triassic strata thinning away towards the south-east of England; and concluded by discussing the views of Sir R. I. Murchison, Professor Ramsay, and Mr. Godwin-Austen regarding the absence or presence of coal under the cretaceous and tertiary strata of the south of England.

On the History and Affinities of the British Coniferæ.—Mr. W. Carruthers. Having pointed out the great divisions of this natural order, the author traced their appearance and development in the stratified rocks. The *Araucarieæ*, now represented by fifteen species, all confined to the southern hemisphere, made their appearance in the carboniferous period, where at least eight species determined from the wood structure had been found. In the secondary rocks six species had been found based on the cones, and these showed an affinity to the group of modern Araucarias found in the Pacific Islands. The *Pineæ*, a large group chiefly confined to the northern hemisphere, appeared in the Old Red sandstone, as determined by H. Miller; a single species had been determined from wood in the coal; the species greatly increased in the secondary rocks, where several species of cedars had been detected. The *Taxodieæ*, represented among living plants by fifteen species, chiefly from the northern shores of the Pacific, made their appearance in the secondary rocks, one species being abundant in the Stonesfield slate, and were continued by species of Sequoia in cretaceous and Tertiary rocks. The two species from the Gault are associated with pines having the characters peculiar to the species associated with the existing mammoth trees of California. The *Cupresseæ*, represented by the cypresses, and in our native flora by the juniper alone, are known only in Tertiary strata by a few species of fruits and foliage. The *Taxineæ*, containing nearly 100 species, found all over the world and represented in Britain by the yew, made their appearance in the carboniferous rocks, as determined by a fruit described by Dr. Hooker, and shown by him to be nearly related to the living *Salisburia*. The supposed Taxineous wood from the North American Devonians, to which Principal Dawson gave the name of *Prototaxites*, was a remarkable *Alga* of enormous size. Several Taxineous fruits had been found in the Eocene strata at Sheppey.

Notes on Fossil Crustacea.—Mr. H. Woodward. A considerable number of new species was described which had been met with during the past years belonging to strata from the Silurian to the Tertiary. The author expounded the changes in the larva of the living King Crab, and showed the remarkable resemblances between its early condition and the palæozoic *Trilobites*. The earliest known King Crab occurs in the Upper Silurian, so that the pedigree of these two ancient forms dove-tailed into each other in Silurian times, and these contemporaneous forms approached much nearer to each other than would be expected from a comparison of the living King Crab with the Trilobite.

Report on Earthquakes in Scotland.—Dr. Bryce.

On the Tertiary Coal Fields of Southern Chili.—Mr. G. A. Lebour. This was a detailed description of the beds of coal, and those intercalated with them. The list of fossils appeared to Prof. Harkness and Mr. Carruthers to indicate a Secondary rather than a Tertiary age.

Section D.—Biology

Mr. Edward Atkinson, of Leeds, read a paper on the *Osteology of Chlamydophorus truncatus*—a fine male specimen of which had been presented to the Philosophical and Literary Society of Leeds. First glancing at the bibliography of this little quadruped, the author proceeded to draw attention to some points in the structure of its skeleton. The general conformation of the head is very remarkable, differing from all other Edentates in its relative dimensions, excelling its congeners both in altitude and in breadth as compared with length. He also alluded in detail to the structure of the lower jaw, the ear, the scapula, sternum, and pelvis. With regard to the dentition, his observations were not quite in accord with those of Harlan or Hyrtl. *C. truncatus* is a true monodont with eight grinders on either side of both maxilla and mandible. Those of the lower jaw perforate the whole depth of the bone, dimpling the inferior margin. The first tooth of the lower jaw has no opponent, and therefore no masticatory surface. The eighth upper tooth is also without an antagonist, but its analogue in front has a double facet.

Mr. R. McAndrew, F.R.S., presented a report on the *Marine Mollusca of the Gulf of Suez*. This report gives the general result of a dredging excursion to the Gulf of Suez in February and March 1869. Mr. E. Fielding accompanied the author. Leaving Suez on the 10th February in a boat of about twelve tons burthen, with one of about five tons for dredging, and a small boat for landing, the party reached Tur in about three weeks' time. Their crew consisted of Maltese and Neapolitans, an Arab, who proved an excellent diver, and a native of Tur, who acted as pilot. From Tur they crossed over to the Point of Zeite and the desolate islands situated towards the western side of the Straits of Jubal. After working about a week among these, and finding it a very rich collecting ground, they bore away to Ras Mahommed, where they ended their labours, proceeding from this to Tur, from whence they went by land to Suez. The number of species obtained (not including the Nudibranchiates) was 818. Of these 619 have been identified, the remaining being still undetermined. About 355 have not previously been recorded as from the Red Sea. Of these 53 species, including three genera, are new to Science, and have been described by Messrs. H. and A. Adams. Professor Issel, of Genoa, records 640 species as from the Red Sea, and his list includes 100 new species. Some of these were figured but not described in Savigny's "Description de l'Egypt." Mr. McAndrew dwelt on the extraordinary dissimilarity between the Fauna of the Red Sea and that of the Mediterranean; the number of species common to Japan, the Philippines, Australia, and to the Red Sea, is worthy of further observation In addition to the Mollusca, a collection of Echinoderms, Crustacea, and Corals, was made and divided among the British, Edinburgh, and Liverpool Museums. The sponges collected were sent to Dr. Bowerbank, except one, which had been described by Mr. Carter as a new genus under the name of *Grayella.*

Professor Wyville Thomson, F.R.S., read a report on *Some of the Echinoderms of the Expedition of H.M.S. Porcupine.* The impression was very general that through the exertions of Forbes, McAndrew, Jeffreys, and others, the marine fauna of the British Islands was now pretty well known. It was also thought that below a depth of some 300 or 400 fathoms animal life became extinct. Through the investigations of Dr. Carpenter and the author in H.M.S. *Lightning*, and since then by investigations carried on in H.M.S. *Porcupine*, with the additional help of Mr. Jeffreys, not only had the number of new species found been very great, but animal life had been found abundant to the enormous depth of upwards of a mile. Confining himself now to the Echinoderms, he might say that the fauna became not so much a local fauna as one of depth and temperature. All the well-known Scandinavian forms were met with in the "cold area"—such as *Pteraster*, *Euryale*, &c.; while in the "warm area," such wonderful genera as *Pourtalesia* and *Brissingæ*, having possibly its nearest ally in forms found in the Ludlow rock, but also a new soft-bodied genus belonging to the Diademidæ, were met with. All the new forms, embracing both new genera and species, would be described in full in the forthcoming report.

Dr. M'Intosh, F.L.S., read a preliminary report on *Certain Annelids dredged in the expedition of H.M.S. Porcupine*. The specimens were chiefly procured from water under 500 fathoms off the coast of Ireland. They are on the whole of a northern type, many of the rarer having been previously procured by Mr. Jeffreys off the Shetland Islands, and well known in the northern seas generally. There were several new and most interesting species, including a *Sthenelais*—a form allied to *Leanira Malmgreni*, but probably requiring a new genus for its reception; a *Eunice*, *Nothria* and *Chætozone*, the *Antinoe Sarsi* of Kinberg, and the *Petta pusilla* of Malmgren were, besides, added to our fauna. The author tendered his thanks to Professors Carpenter and Wyville Thomson, and more especially to Mr. Gwyn Jeffreys, for their kindness in securing the collection.

Dr. G. W. Child read a Paper on *Protoplasm and the Germ Theory*. Mr. Samuelson read a Paper *On the Controversy on Spontaneous Generation, with new experiments*. In the interesting discussion which followed, the President, Dr. Hooker, Mr. G. Bentham, and Mr. Crace Calvert took part.

Mr. P. L. Sclater read a Paper on *Certain Principles to be observed in the Establishment of a National Museum of Natural History*. [This Paper will be found *in extenso* in another column, with a woodcut. The following is an epitome of the interesting discussion which followed.]

Mr. Wallace entirely agreed with all the main principles advocated by Dr. Sclater, such as the separate government of the Natural History Museum, the association of Palæontology with Zoology, and the separation of the collections into a "typical and a scientific series," both of which should be at all times available; but he differed from him on a point which he considered to be no less important than any of these, viz., as to the mode of arrangement of the specimens which would be most efficient for all the purposes such a museum should fulfil. In a national institution, if any part of it was set apart for the elevation, instruction, and amusement of the public, these purposes should be carried out in the most efficient manner, and this could not be done by the system of wall-cases advocated by Dr. Sclater, and which he (Mr. Wallace) believed to be radically wrong. The objections to these wall-cases were numerous:—

1. They admit of any object being seen by the smallest number of persons at once, so that any one person studying an object, almost necessarily monopolises it, and prevents others from approaching it, an inconvenience that reaches its maximum in the recessed cases exhibited in Dr. Sclater's plan.

2. Objects in wall-cases can be seen only on *one* side, which, as *all* sides of natural objects require to be seen, would necessitate many specimens to do the duty of one.

3. The observer on the one side, from which alone he can see an object, will generally stand in his own light, and will often have distinct vision further impaired by reflection from the glass.

4. When small objects occur alternately with large ones, a great waste of space occurs, and the attention is distracted from the less conspicuous object.

5. The use of wall-cases on one side of a gallery for an entire museum, is an expensive and wasteful mode of arrangement.

Objections (1) (2) and (3) are of the greatest importance. A public national museum must accommodate the thousands who throng to it on holidays, when alone the working classes can reap its benefits; and they should be invited and induced to examine and study, not merely to gaze and pass on. Teachers and parents should be able to give information as to the groups exhibited without interfering with other visitors, none of which things are possible with a range of wall-cases. The system advocated by Mr. Wallace was that of detached cases on tables or on the floor, of various sizes, and each exhibiting one typical object or group of objects, capable of being seen on *all sides*, and admitting of convenient examination in the best light by the *greatest number* of persons at once. The system had been adopted in a new museum at the India House, and at South Kensington, and was advocated by Dr. Gray, and partially exemplified in the great gorilla case, the groups of birds of paradise, and other detached cases in the British Museum. The numerous and very great advantages of this system should not be lost for the sake of an infinitesimal increase of convenience to scientific men. The great majority of specimens exhibited in the public galleries would consist of *common species*, of which an ample series of specimens would be preserved in the scientific collection for study. Of the few rare species which it might be advisable to exhibit to the public, perhaps not more than one a week would be required for scientific examination, and all such might be so mounted as to be easily brought into the students' room, adjacent to the gallery, when required. The man of science would thus *lose nothing*, while the public would gain incalculably; and so greatly was Mr. Wallace impressed with the educational superiority of one mode of arrangement over the other, that he believed it would be better to have the very rare and unique species represented by drawings or models only in the public department, rather than have the whole collection arranged in wall-cases, for the one purpose of allowing the scientific man to get them out more easily on the rare occasions when he required them.

Prof. Archer, of Edinburgh, said: However some of us may differ from Dr. Sclater in his opinions about the arrangements of the contemplated National Museum of Natural History, none of us will, in the slightest degree, differ from him in his belief that this is a subject of paramount importance. I am compelled to say that I do not agree with him as to his arrangement of wall-cases and back entrances, for some considerable experience has convinced me that unless under some peculiar circumstances, as in narrow galleries where there is too little space for detached cases, wall-cases are entirely a mistake. In this respect my own personal experience perfectly coincides with the opinions of Mr. Wallace, but Mr. Wallace has even underrated the advantages of the system he advocates, for he has only indicated by his diagrammatic illustrations a series of cases similar in size, placed at equal distances. But at South Kensington, where the question of constructing cases best adapted for the display of objects in a Museum, has received a greater amount of intelligent attention than in any other museum, they have shown that you can make cases which will admit of a perfectly symmetrical arrangement, and yet be of various sizes, so that small objects as well as large ones may be so exhibited as to permit of their being examined from all sides, instead of from only one point of view as in wall cases. Wall space is valuable for illustrations, especially pictorial ones, but when you arrange groups of animals in them, it is certain that if they are tolerably suitable for the exhibition of large specimens they cannot be equally fitted for small ones. There is one other point in which I cannot agree with the author of the paper, and that is, in the line he draws between the requirements of a Public Museum and one for the use of students in natural history. My own views are to exhibit as much as you can without injury to the specimens, because you never know what portion of your visitors are earnest students or pleasure-seeking idlers; and still further, you do not know how soon this class may be converted into the former.

Prof. Newton thought that being connected with a museum which was emphatically "national," he should be wanting in his duty if he did not express his general agreement with the principles laid down in Mr. Sclater's paper. What might be called the "structural" part of this very important question had been dwelt upon by previous speakers, but there was another part on which they had scarcely touched. This was the constitution of the governing body and officials of the New Museum. First it had been stated in the paper (and the statement was true) that of the fifty trustees of the British Museum only two or three were scientific men. That the museum was what it was, reflected, then, the greatest credit on the energy of those two or three. But care must be taken that the museum of the future, whether sent to South Kensington or kept in Bloomsbury, should be relieved of the burden of the Trustees; it was essential that their authority should cease, and that scientific authority alone should be supreme. Secondly, with regard to the mode of appointment of the officials—that was a matter for great deliberation. He believed that the system adopted a few years ago had not yet had time to produce all the mischievous results which would follow if it were persevered in; but it was clear to him that in future they should have nothing to do with competitive examinations and Civil Service commissioners, in appointing assistants to the different departments, and he would prefer, as was suggested in the paper, that appointments should be made by the mild despotism of the director or superintendent of the museum.

Department of Zoology and Botany

Dr. B. W. Richardson read the *Report on Methyl Compounds.* He commenced his report by giving a review of some results of his previous reports, describing at length the action of nitrite of amyl and hydrate of chloral, both of which had proved of the greatest service in the treatment of disease. The former had been applied most usefully in the treatment of tetanus; the latter had been so largely applied as a narcotic, that since the discovery of its narcotic properties by Liebreich, more than a million persons had been successfully subjected to its influence. After his review of the past, the author brought forward new matter of research, introducing detailed accounts of the action of ethylate of sodium, ethylate of potassium, sulphur alcohol, sulphide of ethyl, bromide of ethyl, and triethylic ether. The facts respecting the action of these substances were all rich in interest, but two may be named specially, viz., in relation to the ethylates of sodium and potassium, and to triethylic ether. The first, when brought into contact with the surface of the body, acts as the most potent of known caustics, and promises to be rendered painless as well as caustic. The second is a new volatile anæsthetic, the sleep produced by which is deep, gentle, and apparently free from danger. In a final part of his report, Dr. Richardson dwelt on some general physiological observations, which attracted considerable attention. He showed that by the action of some of his anæsthetics, he could induce insensibility to pain without fully destroying consciousness; and he explained that in time this progressive step would be entirely realised. He described the effect produced by repeating applications of volatile agents upon the external nerves' expanses; and on the results of direct experiment, he explained that certain agents, such as nitrite of amyl, act immediately through the nervous system without any absorption of them by the blood. At the close of his report, Dr. Richardson showed how the elementary modification of the bodies of an organic series influences the physiological action of each compound, and expressed a hope that, by continued research, physiologists, moving with the chemists, would speedily bring the subject of the action of medicinal agents into the ranks of positive science.

Dr. Brown-Sequard read two papers on the *Apparent transmission of abnormal conditions due to accidental causes, and on various alterations of Nutrition due to Nervous Influence.*

The President of the Association (Professor Huxley) said: The great theoretical problem they had now to determine was what effect artificial modifications and external conditions had upon living organisms—whether they produced changes which, being transmitted hereditarily, became the basis of new races. Referring to a resolution which had been brought forward at a former meeting, which endeavoured to pledge the Association to abstain from making grants of money to persons engaged in experiments which involved vivisection, he said they had before them that day one of the most experienced physiologists and vivisectors of his day, and he had only to ask the audience to form their own judgment as to whether Dr. Brown-Sequard was likely to inflict one particle of pain upon any creature whatever without having a plain and definite purpose in view. For himself he might say that nothing was more grievous to him than to think of the existence of pain in anything whatever. He hated to see it inflicted upon animals, and he carried his objection to its infliction so far that he disliked even to see a man beating his wife. Neither Dr. Brown-Sequard nor himself were indifferent to pain, and he hoped that in no sense were they cruel. He thought that the gentleman who brought forward the resolution to which he had referred, hardly knew what he was dealing with. If his friend Dr. Brown-Sequard would pardon his referring to a matter personal to him, he would remind the meeting that that great experimental physiologist, and that accomplished vivisector, who had, he supposed, performed as many vivisections as any man in the world, some years ago thought it advisable to turn the vast knowledge of the diagnosis of disease which he had obtained by this means into actual practice, and he (Professor Huxley) could assure them, from what he knew, that before long his wonderful mastery over symptoms caused his consulting rooms to be absolutely crowded by human beings suffering under multiform varieties of nervous disorders, who sought at his hands and from his knowledge that relief which they could not obtain elsewhere. The prevention of cruelty to animals, when understood in its proper sense, was as good an object as men could devote themselves to, but when they confounded the brutal violence of the carter or the wife-beater with an experiment carried out by a man of science, gently and for the purpose of relieving misery, the enthusiasts in that cause should change their name, and convert themselves into a society for the promotion of cruelty to mankind. If that question came before the Association again, and he hoped it would, he trusted they would recollect that the order of nature was such that certain kinds of truth were only attainable by experiments upon living animals, and that when they might result to the welfare of thousands and thousands of untold human beings who might otherwise be suffering unimaginable misery, those experiments were perfectly justifiable.

Dr. R. McDonnell, F.R.S., of Dublin, said that the President of the Association had viewed the admirable communication of Dr. Brown-Sequard from the Darwinian point of view, one of the greatest interest. He, like Professor Humphry of Cambridge, regarded such communications rather in their practical bearings, but first he might be allowed to say, how entirely he concurred with the President in his observations on the subject of experimental researches conducted upon animals. Indeed Dr. Richardson's report was in itself the most unanswerable argument that such experiments are undertaken with the hope of diminishing human suffering, and whosoever would oppose such an important and indeed successful means of attaining this end must be prepared to submit to the imputation of desiring that pain should remain unalleviated. Dr. McDonnell then alluded to the subject referred to both by Dr. Richardson and Dr. Brown-Sequard in speaking of the transmission along the nerves of certain sensations, and their being intercepted. He said that he had long felt some difficulty about adopting the hypothesis of Dr. Brown-Sequard that there existed distinct conductors for various sensations, as those of heat, pain, tickling, contact, &c. In explanation of the remarkable cases sometimes met with in which an individual who felt perfectly the contact of one's hand yet could not distinguish heat or cold, he proposed another hypothesis than that of distinct conductors, and he was indeed happy, on this occasion, to have an opportunity of submitting this hypothesis to the section and to Dr. Brown-Sequard for consideration. His (Dr. McDonnell's) hypothesis was, in fact, an application of the undulatory hypothesis to the propagation of nervous sensation—he supposed that sensations such as those of heat, pain, contact, as well as those of various colours, of form, of sound, were waves of different wave-lengths; and that, under certain circumstances, some waves were absorbed or intercepted while others passed on to the sensorium. He, in fact, drew an analogy or illustration of his hypothesis from Prof. Tyndall's well-known experiments on the absorption of radiant heat by vapours or scents passed into the air filling a glass tube. The glass tube in this experiment represented the nerve tubule, the slight change effected in the air contained within it produced by the introduction of the minutest quantity of scent causes an absorption *in transitu* of some waves of heat, others pass; thus, according to his supposition, might be explained the effect on vision of santonine. The experiment of seeing the complementary colour upon gazing at a white ground after looking upon a coloured disc, might be explained thus: A slight chemical change is effected in the nerve tubule by gazing at the coloured disc; when the white ground is looked upon, all undulations pass through *save* those which are absorbed, viz., those of the colour previously looked at. This, of course, gives the complementary colour. Many phenomena connected with sensation, Dr. McDonnell conceived, would find in this hypothesis a simpler explanation than in that of distinct conductors.

Department of Ethnology and Anthropology

On the Anthropology of Lancashire.—Dr. Beddoe, President of the Anthropological Society of London. The author drew a marked distinction between the inhabitants of North and South Lancashire, both as to their ethnological history and their present physical characteristics. In the former, he believed the Norse element to preponderate, having been introduced, probably, by colonisation from the Isle of

Man and even from Dublin. The people were still tall and fair, and often strikingly Scandinavian in aspect. The remaining British element might be partly Gaelic. In the south of the county, immigration and physical degeneration connected with the great development of the cotton manufacture, had been, and were, effecting changes in the prevailing physical type, which had previously been more Anglian and British, while the Norse element had been comparatively weak. The paper was partly based on numerical data.

On the Ottoman Turks.—Dr. Beddoe. This paper mainly consisted of a minute physical description of the Ottomans of Anatolia, with notices of certain tribes of Yuruks and Turkomans scattered about Asia Minor. The physical type, which for brevity's sake, he called Turanian, was much more prevalent among the former than was generally supposed. It was doubtful whether there was any need for invoking the influence of climate or other *media* to account for the elevation that had occurred in the Ottoman physique. Inter-marriage with the women of subjected races soon after the conquest, and absorption of foreign elements, might sufficiently account for it, and as these had been most prevalent in Rumelia, and in the large towns, it was there that the original Turanian type had been most obscured.

Mr. John S. Phené read a paper on *A recent examination of British Tumuli and Monuments in the Hebrides, and on the western coast of Scotland.*

On the Builders of the Megalithic Monuments in Britain.—Mr. A. S. Lewis. The author divided the inhabitants of Britain into three leading types, the Kymric, long-headed, dark-haired, and light-eyed; the Iberian, dark-eyed and dark-haired; and the Teutonic, round-headed, light-haired, and light-eyed. He controverted the idea now gaining ground that the Iberians represented the aboriginal race, and that they exclusively were the builders of megalithic monuments. He attributed these monuments to Iberians and Kymry indifferently, and believed the latter race to have come to Britain before the former. These views he supported by, among other arguments, a careful consideration of the statistics of the physical characteristics of the inhabitants of Great Britain, collected by Dr. Beddoe, President of the Anthropological Society of London, from which he showed that the Iberians were found in the largest numbers in the southern part of the island, while the monuments were found throughout it, and this distribution of races seemed also to show that the Iberians were a later arrival than the Kymry. Mr. Lewis stated, however, that the statistics were not sufficiently numerous to be absolutely conclusive, and appealed to the members of the Association to assist in collecting further statistics of the physical characteristics of the inhabitants of their own districts.

On the Massagetæ and Sacæ.—Mr. H. H. Howorth. Relying upon the Chinese authorities translated by Stanislas Julien and V. St. Martin, the author identified the Massagetæ with the Ta Yuetchi or Great Yuetchi, and the Sacæ with the Sse or Szu of the Chinese authors. A close criticism of all the information about the Massagetæ and Sacæ furnished by the Greeks, enabled us to say that they were two names for one race, or at most for two branches of one race, Massagetæ being probably the native form, and Sacæ its Persian equivalent. Western writers throw little light on what this race was. The Chinese authors prove that it was a branch of the Thibetan race, called by them the Khiang, which was predominant in Central Asia before the aggrandisement of the Turks in the sixth century. The same authors enable us to connect the Massagetæ and Sacæ with the Indo-Scyths who overthrew Bactria and the Greek civilisation of Asia in the second century, B.C. Sacæ is equivalent to the Sah and Saka of the Indian Epics, and to the more Western Scyth, and in the cuneiform inscriptions is the Aryan substitute for the Semitic Gimiri, the Cimmerii of Herodotus. These facts enable us to destroy the old nonsense about the Sacæ and Saxons, the Massagetæ and Goths, the Cimmerian and Welsh, having been related to one another. Sacæ, Massagetæ, and Cimmerii were all Turanians and in fact Thibetans.

Mr. Dendy read a paper on *Shadows of Genius.*

On the Racial Aspects of Music.—Mr. Kaines. The author drew attention to the settled melancholy which pervaded the music of the north of Europe—a characteristic not observable in the music of the south of Europe, or of the other people of the globe. He endeavoured to account for this physically and practically, and showed there were vast differences in the temperaments in the peoples in the north and south of Europe. Of the one it might be said "melancholy marked it for her own," while cheeriness and brightness marked the other. The first seemed saddened by the mysteries of life, death, God, and immortality. Mr. Kaines noticed briefly the great religious revolution which had taken place in Europe, and how it had (probably) powerfully influenced its music. Protestantism broke the spell under which the human intellect was bound by Roman Catholicism, and enlarged the sphere o man's knowledge only to show him how much there was that he could never know. Catholicism, in engaging to answer all the intellectual and moral needs of man, took from him responsibility, and gave him a restfulness to which Protestantism is a stranger. The change from the old to the new (or rather revised) faith, had not been without its effect on music, and the emotional cravings and wild unrest which characterised the music of our times, might be attributable to this cause.

A long and interesting discussion ensued, in which Mr. James Smith, Dr. O'Callaghan, the Rev. Mr. Owen, Dr. Evans, Dr. Hitchman, and others took part.

Section E.—Geography

Mr. Winwood Reade read a paper on the *Upper Waters of the Niger*, and as we understand that he will shortly read a similar communication before the Geographical Society, a brief abstract of his paper will be sufficient for the present. Last year Mr. Reade made an exploring journey from Sierra Leone to the Niger, and visited the gold mines of Bouré, a country mentioned by many travellers, but which he has been the first to reach. Leaving Sierra Leone on January, he went to Falaba, as Major Laing had done before him fifty years ago, though by a different route. Like Major Laing, he was detained at Falaba, and not permitted to pass that important town. He returned to Sierra Leone, bringing with him messengers from the King of Falaba to the Governor of Sierra Leone, and these, grateful for the kindness and liberality with which they had been treated, promised Mr. Reade that he should be allowed to pass Falaba if ever he should visit them again. He determined to go back with them at once. The promise was kept; Falaba is only fifty miles distant from the Niger or Toliba (great river), and within a month after leaving Sierra Leone he reached that river, which has now, in its western course, been touched by explorers at three distinct points: by Mungo Park, at Segou, in 1796; by Caillié, at Couroussa, in 1828; and in 1869 by Readin, at Farabana, where the river is only a hundred yards broad. The author of the paper claims to have discovered the most direce and the shortest route to the Western Niger. Without presuming to compare himself with such giants in travel as Park and Caillié, he pointed out that while Caillié had not been able to reach the Niger under two months, nor Park (nor subsequently the followers in his footsteps, Dochard in '21 and Mage in '64) under four months, he had reached it in one month. Mr. Reade expressed his thanks to Mr. Swanzy, who had borne the expenses of his two years' African travel; to Mr. Heddle, a merchant at Sierra Leone; and to the Governor-in-Chief, Sir A. Kennedy.

Sir H. Barkly, K.C.B., who was in the chair, having thanked Mr. Reade for his paper, Mr. F. Galton made some interesting remarks on the Niger, and said that the discovery of its being only 250 miles from Sierra Leone would, without doubt, have an important influence on the political future of that colony. Lord Houghton asked why nothing had been done by the Sierra Leone Government during the last fifty years to explore the country lying interior of their colony. Mr. Reade said that he was unable to answer that question, but perhaps the extreme difficulty of getting through the coast tribes had something to do with it; as he had explained in his papers it cost him two journeys to make the insignificant distance of 250 miles. We may explain to those who follow these abstracts with their maps that the position of Falaba is correct; and that Bouré or Buri (which is a country, not a town) is approximately correct, as laid down by Caillié, who passed near it. But the tract of country between Falaba and Caillié's first position on the Niger (Couroussa) must be mapped afresh. Mr. Reade does not intend to alter the position of the Niger's source, as laid down by Major Laing from native information obtained by him at Falaba. He was prevented by the wars constantly prevailing in that region from visiting the source, but the information which he collected respecting its position confirms in all essential particulars that obtained in 1822 by Major Laing.

Section F.—Economic Science and Statistics

On the Aptitude of North American Indians for Agriculture.—James Heywood, M.A., F.R.S. Indian Reservations in Canada are under the control of the Secretary of State at Ottawa. Mr. W. Spragge, Deputy-Superintendent of Indian Affairs, presents annually to the Secretary of State a report on the Canadian settlements of Indians. The Six Nations Indians in the Tuscarora reserve, near Brantford, on Grand River, in the province of Ontario, form the most important settlement of aborigines in Canada. Their reservation comprises 55,000 acres, surrounded on all sides by thriving communities of white settlers. The Indian population of this reserve amounts to about 3,000 persons, including 2,800 of the Six Nations, and about 200 of the Mississaguas, or Ojibbeways, located near the river New Credit, at the southern extremity of the Tuscarora reserve. According to a report of Commissioners, appointed by Sir Edmund Head, Governor-General of Canada, in 1856, the Six Nations Indians were settled in the Tuscarora reserve, by Mr. Thorburn, the Commissioner, in "farm lots, averaging 100 acres each by actual survey." The total clearing of the Tuscarora reserve "amounted in 1856, to 7348 acres, more than half of which had been done by the Indians themselves, the remainder having been chopped by squatters, who had been removed from the land." "Most of these squatters were compensated for their improvements to the amount of more than 8,000*l.*, paid from the funds of the Six Nations Indians." The Commissioners of 1856 report that the Six Nations Indians cultivate on their reserve "separate farms, and each is secure in his possession from the other Indians on the lot he occupies. His heirs inherit his improvements, but the soil belongs to the Six Nations in common. The Indian has no right of transferring his portion of land to another. The revenue of the Six Nations Indians amounts to 39,489 dollars annually." Besides the two Schools in the New Credit district, maintained by the Indian bands of that locality, there are in the portion of the Tuscarora reserve inhabited by the Six Nations, eight Schools, principally supported by the New England Company, a London corporation, formed under the Commonwealth, whose funds are devoted to the extension of civilisation and Christianity among the aborigines in British Colonies, and especially in Canada. Mr. Henry Lister, a member of the New England Company, visited the Tuscarora reserve in 1868, and reported of the Six Nations Indians that their chief crops were "wheat, Indian corn, oats, and hay." Most of the Indian houses in this reserve, Mr. Lister described as "cottages of one or two rooms, built of boards or logs, and usually heated by a stove. There is not a single village," Mr. Lister remarks, "on the reserve; each house stands in its own lot of about 50 acres." An agricultural society was formed in 1868, among the Six Nations Indians of the Grand River, at an annual subscription of one dollar (about four shillings), for each member, and their first show was held on the 15th of October, 1868, on a farm within the reserve. The policy hitherto pursued in Canada, with regard to Indians, has been to induce them by means of small annuities to remain, to a great extent, as residents in the Indian reservations of the Dominion to which their lands or settlements may respectively belong. According to the Rev. Edward R. Roberts, missionary to the New England Company at Chemong, near Peterborough, in Canada, the province of Ontario was "divided into districts, with reference to the Indians. The land of each district was valued at a certain rate per acre, and the interest of the aggregate sum was paid half-yearly to the Indians included in that district, which constituted their annuity. And, in addition, each band of Indians had a reserve of land in a particular locality for their settlement. The aggregate annuity of the several bands," Mr. Roberts observes, "remains the same, whatever changes by death, birth, or emigration may take place. If a band of Indians becomes less in number, those who remain receive proportionably more annuity. While, however, an individual Indian (or family) ceases to receive his annuity from the fund appropriated to the band he leaves, he may be received into another band, by application, and a vote of the people; but as such an accession to their numbers diminishes their individual annuity by allowing others to share it, an application of this sort is seldom acceded to, as might be expected."

Section G.—Mechanical Science

On the Extent to which existing Works and Practice militate against the profitable Utilisation of Sewage.—Mr. J. Bailey Denton, M. Inst. C.E. The author stated that, notwithstanding the great amount of attention devoted by chemists and other scientific persons during the last twenty-five years to the treatment of sewage, the general opinion arrived at now is that the refuse of towns can only be made to give up its fertilising elements by transporting it direct to the land either by the agency of matter or earth. In support of this view he made two quotations from the reports prepared by the Rivers' Pollution Committee of Inquiry. It is generally admitted that wherever people are congregated, and a number of dwellings exist together, it is not possible to provide for the largely increasing use of water, by a population doubling itself within the period of fifty years, without underground conduits for the discharge of liquid sewage. In nearly all our cities and large towns systematic sewage already exists. In the midland and southern towns water-closets are comparatively numerous, though privies with cess-pools still predominate, but in the northern towns water-closets are comparatively few, and the middens nearly universal. After mentioning various instances in which there is infiltration of subsoil water into the sewers, doing mischief in a variety of ways, the author called attention to the evil of indiscriminately admitting a largely disproportionate quantity of water into the sewers, without any power to regulate the time and extent of dilution. Assuming, with the Rivers Pollution Commissioners, that sewage must be utilised upon the land by the process of irrigation, Mr. Denton proceeded at some length to consider the conditions which should be observed in order to obtain the maximum amount of benefit from sewage farms. He concluded by saying, "With a sewage farm naturally or artificially drained, and the surface sloped so as to make the absorption and filtration of sewage certain; intermittent filtration may be practised by itself at any time when it is desirable to resort to it independently of irrigation. At seasons when the sewage may be applied profitably to vegetation, of course the two processes will proceed together; but it will only be by operations admitting alike of combined or separate action that purification and profit may be secured free from all chance of malaria. With the prospect of applying the sewage of towns extensively to land by way of irrigation, it is most desirable that the proper preparation of land to receive it should be indisputably understood and acted upon.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Sept. 12.—M. Faye communicated a note on the mode of observing the approaching transit of Venus, in which, after giving some account of Mr. Newcomb's memoir on the same subject, he suggested an application of photography by means of electrical apparatus. M. Faye also presented a note on the chemical agents to be employed in opposition to miasmatic infection, in which he remarks upon the application of the phenic compounds to this purpose.—M. Dumas and M. Chevreul made some observations on the subject of this paper.—A letter was read from M. Sédillot on the surgical indications and the consequences of amputations in connection with wounds.—M. C. Bernard presented a note by M. Rabuteau, on the means of annulling the effects of insufficient alimentation. The author described the effects produced by Coffee in diminishing the waste of material in vital operations, and maintains that by the free use of coffee life may be supported in full activity with much less than the theoretical amount of nourishment. Cocoa and Tea partake of the same qualities.

THURSDAY, OCTOBER 13, 1870

NATURAL HISTORY SOCIETIES

I.

EXISTING Natural History Societies, or Field Clubs, may be divided into two classes: those which have already a definite scientific position, and aim especially at working out the flora and fauna of their country or district; and those which have for their object the popularising of the various branches of Natural Science, always with due regard to scientific exactness. The first consist chiefly of professed naturalists; the second of intelligent persons who have some desire to gain a little insight into the wonders with which they are surrounded. Some societies combine the two; and these are, perhaps, the most useful of the three classes. Although taking a somewhat lower tone, our second class is to the full as important as the more advanced one; and if by its means our fellow-countrymen obtain even a slight knowledge of some branch of Natural History, something will have been done to diminish in some measure the mass of ignorance on matters connected with Natural Science which still prevails among educated people. Apropos of this, we may mention one instance which has lately come to our knowledge. Some people, of average education and intellect, who had resided for fifteen years in a country district, had brought to them a full-grown larva of the Privet Hawk-moth. Having no idea of its nature,—although one suggested that it was a "locust!"—but a sort of dread of its mysterious appearance, and of the horn on its tail, a council of war was held, and, it being considered too large to "squash," the unfortunate creature was forthwith placed in a pail of water, where it remained for eight or ten hours. At the end of this time a naturalist intervened, and the caterpillar was rescued from its bath; when, strange to relate, it positively lived for three or four days, but died while passing into the state of pupa.

Having had some practical experience in the working of more than one local society, and somewhat special opportunities for becoming acquainted with the *modus operandi* pursued by others, a few notes on some of the more salient points which they present may be of some interest, and possibly of some use, to those who purpose taking part in establishing such a body. On the present occasion, we will confine ourselves to those societies which, either from the long period for which they have been established, or from other favouring circumstances, have attained a definite position, and are chiefly maintained by experienced naturalists, deferring for a future paper some hints and suggestions on the formation of less pretentious bodies.

One of the most important duties which devolves upon a society or field club possessing a fair proportion of working members, is the investigation of the flora and fauna of the district in which it is placed. Agreeing, as all will do, with Linnæus, that "turpe est in patriâ vivere, et patriam ignorare," it is evident that it is mainly through the agency of such bodies that a knowledge of the Natural History of the country generally is to be obtained. For such purposes there is no plan so satisfactory as that which is termed "working by sections." On this system, the society is divided into a number of smaller bodies, each having for its object the investigation and reporting upon some one branch, and consisting exclusively of those who are able and willing to devote both time and attention to the subject. Each section has its chairman and secretary, and holds its meetings independently of the remainder of the society. This plan has two advantages—only those who really *work* will undertake to join a section, and their meetings are kept free from any hindrance arising from the "drones," who, it must be confessed, are to be found more or less in every society, great or small. Besides, the three or four members forming each section can always conveniently meet at each other's houses, a proceeding which could not be so readily carried out if the whole number were assembled for each meeting; and as the societies which have the advantage of a room specially retained for meetings are but few in number, this consideration is not unimportant.

The thorough and convenient investigation of the Natural History of a district, though an important, is not the only duty of a field club; the same body may be of yet greater service in aiding in the publication of the facts which have been collected by its members. In this manner local societies have already done good service to science; thus, in botany alone, we owe to the Tyneside Naturalists' Club, Mr. J. G. Baker's valuable "Flora of Northumberland and Durham;" to the Holmesdale Naturalists' Club, Mr. Brewer's "Flora of Surrey;" to the Worcestershire Field Club, Mr. Lees' "Botany of Worcestershire;" while of similar works in preparation we may mention the "Flora of Herefordshire," by the Woolhope Club (of which Part 1 is already published); that of East Kent, by the East Kent Natural History Society; of Folkestone, by the Folkestone Society; of Berkshire (a much needed contribution to British botany), by the Newbury District Field Club; and many more. The Tyneside naturalists certainly stand first in the value and importance of their published proceedings, which, especially since their union with the Natural History Society of Northumberland, Durham, and Newcastle, have attained a scientific position which renders them indispensable to those who would obtain a complete knowledge of the Natural History of the country at large. As a proof that local matters are not neglected in these volumes, catalogues of the Lepidoptera, Mollusca, Zoophyta, recent Foraminifera, and Fossils, have been published in them, and also issued separately at a moderate cost; and the last volume contains a paper on the "Crustacean Fauna of the Salt Marshes," and a "Catalogue of the Aculeate Hymenoptera," of the two counties. We have been thus particular in commenting on these transactions, as they appear to us to afford a very good example of what the publications of the higher class of field clubs ought to be: essentially local, yet at the same time of sufficient general interest to be really valuable contributions to the Natural History of England. Second only to them in importance are the "Proceedings of the Berwickshire Naturalists' Club," of which the sixth volume is now in progress. This society is of especial interest as being the first local field club established in the kingdom.

Another advantage attending the publication of local floras by field clubs, is that by their means the expenses attendant upon such works fall less heavily upon those who undertake their compilation, and a fair number of subscribers is more readily obtained. Although much has already been done in publishing such works, there is still much remaining to be done; we could wish, for example, that the Manchester naturalists would publish a new and more complete edition of the "Manchester Flora," and that the Liverpool people would issue in a separate and completed form the flora which appeared in part in their journal. These floras, with that of Birmingham, if carefully worked out, with full references to the older writers, would be of a value second only to that of Trimen and Dyer's "Flora of Middlesex," as showing the influence of cultivation upon the botany of a district.

We must not dismiss the subject of publications without a reference to one or two of those emanating from more recently established societies, which have been favourably received. The Woolhope Club has now issued four volumes, copiously illustrated with photographs and coloured lithographs, the contents of which are of somewhat more general interest than those we have already referred to. This being the case, we can but regret that the volumes are inaccessible to the general public; but a limited number only are printed, which are almost confined in circulation to the members of the club. Noteworthy papers are those on the remarkable trees of Herefordshire (adorned with some exquisite photographs), on the fungi of the county, and on its geology; while the antiquarian will find some prominence given to archæology. The Malvern Naturalists' transactions are similar in general features to those of the Woolhope Club, and we observe that the two societies vie with each other in the attention they bestow upon edible fungi. The Birmingham Society has just issued the first volume of its proceedings—a very creditable one—which has the additional advantage of being obtainable by outsiders at the moderate cost of half-a-crown. We need not remark further upon this, as a notice of it lately appeared in our columns.

The general arrangement of meetings, &c., must depend almost entirely upon local circumstances; and the same remark will apply to rules, which should be as few and simple as possible. As we are now speaking only of firmly established bodies, any hints upon these matters are deferred for a second paper.

A WORD ABOUT YALE

THE following account of the Yale University scheme, by Professor J. D. Dana, is taken from the *Yale College Courant*:—

1. The Classical or Academic and the Scientific departments (ordinarily called Yale College, and the Sheffield School of Science) are distinct colleges for the undergraduate students of the University—distinct in teachers, scholars, buildings, apparatus, and special working libraries. They have in common a general library, and the officers meet for the discussion of University questions in a common University Faculty.

2. In each college the first two years of the four* are years of preparatory study without optional or elective courses, except perhaps in place of the higher mathematics of the second year. After the close of the second year a number of elective courses are before the student.

3. In the Academic College—whose special subjects of study are the classics, modern languages, mathematics, astronomy, history, intellectual and moral philosophy, political economy, general literature, &c.—the principles of natural science, physics, and chemistry are taught so far as is necessary to give depth and breadth to an academic education; a general knowledge of the laws or systems of nature, both organic and inorganic, being essential in these days to a true scholar, whatever his purpose in life.

4. In the Scientific College—whose special subjects of study are the various natural sciences, physics, chemistry, mathematics, and the practical applications of these sciences—literary subjects are added, including modern languages (some knowledge of the ancient languages being required for entering), political, moral, and intellectual science, history, physical and political geography, &c.—in order to give in this branch of the University a thorough and well-grounded education, and make the graduate a man of high culture.

5. In the Academic College, optional or elective courses are confined to its special subjects of study: (1) the classics, (2) modern languages, (3) English language and literature, (4) mathematics. None are allowed in the departments of natural, chemical, or physical science, as these subjects are admitted into this college only so far as is necessary to give that breadth and depth to education which every graduate should have.

6. In the Scientific College also, elective courses are confined to its special objects of study—that is, to the natural sciences, physics, geology, metallurgy, mechanics, engineering, &c.

7. The post-graduate courses of the University comprise many distinct departments in the lines of the Academic and Scientific Colleges. Connected with the former, there are (or may be) courses in Latin, Greek, different Oriental languages, linguistics, English language and literature, history, intellectual philosophy, mathematics, astronomy, &c. &c. Connected with the latter there are (or may be): First, in *pure science*, courses severally in the different physical sciences, general chemistry, organic chemistry, mineralogy, botany, zoology, palæontology, geology, mathematics, astronomy, &c.; Secondly, in *applied science*, courses in civil engineering, mechanical engineering, mining and mining engineering, practical mechanics, metallurgy, agriculture and agricultural chemistry, &c.

8. The students of the Academic College take, on graduating, the degree of Bachelor of Arts; and those of the Scientific College that of Bachelor of Philosophy.

The students of the post-graduate courses, after two years of study, in which high scholarship is attained as tested by a rigid examination, take the degree of Doctor of Philosophy; except in the case of students in Civil Engineering, who may receive that of Civil Engineer after one year of study.

The University includes also the Schools of Law, Medicine, Theology, and the Fine Arts. But of these it is not necessary here to speak. Neither of them has, in any part of its curriculum, an undergraduate department analogous to that of the Academic or Scientific College.

* The three-years' course of the Scientific School will probably be made a four-years' course within a year or two.

In connection with the above brief statement I offer the following remarks:—

1. The ranges of studies in the two colleges, the Academic and Scientific, are so diverse in character, that the interests of the students and of education are better subserved by two distinct faculties working separately, than by one single combined faculty. There is not in the Yale scheme that multiplicity of optionals before the students after they have entered the University, which inconveniently subdivides classes, offers inducements to indolence, and tends to break down thorough discipline and study; for, in the act of entering, the student decides as to the range of his optionals; and if afterwards not satisfied (which would seldom be the case) he can join the other college.

2. It might be supposed that the scheme would require an unnecessary duplication of professors. But this is not so at Yale. In the Academic College there are already four instructors in Greek, four in Latin, five in mathematics, physics, and astronomy; and the professors of rhetoric, history, moral and intellectual philosophy, &c., are more than well occupied with their academic labours. The scientific students, if embraced in the Academic College, would actually require as many additional instructors as are needed under the existing system of the University.

3. In some scientific departments in the Academic College (zoology and botany, for example), in which the instruction occupies but a small part of the college course, there is no objection to employing the services of some of the scientific faculty, if this is feasible; and, where possible, the academic faculty may serve the Scientific College. Moreover, while all lecture-rooms had better be separate, the more costly kinds of apparatus may well be used in common, in order to avoid needless expenditure.

4. It may be added that many scientific students commence their training as scholars by first graduating in the Academic College. For the higher training in science, such a preparatory course in the classics is believed to be eminently desirable. They then enter an advanced class in some one of the departments in the Scientific College, and take the degree of Bachelor of Philosophy, or of Civil Engineer; or by special proficiency, after two years of study, that of Doctor of Philosophy. The Scientific College also admits of partial courses of study which do not lead to any degree.

5. The modification in American colleges which is demanded by the vast development of the sciences of nature within the past century—the era of origination for many of them—and also by the contemporary progress of linguistic and other sciences, is accomplished by the Yale scheme through a method which does not sacrifice, in any degree, classical education, and which at the same time combines thorough literary culture with the widest range and highest development of scientific education. The Classical College stands beside the Scientific, open to all who desire to commence with a classical basis; and the Scientific College offers a thorough and liberal education for all who would pursue a more distinctively scientific course.

6. The Yale scheme contemplates no important change in the Classical or Academic College except in the elevation of the department of modern languages and literature; and its ideal with regard to modern languages cannot be wholly realised until a knowledge of French and German is given (like that of Latin and Greek) in preparatory schools, and required for admission to the college.

7. The great change that has taken place at Yale is in the introduction of its School of Science. This school is not the result of any preconcerted plan on the part of the University. It is a gradual growth of the past twenty years, urged on by the demand in the land for scientific knowledge among lovers of science, those seeking to become its teachers, and others interested in its practical departments; and it has been carried forward to its present organisation mainly through the labours and judgment of the scientific men who have been slowly gathered into its faculty. More than two-thirds of its endowments are due to private munificence, and the remainder to the National Agricultural and Mechanical Fund.

WALLACE ON NATURAL SELECTION

Contributions to the Theory of Natural Selection. A Series of Essays. By Alfred Russel Wallace. (London: Macmillan and Co., 1870.)

IN the discussions of the French Academy, to which we referred in a recent number, M. Elie de Beaumont ventured to describe Mr. Darwin's theory as *La Science Mousseuse.* The phrase is a good one, and expresses very happily the kind of work for which some of the speakers in that debate are distinguished. But although we too in England are not unacquainted with this kind of popular science, scientific works do from time to time appear which are popular without being frothy, and to this class the present book belongs. While strictly accurate in matter, it is easy in style, and is so free from technical language, that it may be understood by educated men who are not professed naturalists; so that we hope it will be read by a large number of those to whom Mr. Wallace's delightful volumes have made the Malay Archipelago familiar.

The arrangement of the essays (most of which have been published separately) does not, perhaps, bring out their mutual connection so well as might be, and there is no attempt to blend them into a continuous series. Four main subjects are discussed, and each has its own peculiar interest.

The first and second chapters are reprinted as originally written in the East Indies, and, with the eighth, form Mr. Wallace's contribution to the theory of natural selection in general. It is remarkable that the same pregnant idea which Mr. Darwin has for ever united with his name should have occurred independently to another English naturalist on the other side of the globe. The public opinion of the scientific world will no doubt assign Mr. Wallace the full credit which the preface to this volume so modestly claims; and the highest respect is due to his varied and fruitful labours in both hemispheres; but a warmer feeling than respect will be paid to the spirit by which the following passage was prompted:—"I have felt all my life, and I still feel, the most sincere satisfaction that Mr. Darwin had been at work long before me, and that it was not left for me to attempt to write 'The

Origin of Species.' I have long ago measured my own strength, and know well that it would be unequal to the task. Far abler men may confess that they have not that untiring patience in accumulating, and that wonderful skill in using, large masses of facts of the most varied kind—that wide and accurate physiological knowledge, that acuteness in devising and skill in carrying out experiments, and that admirable style of composition, at once clear, persuasive, and judicial—qualities which in their harmonious combination mark out Mr. Darwin as the man, perhaps, of all men now living, best fitted for the great work he has undertaken and accomplished."

The third chapter is on so-called Mimicry among Animals, and contains an account of some of the remarkable cases of dimorphism observed by the author and by Mr. Bates, and of those in which one species closely resembles not only leaves and inanimate objects, but other specially protected animal forms. The facts thus established are explained with great ingenuity, and often with equal probability, by the operation of the natural laws of selection. The ways in which even brilliant colouring may become a means of protection are well illustrated, so that this branch of study is made to yield support instead of difficulty to the Darwinian theory. The following chapter, the only technical one in the book, is an application of the same law to explain the various forms and distribution of the group of *Papilionidæ.* It may be compared with Fritz Müller's study of the Crustacea from a similar point of view; and we believe that more solid progress will be made by carefully working out the application of natural selection to restricted and well-known animal groups than by attempting the construction of more comprehensive and imposing phylogenies.

In the seventh chapter Mr. Wallace makes a somewhat similar inquiry into the relation of the colour of birds to the form of their nests, and concludes, from a very wide survey, that when the female is of conspicuous colours, the nest is adapted to conceal her during incubation, while open nests are made by those already sufficiently protected. The exceptions to the rule are candidly stated, and most of them satisfactorily met. That the true law of the habit has been discovered is, perhaps, too much to say; but the evidence is at least enough to lead to further investigation on this interesting subject. Another essay, styled, not very happily, "The Philosophy of Birds' Nests," attempts to explain the building of nests and also the song of birds as the result not of "instinct," but of conscious imitation; gradual improvement being of course brought forward by the survival of the most skilful architects and the constant sexual demand for the best musicians. But not only does Mr. Wallace thus raise nest-making to the rank of an intelligent art, he also shows how much of human construction is simply imitative, and therefore as fairly to be called instinctive as a bird's; while in another passage he shows how the alleged wonderful displays of instinct in savages are really the result of habit and of reason.

This chapter on Instinct in Men and Animals would naturally introduce the last two, in which the working and the limits of the law of natural selection on the human race are considered. This is probably the most difficult, as it is certainly the most generally interesting, of the questions affecting the origin of animal species Those who are not satisfied with the genealogies of Haeckel, and wait for the more cautious and philosophic conclusions expected from the master of the subject, will scarcely, we think, accept the views propounded in this volume by Mr. Wallace. He points out very clearly how most of the human peculiarities of structure may be supposed to have originated by the survival of the forms fittest for their mode of life, and is fully aware of the necessary change going on at the same time in the various functions, to bring them also into harmony with structure. And he shows with great justice how mental and moral qualities must interfere with the absolute carrying out of the law of natural selection—not only in civilised communities, where it is continually and designedly contravened, but among all savages who take, for instance, the least care of the sick and aged of their tribe. But, beside and apart from the operation of the general law of organic life, with these various modifications and restrictions, Mr. Wallace believes that another and independent cause has been at work in the evolution of the human frame, and that this has been a supernatural one. He maintains that the large size of the brain in man, the scantiness of his hairy covering, the great specialisation of his extremities, and some other peculiarly human characters, cannot be explained, except as the result of the direct action of the Creator's will. In fact, he compares man as he at present exists with such products of artificial human selection as the seedless banana or the London dray-horse; so that, if we may thus express Mr. Wallace's theory, man is God's domestic animal.

A great deal of the metaphysical discussion which occupies the last pages of the volume, including the verses quoted from an American poetess, has, we confess, to our mind, the same "double disadvantage" which the author finds in "the law of unconscious intelligence pervading all organic nature put forth by Dr. Laycock, and adopted by Mr. Murphy," that, namely, of being "both unintelligible and incapable of proof;" but the theory of divine artificial selection supplying the deficiencies of natural selection in the formation of man may, we think, be at once met by the following considerations.

The theory of natural selection does not suppose a kind of large female divinity, whose name is Nature, and whose function is to select from animals and plants those fittest for survival. The theory rests, as Mr. Wallace, in another part of his work, is careful to remind the reader, on certain proved facts (enumerated at p. 302), which necessitate the survival of certain forms by virtue of the proved physical laws which we see in daily operation. But these so called laws are, to all who believe in a Creator, simply the manner of His action. To say that our brains were made by God, and our lungs by natural selection, is really to exclude the Creator from half His creation, and natural science from half of nature. All the phenomena we know are of necessity ultimately referable to the First Great Cause: the object of science is to discover their secondary causes; and if the theory of natural selection does not explain how the larynx or the brain of man were developed, then we must try to find another which will. To fall back for explanation upon the primary efficient cause of their existence and the design with which they were framed, is only to confuse two distinct branches of inquiry.

At present, however, we may be content to see how far we can work the Darwinian hypothesis, and can only hope that there may be other "contributions" to the theory as interesting and valuable as these of Mr. Wallace.

P. S.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Dr. Bastian and Spontaneous Generation

I FIND that the "Address" which it was my duty to deliver at Liverpool, fills thirteen columns of NATURE. The "Reply" with which Dr. Bastian has favoured you occupies fifteen columns, and yet professes to deal with only the first portion of the "Address." Between us, therefore, I should imagine that both you and your readers must have had enough of the subject; and, so far as my own feeling is concerned, I should be disposed to leave both Dr. Bastian and his reply to the benign and Lethean influences of Time.

But I am credibly informed that there are persons upon whom Dr. Bastian's really wonderful effluence of words weighs as much as if it were charged with solid statements and accurate reasonings; and I am further told that it is my duty to the public to state why such distinguished special pleading makes not the least impression on my mind. With your permission, therefore, I will do so in the briefest possible manner.

The first half of Dr. Bastian's "Reply" occupies seven columns of your number for the 22nd of September. In all this wilderness of words there is but one paragraph which appears to me to be worth serious notice. It is this:—

"In the first place, he does not attempt to deny—he does not even allude to the fact—that *living things may and do arise as minutest visible specks, in solutions in which, but a few hours before, no such specks were to be seen.* And this is in itself a very remarkable omission. The statement must be true or false—and if true, as I and others affirm, the question which Professor Huxley has set himself to discuss is no longer one of such a simple nature as he represents it to be. It is henceforth settled that as far as *visible* germs are concerned, living beings can come into being without them."

If I did not allude to the assertion which Dr. Bastian has put in italics—it is because it bears absurdity written upon its face to any one who has seriously considered the conditions of microscopic observation. I have tried over and over again to obtain a drop of a solution which should be optically pure, or absolutely free from distinguishable solid particles, when viewed under a power of 1,200 diameters in the ordinary way. I have never succeeded; and, considering the conditions of observation, I never expect to succeed. And though I hesitate to speak with the air of confident authority which sits so well on Dr. Bastian, I venture to doubt whether he ever has prepared, or ever will prepare, a solution, in a drop of which no "minutest visible specks" are to be seen by a careful searcher. Suppose that the drop, reduced to a thin film by the cover-glass, occupies an area $\frac{1}{4}$ of an inch in diameter; to search this area with a microscope in such a way as to make sure that it does not contain a germ $\frac{1}{10000}$ of an inch in diameter, is comparable to the endeavour to ascertain with the unassisted eye whether the water of a pond, a hundred feet in diameter is or is not absolutely free from a particle of duckweed. But if it is impossible to be sure that there is no germ $\frac{1}{10000}$ of an inch in diameter in a given fluid, what becomes of the proposition so valuable to Dr. Bastian that he has made your printer waste special type upon it?

I now pass to the second part of the "Reply," which, though longer than the first, is really more condensed, inasmuch as it contains two important statements instead of only one.

The first is, that Dr. Bastian has found *Bacterium* and *Leptothrix* in some specimens of preserved meats. I should have been very much surprised if he had not. If Dr. Bastian will boil some hay for an hour or so, and then examine the decoction, he will find it to be full of *Bacteria* in active motion. But the motion is a modification of the well-known Brownian movement, and has not the slightest resemblance to the very rapid motion of translation of active living *Bacteria*. The *Bacteria* are just as dead as those which Dr. Bastian has seen in the preserved meats and vegetables; and which were, I doubt not, as much put in with the meat, as they are with the hay, in the experiment to which I invite his attention.

The second important statement in the second part of the "Reply" is:—

"Professor Huxley is inclined to believe that there has been some error about the experiments recorded by myself and others."

In this I cordially concur. But I do not know why Dr. Bastian should have expressed this my conviction so tenderly and gently as regards his own experiments; inasmuch as I thought it my duty to let him know both orally and by letter, in the plainest terms, six months ago, not only that I conceived him to be altogether in the wrong, but why I thought so.

Any time these six months Dr. Bastian has known perfectly well that I believe that the organisms which he has got out of his tubes are exactly those which he has put into them; that I believe that he has used impure materials, and that what he imagines to have been the gradual development of life and organisation in his solutions, is the very simple result of the settling together of the solid impurities, which he was not sufficiently careful to see, in their scattered condition when the solutions were made.

Any time these six months Dr. Bastian has known why I hold this opinion. He will recollect that he wrote to me asking permission to bring for my examination certain preparations of organic structures, which he declared he had clear and positive evidence to prove to have been developed in his closed and digested tubes. Dr. Bastian will remember that when the first of these wonderful specimens was put under my microscope, I told him at once that it was nothing but a fragment of the leaf of the common Bog Moss (*Sphagnum*); he will recollect that I had to fetch Schacht's book "Die Pflanzenzelle," and show him a figure which fitted very well what we had under the microscope, before I could get him to listen to my suggestion; and that only actual comparison with *Sphagnum*, after he had left my house, forced him to admit the astounding blunder which he had made.

To any person of critical mind, versed in the preliminary studies necessary for dealing with the difficult problem which Dr. Bastian has rashly approached—the appearance of a scarlet geranium, or of a snuff-box, would have appeared to be hardly more startling than this fragment of a leaf, which no one even moderately instructed in vegetable histology could possibly have mistaken for anything but what it was; but to Dr. Bastian, agape with speculative expectation, this miracle was no wonder whatever. Nor does Dr. Bastian's chemical criticality seem to be of a more susceptible kind. He sees no difficulty in the appearance of living things in potash-alum, until Dr. Sharpey puts the not unimportant question, whence did they get their nitrogen? And then it occurs to him to have the alum analysed and he finds ammonia in it.*

And as to the elementary principles of physics—in his last communication to you, Dr. Bastian shows, that he is of opinion that water in a vessel with a hole in it, from which the steam freely issues, may be kept at a temperature of "230° to 235° F. for more than an hour and a half."† I hope that Professor Tyndall, whom Dr. Bastian scolds as authoritatively and as unsparingly as he does me, will take note of this revolutionary thermotic discovery, in the next edition of his work on Heat.

It is no fault of mine if I am compelled to write thus of Dr. Bastian's labours. I have been blamed by some of my friends for remaining silent as long as I have done concerning them. But when, because I have preserved a silence, which was the best kindness I could show to Dr. Bastian, he presumes to accuse me publicly of unfairness, and to tell your readers that my Address "is calculated to mislead" them, I have no alternative left but to give them the means of judging of the competency of my assailant.

Jermyn Street, Oct. 10 T. H. HUXLEY

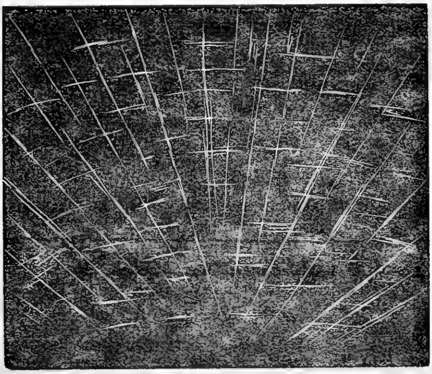
Ozone developed by Humidity and Electricity

IN confirmation of the idea as to the connection of excess of ozone with humidity and electrical action, to which attention was drawn in my previous letter of August 4, I forward you the following observations.

* See NATURE, No. 36, p. 198. † Ibid, No. 48, p. 433.

Between August 19 and September 9, the average of ozone registered was very great, being about eight by Schönbein's test-paper. On the five days ending September 9, the quantity each morning was nine. During the longer period mentioned, humidity was also in excess. Rain fell every day from September 1 to 9.*

The weather during the last month has been very pleasant—we have not had more than one really wet day, and rain has generally fallen in the night. Though there have been no thunderstorms, we have had evidence of their occurrence in other parts by the presence of electrical cumulus. But the most remarkable phenomenon in connection with electricity was the appearance of an Aurora Borealis *in the daytime*, which happened on



the afternoon of September 4. I pointed this out (about 4 P.M.) in the form of thin reddish streaks resembling linear cirrhus, which radiated in a symmetrical manner from the north, at the same time anticipating a luminous appearance after nightfall. This took place: yet the light was not in the northern part of the heavens, but stretched clear across from W. to E. in a broad band of glowing white light. Fainter streaks appeared afterwards in the north. A dark cirrhus mist overspread the sky at the time.

The radiating cirrhus, or Auroral cloud that appeared in the daytime, was crossed by lighter streaks, as in the accompanying sketch.

The day previous this phenomenon was seen at Edinburgh, and also in this neighbourhood, though I did not observe it.

These manifestations, followed each time as they have been lately by change of weather, seem to confirm the theory of Mr. Buchan and M. Silbermann; and I could adduce other observations pointing to the same inference, viz. that the Aurora Borealis is an atmospheric phenomenon, connected with the polarisation of vapour.

Great Malvern, Sept. 12 S. B.

* The above notes were taken by Mr. R. J. Wood.

Aurora Borealis

On going out this evening I saw a very fine Aurora Borealis, which literally covered the whole sky to within 15° of the southern horizon. The streamers were of a yellowish white colour, but at times very decidedly red. They shot up from the east, north, and west strongly, feebly from the south. The radial point was within 5° of Scheat (β Pegasi) A.R. $22^h\ 56^m$., dec. N. 27° 15′±.

This radial point remained constant for about one hour and a half, when it suddenly shifted, at 11.30, to within 5° of the zenith towards the east.

The light was sufficient during the flashes to see my watch, and read the second hand with ease.

Altair (α Aquilæ) was quite blotted out by the glare as it passed over; also the stars in Cygnus and Andromeda.

I used a spectroscope on the light, and found that I could distinguish the bright line near the group of calcium lines (wave-length 5,567) almost anywhere I pointed to in the sky, excepting on the south horizon; while to the north, I not only saw the bright line, but also others apparently near F, one bright, the other very faint.

I hope that there will be other notices in your paper of this very fine Aurora.

My latitude is N. 57° 8′ 56″. LINDSAY

Dunecht, Aberdeen, Sept. 24

A MAGNIFICENT display of Aurora Borealis was observed here this evening, between 9^h and 12^h P.M. During the early part of the morning the suspended magnets were so much disturbed that I considered it useless to continue a series of absolute determinations of the magnetic elements on which I was engaged. The auroral display when first noticed bore a very striking resemblance to the effect produced by a brisk and squally wind passing over an otherwise calm lake. Magnetic clouds overspread the northern half of the sky, and were abruptly terminated by an irregular arch, stretching from the magnetic E. to W., and passing almost through the zenith. This arch was never very well defined, but it served for some time as an apparent barrier to the rapid passage of the waves of magnetic light from the N. towards $9^h\ 45^m$ P.M. The whole N. horizon was brilliantly illuminated, but in some points more so than in others, and from these points broad streamers darted forth, extending often from the horizon to the zenith. Several of these stupendous beams of light, many degrees in breadth, were sometimes seen at once, and occasionally the whole N. horizon shot forth these brilliant streamers. The colour of the beams was often red, but more frequently white, but many changed from white to red, or red to white, before vanishing from sight. The sky at times was partly of a deep red hue.

At $10^h\ 45^m$ some of the beams assumed a more stationary character, and radiated from a point some 70° above the E.S.E. horizon. The whole sky then became covered for a short time with the magnetic clouds, which were rarely dense enough to obscure stars of the second magnitude. At about eleven o'clock the phenomenon again completely changed, returning suddenly to its former aspect, of a lake violently agitated by a gusty wind, which brilliantly lit up the thin clouds as it passed rapidly onwards from the N. Towards midnight the activity of the forces considerably abated.

During the storm the vertical force magnet was completely thrown off balance, and the declination and horizontal force magnets suffered considerable perturbations.

Stonyhurst, Sept. 24 S. J. PERRY

Botanists and the Halfpenny Postage

FOR several years I have been in the habit of sending herbarium specimens by "book post," by merely placing the plants between sheets of white cardboard, which were invariably fastened by string, without wrappers, and the address written on the cardboard itself; so that, in fact, the parcel was open at both ends and sides. On Tuesday last I did up a small packet of green or living plants, and sent them to the village post-office. As the parcel weighed under four ounces, I affixed two halfpenny stamps. On calling at the post-office the next day, imagine my disgust at seeing my parcel of plants stuck up in the window to be sundried! Upon inquiry, I found that the postman had very *wisely* declined taking it to the borough office, as "several similar parcels were lying about there now, and would not be forwarded until the senders had prepaid the postage at letter-rate."

I say the postman acted wisely in refusing to take my parcel, because, on taking it to the Newbury post-office myself on Thursday, I found that unless I paid eightpence, or rather put on seven more penny stamps, *double* that amount would have actually been charged to the recipient, at which I should have felt much grieved, as the specimens were really not worth half the amount.

Another gentleman of my acquaintance sent a parcel to the same office with a fourpenny stamp on; this the clerk kindly *defaced*, and returned the parcel as "not sufficiently paid"!

I have read the new rules, and can see no clause bearing on this subject—either for or against herbarium specimens, or other objects of natural history, being sent between cardboard with open ends at the old rate of four ounces and under for one penny, and should therefore be glad of any correct information from you or the readers of NATURE.

East Woodhay, Oct. 7 HENRY REEKS

Working Men's Colleges

I HAVE only just seen your remarks on Working Men's Colleges, and your suggestion that "men and women should be treated, not as artizans, mechanics, or gentlemen, but simply as men and women." May I, speaking as a member of the College in Great Ormond Street, and also of the younger college here, and having an intimate knowledge of both during the whole of their existences, assure you that both these colleges were opened and have been carried on in the spirit you suggest, and in no other? Certainly, we have never in either college desired to treat *women* as either "artizans, mechanics, or gentlemen."

Secondly, I do not think either college is second, even to the "Berlin Working Men's Club," in *catholicity*. Each college puts forth a programme of what it can give its members, and there is not in either college the slightest effort to induce any member to do anything but what he has a spontaneous desire to do. Neither college "belongs to any religious or anti-religious body." Neither college has any "Shibboleth of any kind whatever."

Thirdly, your suggestion that all the colleges and clubs should be united into one, would have more value in a small town than in London, with its hundreds of miles of streets and its millions of inhabitants.

Lastly, there is an essential difference between a college and a club. The one has a foundation in work, the other in recreation; the chief work of the one is mental, of the other social; in both it is moral. Both are necessary, but they need not necessarily be carried on in the same building.

Another point is that working men *cannot* form a college *for* and *by* themselves, except they scarcely need it. The number of members needful to defray the expenses is so large, and the number of men in London possessing the elementary education requisite to give them an intelligent and persistent desire for such a place is comparatively so small, that I do not think any college in London can be wholly self-supporting for some years to come.

If any of your readers desire to know what kind of work the two colleges are doing, I shall be happy to give them full particulars of the work and of its difficulties, and still more of its need to be done. I think you are in error in speaking of the *extension* of the scientific programme of Great Ormond Street College. I have before me the new programme of that college. In *this*, the younger college, we have put before our students a larger number of science classes than we have hitherto done, because we are beginning to find that the men who have passed through our night schools and elementary classes give us hopes of doing good in this way. Possibly it is to this that you meant to refer.

W. ROSSITER, Hon. Sec.

October 4 South London Working Men's College

[We wrote by the card in speaking of a projected extension of the scientific instruction at the Working Men's College in Great Ormond Street.—ED.]

Lunar Rainbow

I HAVE just witnessed this evening (Monday, 10th, 7.30 P.M.) a magnificent lunar rainbow, distinctly coloured throughout, and with the reflection bright towards the west. The space within the bow appeared lit up by a silvery haze, offering a marked contrast to the inky appearance of the cloud beyond the bow.

The moon was shining brightly as the shower commenced during which the rainbow was seen. It was observed at different times during the evening by several persons.

Cromer, Norfolk J. G. DUTHIE

NOTES

WE have great pleasure in announcing that the American Government have voted 6,000*l*. for the expedition which will be sent to Spain and Sicily to observe the coming eclipse. It will be in the recollection of our readers that our own Government have refused to give either a single ship or a single shilling in aid of our own observations; as we said before, comment is useless.

WE have also a word to add to another instance of American enlightenment which we chronicled last week, namely, the vote of 50,000 dollars towards the construction of a refractor similar to that recently erected by Mr. R. S. Newall at Gateshead. The Superintendent of the U.S. Naval Observatory, Washington, has written to Mr. Newall a letter which we have been permitted to see, in which, after referring to the munificence which has endowed astronomy with such an instrument as the Newall telescope, he requests permission for Prof. Newcombe to inspect it, with a view of judging what devices and mechanical arrangements are best adapted to secure the successful and easy manipulation of the American instrument.

THE death of Prof. Miller has been followed by another heavy loss to Chemical Science in that of Dr. Augustus Matthiessen, one of the rising chemists of greatest promise in this country. The work which he had already done had acquired for him a reputation equalled by few, and exceeded by none of his fellow-workers of his own age; to this we hope to refer more at length next week. He occupied the position of Lecturer on Chemistry at St. Bartholomew's Hospital, and was, at the time of his death, one of the Examiners to the University of London. He was in his 39th year.

THE "fish torpedo" which, as we stated some little time ago, has been for some time subjected to various experimental trials by a committee of naval officers, under Captain Arthur, R.N., was put to a practical proof on Saturday, at Sheerness. The *Oberon*, paddle-wheel steamer, had been specially supplied with a 12-horse power engine and air pumps for filling the torpedo with compressed air, and fitted with a large discharging tube at the bow for launching it under water. The peculiarity of the torpedo is that it will maintain its passage at any particular depth between five and fifteen feet from the surface; the propulsion being entirely submarine and effected at the rate of six or seven miles an hour by the action of the compressed air on a screw propeller. Two torpedoes were run against the *Aigle*, a large hulk lying in the harbour, both from a distance of 140 yards. The first contained a charge of 67lb. of gun-cotton, and hit the hulk, exploding on impact, and making a clean hole, 20 feet by 10 feet in area, and sinking her at once. Nets were placed at 15 feet from the side of the hulk, and the second torpedo run at them, being launched from a framework attached beneath a boat. This torpedo, containing a charge of 18lb. glyoxiline, was caught in the nets and exploded there, doing no damage whatever to the side of the hulk. The machine is the invention of Mr. Whitehead, an English engineer, having works at Fiume, in Hungary.

WE must refer our readers to the October number of the *Astronomical Register* for an account of a discussion on the great Melbourne telescope, at the Royal Society of Victoria. The colonists mistrust their great reflector, and we do not wonder at it, the day for metallic specula is past, and we regret that our Royal Society had anything to do with sending out such an instrument.

THE *Astronomical Register* announces that the post of Government Astronomer at Sydney is vacant by the death of Mr. George K. Smalley.

NOW that the Government are accused by a tribunal appointed by themselves, of having built a top-heavy ship "in deference to public opinion, as expressed in Parliament and in other channels" (*sic*) and "in opposition to the views and opinions" of their scientific adviser, might we be allowed to suggest that the more Government attempts to encourage the advancement of scientific ideas and studies among members of Parliament and other channels, the better? The cost of the *Captain* in hard cash would have helped to disseminate a vast amount of scientific education and interest throughout the land had it been properly spent; and now it is quite lost, because the Government are Philistines, and do not like Science, and build top-heavy ships because ignorant members of Parliament and other "channels" clamour for them.

ARTISTS, manufacturers, and others who have not expressed their desire to be admitted as exhibitors at the International Exhibition of 1871, are requested to do so before the 10th of November next. Her Majesty's Commissioners, as already notified to the public, do not intend to award prizes to exhibitors. They will, however, afford every facility to societies and individuals desirous of offering prizes for the encouragement of Art or industry in connection with the Annual International Exhibitions; and are prepared to receive such offers, and to publish the conditions of competition which the donors may wish to prescribe. The conditions are announced of a competition of prizes for the best fan, the first prize of 40*l*. being offered by Her Majesty the Queen. The painters and decorators are completing their work in the fine art galleries. We understand that it is the intention of Her Majesty's Commissioners to invite artists and exhibitors of all fine art works to inspect these galleries shortly.

THE American Association for the Advancement of Science closed its nineteenth meeting on the 25th of August, at Troy, N.Y. Owing to the illness of President William Chauvenet, of St. Louis, the Vice-President, Dr. T. Sterry Hunt, of Montreal, presided. The meeting was largely attended, there being about 300 names enrolled on the treasurer's books. The next meeting is to be held in Indianapolis, and the meeting in 1872 will probably be held in San Francisco, upon the invitation of the California Academy of Sciences. The president-elect for the next meeting is Prof. Asa Gray, of Cambridge; general secretary, Prof. F. W. Putnam, of Salem, Mass.; treasurer, Mr. William S. Vaux, of Philadelphia.

WE learn that the building for the New York Industrial Exhibition will be commenced on the 15th of December. Twenty-three acres have been purchased between 98th and 102nd Streets, the purchase money amounting to 2,658,000 dollars. It is intended to make this one of the finest, or perhaps we should rather say *the* finest permanent institution of the kind in the world. The building will probably cost not less than 8,000,000 dollars, and it is the intention of the managers to advertise for designs at an early day. The importance of such an enterprise to New York can hardly be over-estimated. The benefits that have been conferred by the Central Park in opening up a place of resort uncontaminated by beer-saloons and other demoralising agencies has been very great, and the present effort to extend facilities for instructive pleasure and innocent amusement deserves well of all who desire the good of the city.

WE understand that the following are candidates for the Regius Professorship of Natural History in Edinburgh, vacant by the resignation of Professor Allman:—William N. McIntosh, M.D. Edin., F.L.S.: H. Alleyne Nicholson, M.D., D.Sc. Edin., F.R.S.E.; and Wyville Thomson, LL.D. St. Andrew's, F.R.S. We believe we are correct in stating that there is no truth in the rumours that either Prof. Flower, of the Royal College of Surgeons, or Prof. E. Perceval Wright, of Dublin, is a candidate for the chair.

THE authorities of King's College, London, have arranged that the duties of the chair of chemistry, vacant by the death of Prof. Miller, shall be performed, pending the appointment of a successor, by Prof. Odling.

THE First Commissioner of Works intends to have distributed this autumn, among the working-classes and the poor inhabitants of London, the surplus bedding-out plants in Battersea, Hyde, the Regent's, and Victoria Parks, and in the Royal Gardens, Kew. If the clergy, school committees, and others interested, will make application to the Superintendents of the Parks nearest to their respective parishes, or to the Director of the Royal Gardens, Kew, in the cases of persons residing in that neighbourhood, they will receive early intimation of the number of plants that can be allotted to each applicant, and of the time and manner of their distribution.

THE Horticultural Society held a Fungus-show on the 5th inst. for competition for prizes offered by Mr. W. W. Saunders, F.R.S., for the best collection of Edible and Poisonous Fungi. Several exceedingly good collections were shown, which attracted a great deal of attention, many of the visitors being evidently astonished at the large number of common fungi which are warranted by experts to be not only innocuous, but wholesome articles of diet.

ON the 4th inst. a large public meeting was held in the Mechanics' Hall, Dewsbury, for the promotion of Technical Education in Yorkshire. Classes for instruction in drawing and elementary science are to be opened under certified teachers. The inaugural address was delivered by Mr. J. Buckmaster, of the Science and Art Department. After explaining the aid rendered by the Government, he pointed out at some length the industrial and moral advantages derived from the acquisition of scientific knowledge.

THERE has just been started in the city of Baltimore, U.S.A., a society of fifty members, called "The Maryland Academy of Sciences." It is intended to pay special attention to microscopy. The principal officers are Philip T. Tyson, President; John G. Morris, Vice-president; Edwin A. Dalrymple, Corresponding Secretary.

THE annual examinations for degrees in the Queen's University, in Ireland, commenced last week, and will be continued during the greater part of the present week. The examining body of the University consists for the most part of the professors in the different faculties in the three Queen's Colleges. We regret to learn that Prof. Wyville Thomson is unable to take his part in these examinations owing to continued ill-health.

PROF. VERRILL, of New Haven, has just returned from an expedition to the Bay of Fundy. The greatest depth encountered in dredging even as far as fifty miles from the coast, was not beyond 120 fathoms. Very large collections were made, many rare and about sixty new species were discovered, the number of species in Prof. Stimpson's list being more than doubled. We hope soon to have a catalogue of the fauna of the bay from Prof. Verrill.

SIR WALTER ELLIOT is compiling a record of what has been done by local societies in Great Britain and Ireland, towards elucidating the natural history of the districts in which the societies meet. Any information, as when such societies were established and by whom, and details generally as to their proceedings, will, we hope, be forwarded to Wolfelee, Hawick, N.B.

MR. JAMES BRITTEN, of the Royal Herbarium, Kew, and Mr. Robert Holland, of Mobberly, Knutsford, Cheshire, have in preparation a work on the folk-lore connected with plants. Any assistance will be gladly received by either of these gentlemen at the addresses given above.

A WORK is announced on the land and fresh water shells of British India, "Testacea indica, terrestria et fluviatilia," by Sylvanus Hanley, F.L.S., and William Theobald, of the Geological Survey of India. It will be issued by Messrs. L. Reeve and Co., in monthly parts, and will contain sixty to eighty 4to plates.

IN another column we give an abstract of Capt. Carmichael's paper read to the Geographical Section of the British Association, relating to the aboriginal Indians of Central America. Since then, the following interesting information has come to hand. A correspondent, writing from Santa Fe, New Mexico, to the *New*

York Tribune, says:—"Governor Arny, the indefatigable special Indian agent for this territory, has lately returned from a point north of the San Juan country, and reports that during his tour to reach the Utah Indians, his party found the Canon de Chelly in the great Sierras, which was explored for more than twenty miles. Among canons towering precipitously to the height of 1,000 to 2,000 feet, they found deserted ruins of Aztec cities, many of which bear the evidences of having been highly populous. In one of these canons, the rocky walls of which rose not less than 2,000 feet from the base, and whose summits on either hand inclined to each other, forming part of an arch, there were found high up, hewn out of the rocks, the ruins of Aztec cities of great extent. In each of these rocky eyries there remained in a state of good preservation a house built of stone, about twenty feet square, containing one bare and gloomy room, in the centre of which were traces of fire, and also a single human skeleton. The only solution of this enigma thus far advanced is that these solitary rooms were the altar places of the Aztec fires; that from some cause the people at a remote period were constrained to abandon their homes, but left one faithful sentinel in each instance to keep alive the flame which, according to the Indian traditions of these regions, was to light the way of Montezuma, their so long hoped for Messiah, again to his people. A close examination of many of the ruins proved that the builder must have been skilled in the manufacture and use of edged tools, masonry, and other mechanical arts." A good idea of these rocky canons or mountain gorges will be obtained by reference to the description and illustrations of the Canons of the Sierra Nevada, given in NATURE, vol. i. p. 434.

IN directing attention to the recent regulations with regard to scientific teaching in force at Yale College, in our present number, we alluded to the exploring party which left Yale College under the charge of Prof. Marsh. We are glad to announce that their endeavours have been crowned with great success. They spent three weeks examining the geology of the country between the north and south branches of the River Platte, and discovered in Northern Colorado an extensive tertiary deposit, abounding in fossil remains. The formation is identical with the "Mauvaises terres" deposit of Dakota, and apparently forms the south-western border of some ancient fresh-water lake (see NATURE, Vol. II., p. 385, "The Ancient Lakes of Western America"). These beds were traced to the north, and along the North Platte River; several thousand specimens were collected, and among them a number of new species of tertiary mammals.

ARRANGEMENTS are being made to light the stations of Rawul Pindee in India with gas from the local deposits of petroleum, being one of the first examples of their utilisation.

FULLER details have now arrived of the great earthquake we reported as having occurred in Thibet in May, and which extended over a wide area of country.

MR. BROUGHTON, the Government quinologist in India, has been called upon to examine the bark of an indigenous Indian tree, *Hymenodictyon excelsum*, supposed to be a powerful febrifuge. He reports that it contains a bitter principle, identical with æsculin, and also found in the horse-chestnut tree, but of little therapeutic value.

THE experiments in growing Carolina rice in our great rice-country of English Burmah are reported as having failed.

IT may be esteemed a benefit that we have a local press in India, which may collect for us more facts as to natural phenomena, but the acceptance of anything from such sources must be received with caution. New facts about snakes are in this class. The Vellore correspondent of the *Madras Standard* asserts on reliable information that a native woman near that town lately gave birth to a child and a snake, and that another has produced twins, and a third child, which looked like a toy elephant. A very respectable and well-educated Mussulman lately reported the exhibition, we think at Benares, of a mermaid from Japan, which he accepted on the evidence of his own eyes and the statements of the highly respectable Mussulman showmen, and duly reported to the paper of which he is the correspondent.

A GOOD example of the value of agricultural shows and their influence on produce, is shown in India by the Vellore shows, which have now been held for twelve years. At the same time the results show the difficulty of organising cattle-shows there, and how it may be overcome. As is well known, the superstition about the sacred cow is strong in India, and the ryots can hardly be got to exhibit, and the first cows shown were scarcely worth a prize. Now the exhibition of the famous Vellore breed has reached 173 cows and heifers, and a great improvement is visible. It is suggested that the exhibition of Vellore bulls will also be attended with advantage. In India the greatest care is requisite in the most trivial undertakings in dealing with the superstitions of the natives.

THE Cinchona cultivation has so well succeeded in the English hill settlement at Darjeeling, in the Himalayas, that last year 5,000lbs. of bark was sent to London from Cinchona trees planted in 1862 on one plantation. Tea produced, in 1869, 1,319,743lbs. from 10,769 acres of hill land formerly said and reputed to be worthless, and unsuited to give a return to Englishmen. We shall now hear of Indian bark as well as Peruvian, as we know Indian tea to hold its own against Chinese.

CONGRESS has granted 30,000 dollars for the erection of a Government Winter Garden, either at New York or Washington, somewhat similar to that at Kew, but on a smaller scale. This will partake partly of the nature of an economic garden, in which useful plants can be raised and then disseminated far and wide throughout the States.

"THE Reign of Law," by the Duke of Argyll, which has been published so long in England, has at last been republished in America. It is announced as the first American from the fifth London edition, published by C. Leat and Co., New York. We also hear of a Canadian reprint of Prof. Huxley's "Lay Sermons."

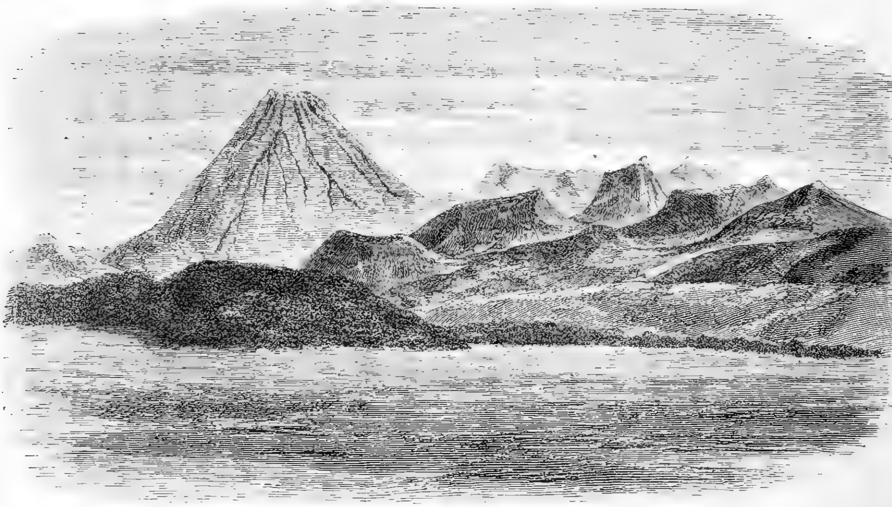
THE cinchona trees are taking well in Jamaica. Experiments on the culture of American tobacco in India are being made by the Maharajah of Burchwan in Midnapore and Cuttack. The last year's experiments with seeds from James River, Virginia were very successful.

ARGENTIFEROUS galena has been discovered in the district of Beerbhoom, in India, by Mr. Ball, of the Geological Survey. The assay of some picked specimens gives 110 ozs. of silver to the ton of lead, and it is considered there is a sufficient quantity of ore to justify working.

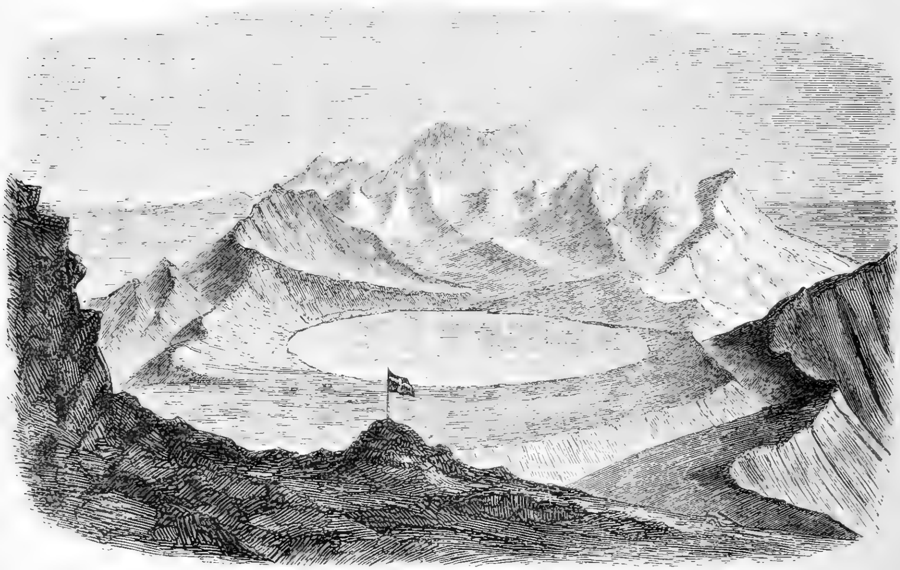
ERUPTION OF THE VOLCANO TONGARIRO, NEW ZEALAND

THROUGH the kindness of Dr. J. D. Hooker, we have received the following important and interesting account of the eruption of this volcano, together with drawings, from the pencil of Dr. Hector, of the most interesting features of the mountain itself, from which we are enabled to copy the accompanying woodcuts:—

Dr. Hector announced, at the meeting of the Wellington Philosophical Society of New Zealand, held July 17th, that Tongariro, the only active volcano in the colony,

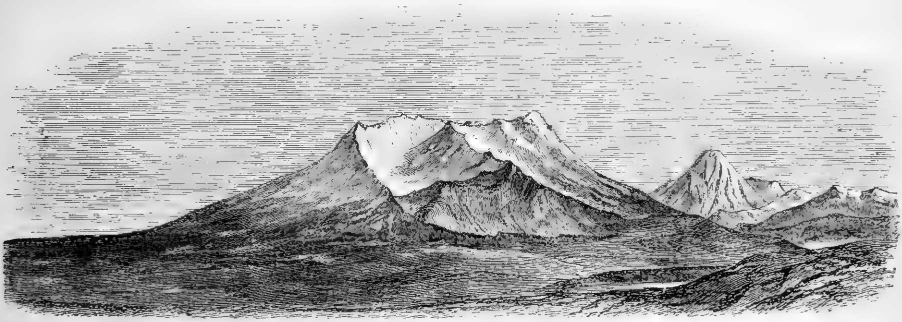


NGAUR HOE CONE OF TONGARIRO, FROM THE EAST



LAKE ON THE TOP OF TONGARIRO, LOOKING SOUTH OVER NGAURUHOE AND RUAPEHU which is situated in the interior of the North Island, had burst into active eruption in the month of April last, and for the first time within the knowledge of the colonists, or even the traditions of the Maories, lava streams have been emitted. On the occasion of previous eruptions, the outbursts have consisted only of ashes and gaseous matters, the former having been spread over a district extending for upwards of thirty miles round the mountain. The volcano is 6,000 feet high, and consists of a group of irregular broken cones, and one very perfect cone, known to the natives as Ngauruhoe. Jets of boiling water and steam continually issue from the north side of the mountain. At an altitude of 3,600 feet, and on the top of Tongariro proper, is a lake 300 yards across, the water of which is of an intense green colour. Ten miles to the south of Tongariro is the ancient trachyte cone of Ruapehu, which is the loftiest mountain in the North Island, having an altitude of 9,600 feet. It is a notable circumstance, that on the 5th of April last, when electrical disturbances were so marked in Europe, and the brilliant displays of Aurora Borealis were generally observed, the corresponding phenomena of the Aurora Australis were extremely well marked in the Southern Hemisphere, attended also by electrical disturbances of unusual character; and on the same evening a well-marked earthquake shock was experienced in the volcanic district of New Zealand, and shortly after the above eruption was reported. The country is very inaccessible at this season, but from the north end of Taupo Lake, where there is now a telegraph station, a distant view is obtained. On the 10th July, the immense volumes of dense black smoke which are being emitted from Tongariro were plainly visible from the hills at Napier, as well as from parts of the surrounding plains. Loud reports were distinctly heard for the previous fortnight, like the boom of heavy artillery, or rather the noise caused by the falling of an immense body of matter, at intervals of five minutes or thereabout. These reports (which are very loud in the vicinity) are sometimes accompanied by a quiver of the earth, and in each case by a great up-burst of flame and red-hot masses like molten rock. A broad stream of red-hot lava is distinctly visible flowing down the side of the mountain in a wavy irregular mass; and in the night the flames issuing from the crater are described as forming a highly interesting and beautiful spectacle.

On the 18th a surveyor reports that he observed, about 1.15 P.M., a sudden column of smoke come out of Tongariro (just as if a steamer was firing up), and soon after it seemed to change to white steam; he stood on a hill about eighty miles distant, and could just see the top of Tongariro to the east of the shoulders of Ruapehu.



RUAPEHU AND TONGARIRO, FROM THE ONETAPU DESERT, ON THE SOUTH-EAST SIDE AT THE SOURCES OF THE RANGITIKEI RIVER

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE

The Radcliffe Observer (Rev. R. Main) communicated the *Observations of Shooting Stars made at the Observatory during the past year*, from 1869, August 19, to 1870, August 31.

Since the last report to the British Association, nearly 300 shooting stars have been observed by Mr. Luces at the Radcliffe Observatory, Oxford, distributed as follows:—

27 in the remaining part of August, 1869.
11 on the 1st and 3rd of September.
17 in the month of October.
16 on the 4th and 6th of November.
21 on the nights of the 8th, 9th, and 10th.
None on the 11th in a watch at intervals from $7^h\ 30^m$ till $12^h\ 30^m$.

The nights of the 12th and 13th were thickly overcast. On the 14th there was a break from 11^h to 12^h, but no meteors seen; eight were observed on the night of the 15th, between 8^h and $13^h\ 30^m$, in bright moonlight. On the 28th one was seen.

On December 29 a remarkable meteor, about equal to one-fourth of the full moon, was seen through the window of the sitting-room, with a bright gas-light nearly between the observer and the window. Course from the Pleiades to the south horizon.

None were observed in 1870 till March 30, when one was observed by Mr. Main at $8^h\ 20^m$, larger than Jupiter, of a brilliant white, and a period of about 5 seconds from the zenith, vertically downwards a little to the south of the prime vertical.

On April 12th, at $11^h\ 13^m$, one larger than α Lyræ, of a brilliant white, visible 2^s to 3^s from a point near α Lyræ, northward about 10°.

April 19 at 14^h, 3 in quick succession were seen near α Herculis, of about second magnitude, with a rapid downward motion, one nearly vertical, one slightly inclined to the west, and the other to the east. Watch in bright moonlight till $16^h\ 30^m$.

Only 7 were seen in May, and 1 in June. On July 8, at $9^h\ 20^m$, the sky completely overcast and no star visible, a meteor was seen below the clouds at a point near Cassiopeia, with a downward motion of about 6°, and bursting at the end of two seconds of time.

Another meteor was seen below the clouds for about half a second on July 15, at $12^h\ 25^m$, near β Andromedæ, scarcely any stars being visible in that part of the heavens.

About 20 were seen on the night of July 21 by different persons while Mr. Luces was conversing with them, between 9^h and 13^h, but he did not see any till $13^h\ 43^m$, when one equal to α Lyræ left a point near that star, taking its course, with a long train, towards the north horizon.

Only 5 were seen between this and August 8, when 4 were seen in strong moonlight and clouded sky. 11 were observed on August 9 under the same circumstances; one at $13^h 46^m$, equal to Capella, started from δ Ursæ Majoris with a downward course, of about one second, when it burst, leaving a train visible about two seconds.

On August 10, between $9^h 33^m$ and $15^h 30^m$, 36 were observed, nearly all in the northern part of the heavens, with strong moonlight and clouded sky. One at $14^h 10^m$, equal to α Lyræ, of a bright white colour, burst near β Cygni.

Twenty-six were observed on August 11, between 9^h and 15^h, and on the 12th, 7 between 8^h and $10^h 30^m$, the sky becoming overcast at 11^h.

3 were observed on the 13th, from 10^h to 12^h.
3 on the 15th, from 12^h to 13^h.
7 on the 17th, between $9^h 20^m$ and 12^h.
5 on the 22nd, between $10^h 20^m$ and 12^h.

Four on the 24th, 3 on the 26th, 2 on the 29th and 30th, and 3 on the 31st.

The most noteworthy besides those already mentioned were:—

One on August 19, 1869, in strong moonlight, when few stars were visible, from a point near α Pegasi to near γ Pegasi, about equal to α Lyræ, for about two seconds.

On October 6, at $7^h 5^m$, one about equal to Jupiter appeared to burst near the S.W. horizon.

On October 27, one as bright as Jupiter, visible for two or three seconds, from ψ Tauri to the Pleiades.

November 4, at $6^h 5^m$, 1 equal to one-sixth of full moon, yellowish, was seen by Mr. Béchaux for about three seconds, with a train about 2° in length, from α Arietis to a point above ε Pegasi.

November 8, at $7^h 43^m$, one of the 1st magnitude, yellow, visible about 3^s, with a train from δ Aurigæ to α Draconis, and another at $8^h 10^m$ of the 1st magnitude, white, with a train from α Cygni to θ Lyræ, visible for three seconds.

SECTION B.—CHEMICAL SCIENCE

On the Lancashire Alkali Trade.—Mr. William Gossage. This paper chiefly dealt with the scientific and commercial progress of the alkali manufacture in Lancashire during the last nine years. Mr. Gossage regarded as one of the most important facts of the last nine years the passing of the Alkali Act, 1863, an Act which makes it imperative that all manufacturers decomposing common salt for the production of sulphate of soda should condense not less than 95 per cent. of the hydrochloric acid gas evolved by such decomposition; and he said that the means which he devised in the year 1836 for effecting this condensation were now universally adopted by the soda manufacturers, with such success that not only did they comply with the legislative requirements of condensing 95 per cent. of the hydrochloric acid set free, but in many instances the condensation exceeded 99 per cent. Speaking of the benefits arising from the appointment of Dr. Angus Smith to the office of chief inspector under that Act, he considered that it may be fairly expected that when the same amount of care and attention is applied to subduing the bad effects resulting from other noxious vapours, chemical manufactories will be relieved from the charge of occasioning injury to the neighbourhoods in which they are situated. The most important use of hydrochloric acid obtained by this condensation was the manufacture of bleaching powder. At the date of his former paper, the chlorine required for the manufacture of bleaching powder was obtained by the action of hydrochloric acid on native peroxide of manganese; but recently, Mr. Walter Weldon had perfected a process whereby peroxide of manganese is obtained from the chloride of manganese produced by the action of hydrochloric acid on peroxide of manganese. Mr. Weldon's process has been successfully adopted by some of the largest manufacturers of bleaching powder. Mr. Gossage next referred to Mr. Deacon's method of manufacturing chlorine without the use of manganese, and to the circumstance that Mr. James Hargreaves, of Widnes, has also devised means for producing chlorine without the use of oxide of manganese. In his last paper, Mr. Gossage remarked that nearly all the sulphur used in the soda manufacture was re-obtained in combination with calcium, forming what is designated "alkali waste," and he then suggested that this presented a problem worthy of consideration by his juniors. Mr. Ludwig Mond, a German chemist, had now made the nearest approximation to the solution of this problem, with which he (Mr. Gossage) was at present acquainted. Mr. Mond's process had been carried out successfully by various manufacturers, but unfortunately the quantity of sulphur obtained was far short of that in the waste; and he (Mr. Gossage) considered that the problem he had mentioned still remained as an exercise for ingenuity and perseverance. He had also alluded in his paper before the Association in 1861 to the means he had adopted for obtaining copper and silver from the burnt residue of copper pyrites, which had been used for yielding sulphur in the manufacture of sulphuric acid. This mode of working had now been superseded by a process devised and carried out by Mr. Henderson. After contrasting the quantities of soda and other chemicals manufactured respectively in the Lancashire and Newcastle districts in 1852 and 1869, showing the much greater proportionate increase in the former district, he closed his paper by observing that it might reasonably be concluded that Lancashire was now the largest seat of chemical manufactures in this country.

The President, by way of supplementing Mr. Gossage's remarks, said that in the ten years previous to 1861 the increase in the amount of salt decomposed was 300 per cent. The amount consumed in 1852 was 38,600 tons, and in 1861 it had risen to 135,000. Professor Roscoe proposed a vote of thanks to Mr. Gossage for his valuable paper, and said that he was the father of the alkali trade, and that he held a position second only to that of the illustrious Leblanc, the inventor of the early process of making soda. Mr. Spence seconded the proposal, and said that Mr. Gossage was almost the originator of the soda manufacture; he was certainly the originator of some of the most important processes in it.

On the Hydrogenation and Hydriodate of Cyanogen.—Mr. T. Fairley.

On the Distillation of Sulphuric Acid.—Mr. T. Fairley.

On the Time needed for the Completion of Chemical Change.—Dr. Hurter.

On Reciprocal Decomposition viewed with Reference to Time.—Dr. J. H. Gladstone, F.R.S.

On a Method for the Determination of the Amount of Sulphur in Coal Gas.—Mr. A. Vernon Harcourt, F.R.S.

On the Estimation of Sulphur in Coal Gas.—Mr. W. Marriott, F.C.S.

Notes on Thermal Equivalents—(1) *Fermentation.* (2) *Oxide of Chlorine.*—Mr. J. Dewar, F.R.S.E.

On the Discrimination of Fibres in Mixed Fabrics.—Mr. J. Spiller, F.C.S. The author refers to the fact that silk alone, of all the materials ordinarily used in the production of textile fabrics, is soluble in concentrated hydrochloric acid, so that this reagent may be resorted to for testing the purity of silk, and determining the proportion of this substance entering into the composition of a variety of mixed goods. For the purpose of identifying wool in the presence of cotton, flax, jute, &c., it is recommended to immerse the fabric or loosened fibres in a warm aqueous solution of picric acid, which dyes the wool of a bright yellow, without imparting any colour to cotton. Thus, by testing mixed fabrics successively with hydrochloric and picric acids, valuable indications are afforded regarding their constitution. The chemical properties of certain compounds formed in this manner from silk were described, and a photographic application pointed out which turns to account the extraordinary degree of sensitiveness to light exhibited by a modified form of argentic chloride produced by precipitation from such hydrochloric solutions.

The Chemical Section did not sit on Saturday, but a large party of the members, headed by Professor Roscoe, Mr. C. W. Siemen, F.R.S., and Mr. A. E. Fletcher, F.C.S., Alkali Act Inspector, spent the day in visiting various chemical works at St. Helens.

SECTION C.—GEOLOGY

Report on Hæmatite.—Professor Stokes.

On the Green Slates and Porphyries of the Lake District.—Professor Harkness and Dr. Nicholson. The authors pointed out that in the Lake Country there is most commonly the three-fold series of rocks, occurring between the Skiddaw slates, upon which the green slates and porphyries rest, and the Coniston limestone which succeeds them. This series consists of traps, which form the lowest member of the group, and which are very persistent; of ashes, trappian breccias, tuffs, and amygdaloids, which constitute the middle portion of the series, and of hornstone traps, which form the highest portion of the group. The middle and upper portion of the series are by no means so persistent in their mineral characters as the lower member. The upper member was shown to be absent from the series in the Long Sleddale Valley, its place being represented by ashes and trappian breccias, and the middle series, which is usually composed of slaty ashes, breccias, and traps, was shown to be greatly modified in type in the northern portions of the Lake Country. This middle member of the series is well seen in the country south of Keswick in Borrowdale, having its normal mineral character more abounding in ashy beds, here worked for slates. Eastwards from this the slaty ashes become less abundant, and in the districts north of Ulleswater these ashes were almost entirely absent. In the Vale of St. John, porphyry, with comparatively small felspar crystals, makes its appearance in connection with the ashy slates. North-east from the Vale of St. John this porphyry becomes more developed, and the ashes are less abundant. At Eycott Hill, near Troutbeck station, the lower porphyry also occurs very finely exhibited, and containing large crystals of felspar. Near the south-east of Carrickfell, a hill largely composed of syenite rocks is seen, having a highly crystalline character, and exhibiting all the features of Diorite. These rocks the authors regard as highly metamorphic conditions of the porphyry above referred to or resulting from the action of the syenite of Carrickfell. The Caldbeck fells, which form the northern limits of the Lake district, have on their northern side the representatives of the green slates and porphyries well developed. Here there is an entire absence of the ashy slates of the middle series, the place of these being occupied by a porphyry similar to that of Eycott Hill. This porphyry, however, in the neighbourhood of Roughtongill has been so far influenced by the syenite of Carrick, veins of which penetrate it, that it now assumes a crystalline form, and appears as hypersthene rock.

The average thickness of the green slates and porphyries, or their representatives, in the Lake Country, the authors think does not exceed 5,000 or 6,000 feet, a thickness made up of igneous products, which in the north of England represent the upper Llandeilo series, and a large portion of the Caradoc or Bala group.

The authors regard the terms green slates and porphyries as applied to these rocks in Cumberland and Westmoreland, as inappropriate, since they express merely local conditions, and they propose as a substitute the name Borrowdale series.

On the discovery of Upper Silurian Strata in Roxburgh and Dumfries.—Mr. C. Lapworth. South of the great axis of the lower Silurian rocks of southern Scotland, upper Silurians had been determined many years ago by Professor Harkness in the neighbourhood of Kirkcudbright. The author had further detected these beds in a very wide strip of country extending from near Lockerbie to near Hawick, a distance of forty miles, with a maximum width of eight or ten miles. Another large outlier had been detected extending from Ernton Hill to Oxnam near Jedburgh; and a further small outlier high up in the Cheviots at the head of Kale Water. The rocks in all these districts have the facies of the Kirkcudbright series, and the fossils are common to all of them. They consist of *Graptolithus colonus, Priodon, Flemingii* and *Nillsoni, Rhynconella nucula, Orthoceras tracheale,* fragments of *Pterygotus, Ceratiocaris* or *Dictyocaris,* &c.

On the Age of the Wealden.—Mr. E. W. Judd. The Wealden constitutes one great continuous formation with well-defined palæontological characters. As with the "Poikilitic" series, its beds can only be referred to the different members of our established marine classification by violent and arbitrary divisions. It must therefore stand as one of the terms of that new system of terrestrial classification which Prof. Huxley has shown must be founded. The epoch of the English Wealden commenced towards the close of the Oolitic period; it continued during the whole of the Tithonian (a great system of rocks lately discovered on the Continent), and ceased towards the end of the middle or beginning of the Upper Neocomian. The passage of the Upper Oolite into the Wealden, and that of the Wealden into the Upper Neocomian, was each of them gradual. Fresh water deposits were formed continuously, but not contemporaneously over the whole area of the Wealden, so that in the north-west we find only the lower beds represented, and in the south-east only the upper ones, while in the central portion we find the whole series complete. In the little marine band of Punfield, only twenty-one inches thick, we have the representative of a portion of the Middle Neocomian, a formation only elsewhere found in this country in the middle of the Speeton clay and in Lincolnshire. The fauna of the marine band of Punfield has very striking affinities with that of the coal-bearing strata of Eastern Spain (which are more than 1,600 feet thick), and especially with the middle portion of that series. The North German Wealden, which is quite unconnected with that of England, and is probably the product of another river, is not strictly contemporaneous with the latter, for while it appears to have commenced about the same period, its duration was considerably less, it having terminated the close of the Lower Neocomian.

On the Physical Geology of the Bone Caves of the Wye.—Rev. W. S. Symonds. The author had lately received from Sir J. Campbell fossil bones from Arthur's Cave, on the Great Doward, on the right bank of the Wye, among them the teeth of *Equus fossilis,* and a collection had been sent to Prof. Owen, and been determined by him to belong to the mammoth, rhinoceros, hyæna, reindeer, and the great fossil ox. The caves of the Wye were at a considerable height above the bed of the river. The author considered that the district had been submerged below the glacial seas, the clefts of the precipices and the mountain limestone platform being often covered with boulder clay and angular erratic stones.

On Geological Systems and Endemic Diseases.—Dr. Moffat. From continued observation during a long practice, the author has ascertained that in a carboniferous district goitre and anœmia were prevalent, while these diseases were markedly absent in the New Red Sandstone. This he attributed to the presence of iron in the one set of rocks, and its complete absence in the other.

Report of Sedimentary Deposits of River Onny.—Rev. De la Touche. The author gave an estimate of the rate of accumulation of these deposits from a series of observations.

Notes of a Recent Visit to the Great Tunnel through the Alps and of several points of Geological Interest suggested by the Conditions of the Works in the present nearly complete state.—Prof. Ansted. The operations of the tunnel involved a direct cut through a series of rocks on a line at a great depth below the surface. At the middle of the tunnel there is 5,400 feet of rock above it. Observations on physical phenomena have been made throughout the progress of the works. The temperatures at various distances and depths have been recorded. Borings 10 feet into the rock were made at intervals of 500 metres, and the temperature determined at their extremity. The last observation made in his presence was 20,342 feet from the south end of the tunnel, and 5,000 feet from the surface. The temperature shown was 80·5° F., exhibiting an increment of 1° F. to about 100 feet. Before the value of these observations could be ascertained, the mean annual surface temperature and the depth of the permanent temperature lines must be determined. On the 31st of last month (August) there remained 2,000 out of 40,000 feet of rock to pierce; as the operations progress at the rate of 500 feet per month, the tunnel may be expected to be completed by the end of the year.

On some Points in the Geology of Strath, Isle of Skye.—Profs. King and Rowney. The authors entered into a minute description of the rock structure of the district, from which he drew the following conclusions:—That the ophite of Skye is an altered rock of the Liassic period; that it possesses the same microscopic features as the ophites of earlier geological ages, occurring in Canada, Connemara, and elsewhere; and that igneous action, developing a granitic rock, and producing decided metamorphism in an adjacent deposit, has operated at a later geological period in Skye than in any other part of the British Islands. The authors further maintained that all the features of the so-called organism, *Eozoon canadense,* had been detected by him in the Skye ophites, and asserted that the different structures known as chamber casts, canal system, nummuline layer, &c., were chemical and structural changes, induced by metamorphic action.

Section D.—Biology

On a mode of Reproduction by Spontaneous Fission in the Hydroida.—Prof. Allman, F.R.S. The hydroid in which the phenomenon which formed the subject of this communication had been observed is a campanularian, which in the general form of its trophosome comes near to *Obelia dichotoma.* Since however no gonosome was present in any of the specimens collected, it was impossible to assign to it a systematic position otherwise than provisionally. The remarkable physiological act by which it is distinguished, associated as this is with an important morphological character, would seem to indicate a distinct generic rank, and the author accordingly suggests for it the provisional generic name of *Schizocladium.*

Besides the branchlets, which—as in the hydroids generally—support the hydranths (plypites), others are developed in abundance from all parts of the hydrocaulus. These commence just like the ordinary branchlets, as offshoots from the hydrocaulus, and consist as usual of a continuation of the cœnosarc, invested by a chitinous perisarc. Unlike the ordinary branchlets, however, they never carry a hydranth, but are destined for the multiplication of the colony, by a process of spontaneous fission.

After the entire branchlet has attained some length, the contained cœnosarc continues to elongate itself. In doing so it ruptures the delicate pellicle of chitine which closes the extremity of the branchlet, and extends itself quite naked into the surrounding water.

It is now that the process of fission commences. A constriction takes place in the cœnosarc at some distance below its free extremity, and in the part still covered by the chitinous perisarc. The constriction rapidly deepens, and ultimately cuts off a piece which slips entirely out of the perisarcal tube and becomes a free zooid, while the surface of disseveration soon heals over, and the axial cavity of the free frustule becomes here as completely closed as at the opposite end.

The detached fragment strikingly resembles a *planula* in all points except in the total absence of vibratile cilia. It attaches itself by a mucous excretion from its surface to the walls of the vessel, and exhibits slight and very sluggish changes of form.

The further history of the fission-frustule was traced, and the important and unexpected fact was shown that it never directly develops a hydranth. After a time a bud springs from its side, and it is from this bud alone that the first hydranth of the new colony is developed.

The bud which thus becomes developed into the primordial hydranth remains attached to the fission-frustule which forms for it a sort of hydrorhiza, but which would seem ultimately to perish and give place to true hydrorhizal filaments. In the meantime the primary bud emits others, and a complex branching colony is the result.

The author compared the fission-frustule to the free medusoid element of other hydroids with which it agreed in never becoming directly developed into a new trophosome, but from which it differed in the very important fact of taking no part in the true generation of the hydroid and in giving origin to a new colony only by a simple non-sexual multiplication.

Observations on Protandry and Protogyny in British Plants.—Alfred W. Bennett, F.L.S. The arrangement of the reproductive organs in hermaphrodite plants, the presence in the same flower of both pistil and stamens, suggested to the minds of the older botanists no other idea than that of fertilisation. It is, however, now generally admitted that, even in hermaphrodite flowers, cross-fertilisation is the rule, self-fertilisation the exception. Two sets of facts have been especially observed,—in particular by Darwin in this country, Hildebrand in Germany, and Delpino in Italy,—to favour cross-fertilisation in hermaphrodite flowers; the phenomena of dimorphism and trimorphism, and the special arrangements which render it easier for the pollen to be brushed off by insects visiting the flower than to fall on its own stigma. But, besides these, another arrangement exists by which self-fertilisation is hindered, the simple fact that the stamens and pistil belonging to the same flower are frequently not ripe, so to speak, at the same time. The terms *Protandry* and *Protogyny* used by Hildebrand to express, in the one case the development of the stamens before the pistils, in the other case the development of the pistil before the stamens, are so convenient and expressive that they have been adopted in this paper; the term by which he expresses that the two organs are matured simultaneously, "Non-dichogamy," does not seem so happy, and the author proposes to substitute for it *Synacmy*—the phenomena of *Protandry* and *Protogyny* forming together that of *Heteracmy*.

The most frequent arrangement appears to be that the pollen commences to be discharged from the anthers at a longer or shorter interval before the maturing of the stigma. In some cases there still remains a certain quantity of pollen in the anthers when the stigma is ready to receive it; in other cases, the anthers have either withered up or entirely dropped off before fertilisation of the ovules can possibly take place. Synacmy, or the contemporaneous maturing of the reproductive organs, is nearly as frequent as protandry; while protogyny is a phenomenon of far less common occurrence. The two extremes among the species observed may be stated to be *Campanula rotundifolia* and *Scrophularia aquatica*. In some Natural Orders, as *Leguminosæ* and *Labiatæ*, all the species examined, with scarcely an exception, range themselves in one or other of the three classes; while in others, as *Rosaceæ*, they are distributed over all three, and in some instances, even closely allied species of the same genus differ in this respect, as, for instance, *Potentilla* and *Ranunculus*. Careful observations might even, the author thinks, in some cases, derive from this point a useful diagnosis of difficult species.

In those Natural Orders in which the flowers are furnished with two sets of stamens of different lengths, it is most usual for the longer ones to discharge their pollen at an earlier period than the shorter ones, and they probably have different functions to perform. This is commonly the case with *Cruciferæ*, *Carophyl-leæ*, *Geraniaceæ*, and *Onagrariceæ*, but not, apparently, with *Labiatæ* or *Scrophularineæ*. The same phenomenon is found in those orders where the numerous stamens are arranged in different whorls, as *Ranunculaceæ* and *Rosaceæ*. The author then gave an account of a number of observations on British wild plants.

SECTION E.—GEOGRAPHY

The Ruined Indian Cities of Central America.—Captain Carmichael. The author commenced by giving an account of the impression caused on first beholding these ruins, and showed how the question involuntarily suggested itself as to the originality of their architectural designs, and stated that a certain familiarity of trait and outline was invariably recognised; and that in his opinion, formed from personal investigation, the architecture of the Aboriginal Indians of Central America was but a diversified reproduction of that of Eastern countries. He then pointed out a number of similarities in their architecture, designs, customs, &c., to nations of the East; and showed how, as a general rule, it was very difficult to explore these ruins owing to the hostility of the existing tribes of Indians.

As regards their antiquity, he assigned to many of them an earlier foundation than that accorded to them by Stephens and Squier, and adduced some very convincing, if novel, proofs in support of his theory. The picture he drew of the palaces of Quiché in Guatemala fully bore out the statement of Torquemada that they rivalled those of Montezuma; and he showed that if that city—one of some eight hundred years' standing—was in such a perfect state of conservation some fifty years ago, that the padre of a neighbouring Indian village who then walked among its streets and palaces, imagined himself in Spain, what must be the era of those numerous cities compared with which Quiché was modern?

He then pointed out the great length of these ruined cities, and added that in connection with this a remarkable fact had seemingly been overlooked by most Central American writers, viz., that the stone buildings whose ruins we now find extant were used as temples, palaces, and public offices generally, the poorer inhabitants living in huts of a perishable nature; an arrangement which represented an almost incredible amount of population. He then analysed the various elements composing the architecture of the ruined buildings and monuments, and gave an interesting account of the various uses to which the teocali and tumuli were put by the Toltecan and Aztec priests, viz., for sacrificial and burial purposes, to serve as beacons, for warlike defences, &c.; and explained the relations between the temples and alcazars or palaces, and offered a few hints as to the deciphering of the hieroglyphics, a subject to which he has paid much attention, and for which he is specially qualified from his knowledge of the Maya or Indian language, showing that they were chiefly the works of the Indian priesthood; and, above all, were intended to inculcate moral and religious precepts, chronological events being made quite subservient to them. He then referred briefly to the round towers which contained the estufas for the sacred fire of Montezuma, in connection with the worship of the Sun, and passed on to explain the nature and significance of the various hideous and awe-inspiring idols to whom the human sacrifice was offered on the summit of the teocali, and stated it as his belief that these idols, as well as the planed stones, were carved with clay or flint instruments, as he had often found flint and obsidian implements, but in no instance an instrument of metal.

Referring to the state of decay in which they were mostly found, he stated that there were ruins which had never been visited by the Spaniards at the time of the conquest, and expressed it as his opinion that their crumbling and ruinous condition was mainly brought about by the earthquakes so prevalent throughout Central America, in conjunction of course with the action on them of time and the elements. He gave a most interesting account of a ruined city in British Honduras, called Xmul, which he claims to have discovered, and concluded by pointing out the great extent of unknown and untravelled districts in Central America, particularly in Guatemala, as presenting a fine field for future geographers and naturalists, and expressed it as his firm conviction that there existed at the present day an Indian city—yet to be discovered—whose inhabitants occupy the same splendid palaces and temples as in the days of the Spanish Conquest, whose priests inscribe fresh precepts on their tablets, and who would then read to us their now mystical hieroglyphics. He supported the statement by describing an exploration he made in the southern district of British Honduras westwards towards Guatemala, where, after several days' perilous river navigation and further journey on foot, he discovered in the neighbourhood of the Coxcomb Peak the remains of an abandoned maize plantation, and saw smoke ascending from the distant forest; and believes that the tribe of Indians who occupy this part of the country, which was before considered to be uninhabited, have some connection with the mysterious Aztec city he spoke of.

Mr. H. Howorth corroborated the date of the foundation of the city of Quiché, as verified by a Mr. Spencer, who had also read a hieroglyphic on the lintel of a doorway at Palenqué. Mr. Spencer had also discovered great similarity between the names of the signs of the zodiac and the arrangement of the calendar of the Aztecs and those in use in Thibet. Several members present took part in a discussion, to which Captain Carmichael replied, adding that he had recently returned from California, where he had heard a Japanese and a digger Indian of Nevada, then brought together for the first time, converse intelligibly.

Section G.—Mechanical Science

On the Sewage of Liverpool and Neighbourhood.—Mr. J. N. Shoolbred, C.E. In this paper the author said it was calculated that about 900,000*l.* had been expended in drainage and sewage works in the borough of Liverpool. Of this about 600,000*l.* might be set down as requisite for drainage (the primary object); 300,000*l.* would, therefore, represent the amount due to conveyance of water-closet sewage; and setting aside 20 per cent. upon this as interest, together with a large amount for depreciation and repairs, &c., there would be 60,000*l.*, or about 2*s.* 4*d.* per head, as the annual expense due to the removal of the water-closet sewage. Taking the length of sewerage over the whole of the borough of Liverpool, the probable average distance that the sewage has to travel from its entrance into the sewer till its discharge into the river Mersey is about one mile and a half, or perhaps even more, inasmuch as the inhabited portions of the town mainly lie back away from the river. Liverpool and its neighbourhood are favoured by nature with above the average amount of facilities; first, for the collection of its sewage by water carriage, and then in finding, at a comparatively short distance, an outlet in the river Mersey for the larger portion which it is deemed advisable to get rid of in this manner. Again, Liverpool is fortunate in having an outlet which, at least for the present, secures immunity to the town from the unpleasant consequences which sometimes arise from creating an acknowledged sewage nuisance; while, should the town itself at any time prefer to derive some benefit out of this refuse which it now throws away, Liverpool possesses, at no great distance, a most suitable and extensive site for utilising its sewage by irrigation upon the land, with at the same time a certain market in itself for the vegetable produce of that irrigation. The author then detailed the arrangements made in 1866 and since, or in progress, for the concession of the Liverpool sewage to companies whose object is to use it in irrigation upon sewage farms; and he also described the nature of the lands which are, or may be, used for sewage irrigation.

On Sewers in Running Sand.—Messrs. Reade and Goodison, Civil Engineers. This paper formed a very natural sequel to the preceding one, inasmuch as it dealt with the difficulties of constructing sewers in the sands between Liverpool and Southport, the district traversed by the Liverpool, Crosby, and Southport Railway, and the means which the authors had adopted in order to overcome those difficulties. The whole of the district referred to is one mass of sand, resting on a bed of moss and marl, varying from ten to twenty feet deep below the surface. It has no natural drainage, and in wet seasons in the lower portions or slacks, flushes of water form, in consequence of the elevation of the shore line of sand-hills. After enumerating the manifold difficulties which they had to encounter, the authors described at considerable length the appliances which they ultimately resolved upon using. The primary object which they wished to attain was to get a dry subsoil wherein to lay the pipes, that the cement joints might have time to set and become water-tight, and by securing more time for the laying of the pipes, laying a greater length at a time, and the prevention of disturbance or drawing of the pipes while preparing the next excavations, to ensure greater certainty and perfection in the gradients and junctions, and consequently improve the general system of pipe sewerage. From the experiments which they have made with the subsoil drains, they have thoroughly satisfied themselves as to their efficiency. The subsoil drains are in fact a foundation for the pipes of the sewer, and the sewer itself can be as readily constructed upon them as if the ground were perfectly dry. They have begun to use the subsoil drains in the sewerage works which they are carrying out at Birkdale, a length of 10,000 yards.

On the Ashpit System of Manchester.—Alderman Rumney. The authorities of Manchester have at all times objected to the general use of water-closets in cottage dwellings. In the first place, because they believed that in the limited space available in houses occupied by the working classes, they would prove a greater nuisance than the privy and ashpit outside; secondly, because of the loss of valuable manure which would be occasioned; and thirdly, because, looking at the rapid increase of population in the district, and the limited area of the watershed, the time would come when all the water available would be required for domestic and manufacturing purposes, and could not be wasted in water-closets. Adhering, then, to the dry in opposition to the wet system, the corporation has for some time been engaged in the attempt to improve the existing privies and ashpits, and to discover the best form to be adapted in all new property erected within the city. In the construction of ashpits, the object of the Health Committee appointed by the corporation was to prevent as far as possible the decomposition of the excreta, and consequent generation of gases passing off into the surrounding atmosphere; and as decomposition is accelerated by moisture, they determined that all ashpits should be made dry, excluding the rainfall by covering them over, and the drainage from the yard by requiring the floors and walls to be made water-tight; they required also that the ashes from the pit should be placed daily in the ashpit for the purpose of condensing as far as possible the ammoniacal and other gases, and preventing organic matter impregnating the air in the immediate vicinity. In addition to these arrangements, it was foreseen that in summer time, when decomposition is most vigorous, and the supply of neutralising ashes most scanty, a closed ashpit might become a greater nuisance than an open one, and a ventilating shaft or chimney was determined upon, to be carried from the top of the ashpit up to the side of, and a little above, the eaves of the house, for the purpose of carrying off all the gases and light vapours, and allowing them to mix with the surrounding atmosphere at an elevation which would not injuriously affect the inmates of the dwelling. In the Appendix to the Report of the Medical Officer of the Privy Council just printed, Dr. Buchanan and Mr. Radcliffe express themselves in high terms regarding the new system. Already upwards of 1,500 new privies and ashpits have been erected under the supervision of the committee; the occupants of the houses are perfectly satisfied, and are constantly expressing their approval.

When the reading of the papers was concluded, a long and animated discussion followed, the speakers being Professor A. Reynolds, Mr. Brierly (of Blackburn), Professor Ansted, Mr. Rawlinson, C.B., C.E., Mr. Glazebrook, Mr. Hawkesley, C.E., Professor A. W. Williamson, and Mr. Hope, V.C.

The first paper in this Section on Saturday gave rise to a very unpleasant occurrence, in which the President, according to general report, adoped a rather unusual proceeding. His treatment of the author was somewhat unceremonious. The paper was entitled

On a new Heat Engine.—Mr. A. W. Bickerton, F.C.S., Associate of the Royal School of Mines. After the author had well-nigh done reading his paper, the President quite unexpectedly stopped him, and told him that he had been talking absolute nonsense. If he (the President) had seen his paper first, he would not have permitted it to be read, as there was no time to discuss a thing which was radically fallacious. The idea of an engine worked by the expansion of nitrogen under the influence of heat was fallacious in principle and practically impossible. A gentleman in the body of the room said he had listened to the paper with great interest, and regretted that it had not been allowed to be concluded. This remark was received with applause by the audience, and still greater applause followed when the author said, in retiring, that time would show whether the President or the principle was right. It seems clear that, having been accepted by the Committee of the Section, and the title of it placed upon the programme of business, the paper was entitled to be read. We are glad to lay a short abstract of the "burked" paper before our readers, expressing no opinion, further than that opinion should not be stifled.

The principle of the engine is as follows:—Crude nitrogen gas is heated in a serpentine system of tubes until the pressure is double that of the air. It is then admitted into a cylinder in which it presses forward a piston, and is allowed to expand. Next it passes into an apparatus where it is cooled, and consequently diminished to half its bulk. The cooling is effected in a new arrangement, which is so constructed that the whole of the heat above that of the external air is transferred to an equivalent volume of air passing in an opposite direction. This heated air is then used as a blast for the fire, $\frac{1}{10}$ going to the hearth of the furnace through a tuyere, and $\frac{4}{10}$ mixing with the products of combustion immediately above the fire, so as to complete any imperfect combustion, and also to modify the temperature of the whole mass, so that it may not be likely to injure the iron of the gas tubes, and the remaining $\frac{5}{10}$ being introduced into the system at a point further on. The construction of the system of tubes is such that, by the time the products of combustion reach the open air, they shall have parted with nearly all their heat, and transferred it to the nitrogen contained in the tubes, and hence a chimney draught cannot be used, and the blast has to be produced by a blowing engine. The nitrogen, after having been cooled to half the volume it occupied in the first cylinder, is then compressed and forced into the system of tubes at the point furthest from the fire. It is this forcing the gas back again into the system of heating tubes that appears absurd; but it must be remembered that the gas while leaving the heating tubes occupies twice the space it does when being forced back, hence it fills a cylinder of twice the area, and the force that may now be disposed of is equal to half the pressure exerted in the larger cylinder. But the other half of the power is not lost, it is simply conveyed back to the heating tube, and is used again. The only losses that can arise are those which are incidental to all engines, such as radiation, conduction, &c., inasmuch as there is avoided the enormous loss of heat that usually goes up the chimney, together with the still greater loss that is constantly being carried away by the condensed water,—an amount in itself six times as great as that converted into work in the steam-engine. The inventor considers that he does not expect too much if he expects his new heat engine to convert 60 per cent. of the heat of combustion into work, a duty that is fully 500 per cent. above that of well-constructed steam-engines.

Of course, as the author was not permitted to finish the reading of his paper, no discussion was taken upon it.

REPORTS OF COMMITTEES

THIRD REPORT OF UNDERGROUND TEMPERATURE COMMITTEE

Mr. G. J. Symons, whose observations, extending to a depth of 1,100 feet in a well at Kentish Town, were reported at last meeting, has since repeated his observations at several depths.

The first 210 feet of the well (which is eight feet in diameter to the depth of 540 feet) are occupied by air, and in this portion of the well the second series of observations give temperatures exceeding those observed in the first series by from 2° to 5°, the excess diminishing as the depth increases. The second series were taken in July and August, whereas the first series were taken in January. It is evident that, in this portion of the well, in spite of the precautions taken to exclude atmospheric influences, by boarding over the well and erecting a hut over it, the temperature varies with the seasons, the variations being in the same direction as in the external air, but smaller, and diminishing as the depth increases, but still amounting to 2°·2 at the depth of 200 feet.

We can feel no certainty that even the mean annual temperature in this portion of the well represents the temperature in the solid ground. On the contrary, the mean temperature in the well at any depth is probably intermediate between the temperature of the solid ground at that depth and the mean temperature of the external air.

It is well that such observations should have been carefully made and recorded in this one instance, if only for the sake of warning; and they show that we cannot expect to attain the object for which the committee has been appointed by observations in large shafts filled with air.

Mr. Symons has also repeated the observations at 250 feet (which is 40 feet under water), and at the depths of 600 feet, 750 feet, and every fiftieth foot from this to 1,100 feet, which is the lowest point attainable on account of the mud, which extends 300 feet lower. The differences from the results obtained last year are + ·2, − ·3, − ·4, − ·2, − ·2, 0, − ·1, − ·1, 0; which, upon the whole, strongly confirm the correctness of the observations.

The temperature at 1,100 feet is 69·8, which, if we assume the mean temperature of the surface of the ground to be $\left\{\begin{matrix} 50^\circ \\ 49^\circ \end{matrix}\right\}$, gives a mean increase downwards of $\left\{\begin{matrix} \cdot 0180 \\ \cdot 0189 \end{matrix}\right\}$ of a degree Fahrenheit per foot, or 1° for $\left\{\begin{matrix} 55\cdot 5 \\ 52\cdot 9 \end{matrix}\right\}$ feet.

The curve in which temperature is the ordinate and depth the abscissa, exhibits considerable irregularities till we reach the depth of 650 feet, beyond which it is nearly a straight line, and represents an increase of ·0187 of a degree per foot.

The strata penetrated by the well to the depth to which our observations extend, consist of clay, sand, chalk, and marl, besides flints. (See tabular list appended.)

Mr. Symons, in his report, calls attention to the anomalous position of a column of water, increasing in temperature and, consequently, diminishing in specific gravity downwards, and suggests the inquiry why the warmer and lighter portions do not ascend to the top. The proper reply seems to be that the diminution of specific gravity, amounting to less than one part in 50,000 per vertical foot, does not furnish sufficient force to overcome liquid adhesion, and the water is thus able to remain in unstable equilibrium.

Mr. Symons intends during the remainder of the present year, verifying those of his observations which have not yet been repeated, and concludes his report by remarking that it appears desirable to ascertain by observations from year to year, whether the temperature at a given depth (say 1,000 feet) remains constant or is subject to minute changes, periodical or otherwise—a suggestion which appears fully worthy of being carried out.

Mr. Wm. Bryham, manager of Rosebridge Colliery, Ince, near Wigan, has taken very valuable observations during the sinking of that colliery, which is now the deepest excavation in Great Britain. The principal results have already been given in a paper to the Royal Society by Mr. Edward Hull, director of the Geological Survey of Ireland, who had previously published some important contributions to our knowledge of underground temperature, and has now consented to become a member of this committee. Some of the depths have however been re-measured since Mr. Hull's paper was read, and we are now enabled, through the kindness of Mr. Bryham, to furnish a rather more accurate report.

The temperatures observed, and the depths at which they were taken, are as follows:—

Depth in Yards.	Temperature Fahrenheit.
161	(64½)
200	([illegible]6)
558	78
605	80
630	83
663	85
671	86
679	87
7[illegible]4	88½
745	89
761	90½
775	91½
783	92
800	93
806	93½
815	94

All these temperatures, except the two first, were observed during the sinking of the shaft, by drilling a hole with water, to the depth of a yard, in the solid strata at the bottom. A thermometer was then inserted, the hole was tightly plugged with clay so as to be air-tight, and was left undisturbed for half an hour, at the end of which time the thermometer was withdrawn and read—a mode of observation which appears well adapted to give reliable results. With respect to the temperatures at 161 and 200 yards (which are enclosed in brackets to indicate uncertainty), Mr. Bryham says that he has some doubt as to the correctness of the thermometer with which they were taken, and that they were not taken in the shaft at the time it was sunk, but in the seams at the depths named.

Asuming the surface temperature to be 49°, we have, on the whole depth of 815 yards, or 2,445 feet, an increase of 45°, which is at the rate of ·0184 of a degree per foot, or a degree for every 54·3 feet.

On plotting the temperature curve, including the two observations marked as doubtful, we find that it naturally divides itself into four portions, which are approximately straight lines.

The most remarkable of these portions is the second from the top, extending from the depth of 161 yards to that of 605 yards. It embraces 1,332 feet, and shows an increase of only 1° for every 86 feet.

The third portion, extending from the depth of 605 yards to that of 671 yards, covers only 198 feet, and shows an increase of 1° for every 33 feet.

The lowest portion extends from the depth of 671 yards to 815 yards. It covers 432 feet, and shows an increase of 1° in 54 feet.

The topmost portion will be affected by the assumption we make as to surface temperature. Assuming this as 49°, it shows an increase of 1° in 31 feet.

It is interesting to compare the Rosebridge observations with those previously made by Mr. Fairbairn at Astley Pit, Dukinfield, Cheshire, which have been described by Mr. Hull in "The Coalfields of Great Britain," and by Mr. Fairbairn himself in the B. A. Report for 1861. The results have been thus summed up by Mr. Hull:—

1. The first observation gives 51° as the invariable temperature throughout the year at the depth of 17 feet. Between 231 yards and 270 yards the temperature was nearly uniform at 58·0. And the increase from the surface would be at the rate of 1° F. for 88 feet.

2. Between 270 and 309 yards, the increase was at the rate of 1° for 62·4 feet.

3. Between 309 and 419 yards, the increase was at the rate of 1° for 60 feet.

4. Between 419 and 613 yards, the increase was at the rate of 1° for 86·91 feet.

5. Between 613 and 685 yards, the increase was at the rate of 1° for 65·6 feet.

The result of the whole series of observations gives an increase of 1° for every 83·2 feet.

Mr. Fairbairn's own summary is as follows:—"The amount of increase indicated in these experiments is from 51° to 57¾°, as the depth increases from 5⅔ yards to 231 yards, or an increase of 1° in 99 feet. But if we take the results which are more reliable, namely, those between the depths of 231 and 685 yards, we have an increase of temperature from 57¾° to 75½°, or 17¾° Fahrenheit. That is a mean increase of 1° in 76·8 feet."

Mr. Fairbairn here, by implication, throws doubt on the alleged invariable temperature of 51° at the depth of 17 feet, a determination which in itself appears highly improbable, seeing that at Greenwich the thermometer, whose bulb is buried at a depth of 25·6 feet, exhibits an annual range of 3°·2, while that at the depth of 12·8 feet exhibits a range of 9°. But even if we assume the mean surface temperature to be 49°, we have still upon the whole depth an increase at the rate of 1° in 80 feet, as against 1° in 54·3 feet at Rosebridge.

Mr. Fairbairn's paper gives also the results obtained at a second pit at Dukinfield, which agree with those in the first in showing an exceptionally slow rate of increase downwards. The temperatures at the depths of 167½ yards and 467 yards were respectively 58° and 66½°, showing a difference of 8½° in 299½ yards, which is at the rate of 1° in 106 feet. The increase from the surface down to 167½ yards, assuming the surface temperature as 49°, would be 9°, or 1° in 56 feet, and the mean rate of increase from the surface to the bottom would be 1° in 80 feet, the same as in the first pit.

A tabular list of the strata at Rosebridge is appended to this report. A full account of the strata at Dukinfield is given in Mr. Fairbairn's paper (B.A. Report, 1861).

With strata so nearly similar and in two neighbouring counties, we should scarcely have expected so much difference in the mean rates of increase downwards. In this respect, Rosebridge agrees well with the average of results obtained elsewhere. Dukinfield far surpasses all other deep mines or wells, so far as our present records extend, in slowness of increase.

This implies one of two things, either that the strata of Dukinfield afford unusual facilities for the transmission of heat, or that the isothermal surfaces at still greater depths dip down in the vicinity of Dukinfield.

Mr. Hull has called attention to a circumstance which favours the first of these explanations, the steepness of inclination of the Dukinfield strata. He argues, with much appearance of probability, that beds of very various character (sandstones, shales, clays, and coal), alternating with each other, must offer more resistance to the transmission of heat across than parallel to their planes of bedding, as Mr. Hopkins has shown that every sudden change of material is equivalent to an increase of resistance; and it is obvious that highly inclined strata furnish a path by which heat can travel obliquely upwards without being interrupted by these breaches of continuity.

To this suggestion of Mr. Hull's it may be added that inclined strata furnish great facilities for the convection of heat by the flow of water along the planes of junction. It appears likely that surface water, by soaking downwards in this direction, may exercise an important influence in assimilating the temperature at great depths to that which prevails near the surface. Mr. Hull's own statement of his views is given in the foot-note below.*

Mr. McFarlane has been prevented from continuing his observations near Glasgow during the past year by the press of business incident to the removal from the old to the new college.

Mr. F. Amery, Druid House, Ashburton, Devon, has taken some observations with one of the Committee's thermometers in the shaft of a mine which had been unused for a year, and was nearly full of water. The shaft is 12ft. × 7ft., and descends vertically for 350ft., after which it slopes to the south at an angle of 50°, continuing to the depth of 620ft. The water stood at 50ft. from the surface. Mr. Amery observed the temperature at every 50th foot of depth in the vertical portion, and found it to be 53° at all depths, except at 250ft. and 200ft., where it was 53·4 and 53·2 respectively. A copper lode crosses the shaft at the depth of 250ft.; and it appears to be generally the case in the Cornwall and Devonshire mines, that copper lodes exhibit a high temperature, a circumstance which Prof. Phillips explains by the conformation of the strata, which is such as to cause water from greater depths to make its way obliquely upwards by following the course of the copper lodes.

The nearly constant temperature observed from the surface to the bottom of the shaft seems to indicate a large amount of convective circulation. In this respect small bores have a decided advantage.

Mr. G. A. Lebour has taken observations with one of our thermometers in several shafts and bores near Ridsdale, Northumberland, made for working coal and ironstone. Mr. Lebour does not report the temperatures observed, which he characterises as discrepant and utterly valueless, owing, he believes, to the numerous water-bearing beds which they cut through, and the very varying temperature of these waters. Having now, however, found a dry bore, he hopes to make a useful series of observations next winter.

* "Rosebridge Colliery occupies a position in the centre of a gently-sloping trough, where the beds are nearly horizontal; they are terminated both on the west and east by large parallel faults, which throw up the strata on either side. The colliery is placed in what is known as 'the deep belt.'

"Dukinfield Colliery, on the other hand, is planted upon strata which are highly inclined. The beds of sandstone, shale, and coal rise and crop out to the eastward at angles varying from 30° to 35°. Now, I think we may assume that strata consisting of sandstones, shales, clays, and coal alternating with each other, are capable of conducting heat more rapidly along the planes of bedding than across them, different kinds of rock having, as Mr. Hopkins's experiments show, different conducting powers. If this be so, we have an evident reason for the dissimilar results in the case before us. Assuming a constant supply of heat from the interior of the earth, it could only escape, in the case of Rosebridge, across the planes of bedding, meeting in its progress upwards the resistance offered by strata of, in each case, varying conducting powers. On the other hand, in the case of Dukinfield, the internal heat could travel along the steeply-inclined strata themselves, and ultimately escape along the outcrop of the beds.

"I merely offer this as a suggestion explanatory of the results before us, and may be allowed to add that the strata at Monkwearmouth Colliery, the thermometrical observations at which correspond so closely with those obtained at Rosebridge, are also in a position not much removed from the horizontal, which is some evidence in corroboration of the views here offered."—*Proc. Roy. Soc.*, Jan. 27, 1870.

One of the Committee's thermometers has recently been sent to Mr. John Donaldson, C.E., Calcutta, who has expressed his desire to aid in scientific observation, and being now engaged in examining for coal and iron under Government, is likely to render us effective service.

Shortly after the last meeting of the Association, the secretary of this committee addressed a letter to Prof. Henry, secretary of the Smithsonian Institution, U.S., requesting his co-operation in furthering the object which the committee have in view, at the same time forwarding one of our protected thermometers.

In June of the present year an answer was received from Prof. Baird, assistant secretary in charge, to the effect that Prof. Henry's ill-health during the present season had prevented his communicating to us the results of his labours in response to request.

The letter addressed to Prof. Henry made special reference to an artesian well of extraordinary depth which was understood to be in course of sinking at St. Louis, and at the same time a letter was addressed, and a special thermometer sent, to Mr. C. W. Atkeson, the superintendent of the work of boring at St. Louis. No reply has been received from Mr. Atkeson, who appears to have left St. Louis before the letter arrived; but letters have been received through the Smithsonian Institution from Dr. Chas. W. Stevens, superintendent of the County Insane Asylum at St. Louis, this being the institution for whose uses the well was sunk, together with a very interesting newspaper cutting, consisting of Mr. Atkeson's report on the works. The boring of the well was commenced (at the bottom of a dug well 71½ feet deep) on the 31st of March, 1866, and was continued till the 9th of August, 1869, when the work was stopped at the enormous depth of 3,843½ feet, exceeding by more than one-half the depth of Dukinfield Collery. The strata penetrated consisted in the aggregate of 63 feet of clay, 6 feet of coal, 380 feet of shales, 2,725 feet of limestone, and 620 feet of sandstone.

A cast-iron tube of 11½ inches bore was first put down, reaching from the top and secured in the limestone at the bottom. This tube was then lined inside with a wooden tube, reducing the bore to 4½ inches. A 4½-inch drill was put down through this tube on the above-mentioned date. The bore was afterwards enlarged to 6 inches, and subsequently to 11½ inches to a depth of 131½ feet. A sheet-iron tube was then put down, extending from the top to this depth, and the bore below was enlarged, first to 6 and afterwards to 10 inches diamenter, to the depth of 953 feet. A sheet-iron tube, 79 feet long, was then put down, which rests on the offset at the bottom of the 10-inch bore. The 4½-inch bore was then enlarged to 6 inches to the depth of 1,022 feet, and a wrought-iron tube of 5 inches bore, weighing more than six tons, was introduced, reaching from the top and resting on the offset at the bottom of the 6-inch bore, thus securing the work to this depth, and reducing the bore to convenient size to work in. The 4½-inch bore has been continued to the depth of 3,843 feet 6 inches without further tubing.

At the depth of 3,029 feet the first observation of temperature was taken, and the reading of the thermometer was 107° F. This first observation is stated by Dr. Stevens to be specially worthy of confidence, as having been confirmed by several repetitions, or rather, to use Dr. Stevens's own words, "this was the maximum of several trials." It was taken, as well as those that followed it, by means of a registering thermometer (kind not mentioned); but in answer to our inquiries, Dr. Stevens states, upon the authority of the carpenter who attached the thermometer to the pole by which it was lowered, "that no means were taken to defend the bulb from pressure." In the absence of further information (and Mr. Atkeson himself has not yet spoken), we can place no reliance upon the temperature recorded, as the thermometer had to bear a pressure of ⅝ of a mile of water.

The temperatures registered at lower depths, the deepest being 800 feet lower, were all, strange to say, somewhat lower than this, a circumstance which is all the more remarkable because the pressure (which tends to make the reading higher) must have increased with the depth. At the bottom, or rather at 3,837 feet, being 6½ feet from the bottom, the temperature indicated was 105°. Either of these results, taken apart from the other and compared with the surface temperature, would give a result not improbable in itself. The mean temperature of the air at St. Louis appears to be about 53°, but it seems desirable to avoid publishing calculations till the data are better established.

Unfortunately, the apparatus which was employed in boring has all been removed, after the insertion of two wooden plugs, with an iron screw at the upper end of each, one at the offset at a depth of 1,022 feet, and the other at the offset at the depth of 953 feet, for the purpose of separating the fresh from the salt waters. These plugs were driven in with great force, and can only be withdrawn with the aid of a series of poles and other appliances, such as were used in the boring, which will be rather costly. The poles alone are estimated to cost 1,152 dols., or about 200*l.* If the plugs were withdrawn—and, according to Dr. Stevens, there is nothing but the expense to prevent—the whole well would be available for observation. The committee will make every effort to prevent so rare an opportunity from being lost.

The Secretary has also been in correspondence with Messrs. Mather and Platt, of Salford Iron Works, respecting a boring at Moscow, for which they have furnished machinery, and which is to be carried to the depth of 3,000 feet. They refer to General Helmerson, of the Mining College, St. Petersburg, as the best authority to whom application can be made for particulars of the Moscow boring as to temperature, &c. The secretary has accordingly written to General Helmerson, endeavouring to interest him in the objects of the committee, and offering to forward thermometers. No reply has yet been received.

An element which it is necessary to know, with a view to the correct reduction of our observations, but which in many instances it is difficult to obtain by direct observation, is the mean annual temperature of the ground, at or near the surface. Instances frequently occur in which the temperature at the depth of 200, 300, or it may be 500 feet is accurately known, while the temperature in the superincumbent strata can only be guessed at. This is the case at the Kentish Town well, and partially at Rosebridge and Dukinfield collieries.

It is very desirable that in connection with temperatures at great depths there should in each locality be an accurate observation at the depth of from 50 to 100 feet. At such depths in the solid ground before it has been disturbed by mining operations, one observation suffices to give a good approximation to the mean temperature of many years. At depths of two or three feet it is necessary to observe, once a week, or so, throughout a year, in order to get the mean temperature at that depth for that year; and this may differ by a considerable amount from the mean of a series of years.

In the Report of the Scottish Meteorological Society for the quarter ending December 1862, there is a comparison of the mean temperature of the air with that of the soil at the depths of 3, 12, and 22 inches, at four stations, from observations extending over five years; and in the Journal of the same society for the quarter ending December 1865, there is a comparison of the temperature of drained and undrained land from one year's observations, undertaken for this purpose at two stations, and including also a comparison with the temperature of the year. The mean temperature of the air for each day is, in these comparisons, assumed to be the simple arithmetical mean of the maximum and minimum, as indicated by self-registering thermometers 4 feet from the ground. From these observations, it appears that the mean annual temperature of the soil was in every case rather above that of the air, and that the excess was greater for sand than for undrained clay, and was greater for drained land than for the same land undrained.

The greatest excess occurred in the case of the 22-inch thermometer at Nookten (Vale of Leven), where both surface and subsoil are sandy and dry. The five yearly means at this station were:—

Air 46·1; soil at 3 inches 46·3, at 12 inches 47·3, at 22 inches 48·0; giving an excess of 1·9 for the temperature at the depth of 22 inches as compared with air.

The smallest excess, in the case of the 22-inch thermometers, observed for five years, was at Linton (East Lothian), where it amounted to 0·7; but the observations on the effect of drainage gave for the year of observation an excess of only 0·2 at the depth of 30 inches in light sandy but undrained soil under a ryegrass crop, at Otter House near Loch Fyne, the corresponding excess for drained land of the same kind and in the immediate vicinity being 0·9.

The mean temperature at the depth of 3 feet at Professor Forbes' three stations at Edinburgh, from five years' observations, gave an excess of 0·55 above the mean temperature of the air at Edinburgh as determined by Mr. Adie's observations.

Observations on soil temperature in England are much needed, but the Greenwich observations give an excess of soil above air temperature falling within the limits above quoted, the excess at 3 French feet being 1·7, while at 24 French feet it is reduced to 1°. The soil of which the Observatory Hill is composed, and in which the thermometers are sunk, is dry gravel, and the unusual circumstance of decrease of temperature downward observed in the comparison of the 3 feet and 24 feet thermometers, seems to indicate that the surface of the hill is warmer than the surrounding land.

In the present state of our knowledge, then, it appears that when the temperature of the earth has been observed at a depth of some hundreds of feet in any locality in Great Britain, and has not been accurately determined at a less depth, some knowledge of the rate of increase downwards may be obtained, by assuming provisionally that the mean temperature of the surface is about a degree higher than the mean temperature of the air, supposing the latter to be known.

It is to be wished that the Meteorological Society would, from the ample materials in their possession, publish a map of annual isothermals for Great Britain; and the objects of this committee would be greatly furthered by an extensive series of soil temperature observations at the depth of about 3 feet.

The committee are anxious to carry into effect Mr. Hull's proposal (quoted in their last Report) to bore down from the bottom of a deep mine; and as Rosebridge Colliery appears to be an eminently suitable locality for such an operation, the Secretary has consulted Mr. Bryham respecting its practicability and probable cost. Mr. Bryham's reply is that there would be no difficulty in carrying out the proposal at Rosebridge, that to make preparations and bore 300 feet would, on a rough estimate, cost £150, and that the second 300 feet would probably cost about the same sum.

The committee would earnestly appeal to the liberality of the Association to enable them to put this design in execution, and they would remark that the sooner it is carried out, the more valuable the results obtained will be, as the mine has been but recently opened to its present depth, and the influence of atmospheric temperature will every year become more sensible in the strata below.

SCIENTIFIC SERIALS

In the *Annalen der Chemie und Pharmacie* for May 1870, we find several important papers, of which the following are abstracts:—"Investigations on some derivatives of cinnamic acid," by Carl Glaser." In this lengthy and most interesting paper is described the Phenylpropiolic acid $C_9H_6O_2$, a new acid which differs from cinnamic acid by containing H_2 less. It is obtained either by the action of sodium and CO_2 on β bromstyrol, or by the action of alcoholic potash on a bromcinnamic acid. On heating with water to 120°, it splits up into CO_2 and acetenylbenzol $C_2H.C_6H_5$, which latter can also be obtained by the abstraction of 2 HBr from dibromstyrol. Silver, copper, and sodium derivatives of this remarkable hydrocarbon are described, from the latter of which, by the action of CO_2, the author succeeded in regenerating phenylpropiolic acid. The paper concludes with an account of some Cl and Br derivatives of styrol.—"On mercuryditolyl," by E. Dreher and R. Otto. A white crystalline compound obtained by the action of Na_2Hg on bromtoluol. The authors did not succeed in preparing the corresponding mercury compound from the isomeric brombenzyl.—Note on the behaviour of dibenzyl at high temperatures, by the same authors. This compound is split up according to the equation

$$2\left\{\begin{matrix}CH_2C_6H_5\\CH_2C_6H_5\end{matrix}\right. = 2\,C_6H_5CH_3 + \left\{\begin{matrix}CH\,C_6H_5\\CH\,C_6H_5\end{matrix}\right.$$

Toluylen

"Note on the conversion of Thiophenol (Phenylic sulphydrate) into Phenylic disulphide," by the same authors. This is effected by distilling the mercury compound of the former, when it splits up into mercury and the bisulphide, which is probably due to the decomposition taking place at a temperature at which the affinity of Hg for S does not yet come into play, since the homologous toluol and benzyl compounds, which require a much higher temperature, give mercuric sulphide and a monosulphide.—"On two isomeric pentachlorbenzols and bichlorbenzols-chloride," by R. Otto. A short description of the mode of preparation and properties of the above compounds. The existence of two pentachlorbenzols, which now seems to be placed beyond all doubt, is of great interest, as it is one of the very few facts irreconcileable with Kekulé's benzol theory, which does not admit of the existence of more than one.—"On sulphotoluid," by R. Otto and Gruber. Obtained by the action of sulphuric anhydride on toluol.—"On aceto-mercury monomethyl and aceto-mercury monethyl," by R. Otto. These two compounds are prepared by the action of acetic acid on mercuric methide and ethide respectively.

$$\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right\}Hg + \left\{\begin{matrix}CH_3\\CO\,OH\end{matrix}\right. = \left.\begin{matrix}CH_3\\C_2H_3O_2\end{matrix}\right\}Hg + CH_4$$

—"On the preparation of organic sulphur compounds by means of sodic hyposulphite," by the same author. Alcohol heated with a concentrated solution gives mercaptan; ethylic iodide mercaptan and ethylic sulphide; chlorbenzyl gives benzylic mercaptan and sulphide.—"On diamidonitro phenylic acid, a new derivative of picric acid," by Peter Griess. This acid is prepared by the reduction of picric acid with ammonic sulphide.—"On azobenzol sulphuric acid," by P. Griess. A product of the action of hot fuming sulphuric acid on azobenzol. By fusion with potash, phenoldiazobenzol $C_{12}H_{10}N_2O$ is obtained, which on treatment with ammonic sulphide, is converted into oxybenzidin $C_{12}H_{12}N_2O$.—"On ozone and antozone," by C. Engler and O Nasse. In this lengthy paper are described a long series of experiments, all of which seem to prove conclusively the non-existence of the third modification of oxygen, called by Schönbein and others antozone, and which the authors prove to be hydric peroxide formed by the oxidation of water, which was present in all those cases where the so-called antozone has been observed by ozone.—"On the constitution of arbutin," by Hugo Schiff. The author considers arbutin to be derived from one atom glycose + one atom hydroquinone $- H_2O$, and describes a number of acetyl and benzoyl derivatives in support of his views.—"On the action of hypochlorous acid on allylic chloride," by H. v Geyerfell. The author has obtained the compound $C_3H_6OCl_2$ by direct addition of the elements of hypochlorous acid to allylic chloride. This on reduction with sodium amalgam yields a liquid, probably allylic alcohol. (?)—"On a new method for the estimation of grape sugar," by Karl Knapp. This method is based on the fact that an alkaline solution of mercuric cyanide is entirely reduced to metallic mercury by grape sugar. By direct experiment it was found that on boiling, 400 mgr. $Hg(CN)_2$ are reduced by 100 mgr. sugar. The solution is prepared by dissolving 10 grm. pure dry $Hg(CN)_2$ in water, adding 100 cc. of a sodic hydrate solution of 1·145 sp. gr., and diluting to 1,000 cc. Pure grape sugar is prepared by recrystallising the commercial dried at 100°, from absolute alcohol. The experiment is performed by heating 40 cc. of the mercury solution—this amount corresponds to 100 mgr. sugar—to boiling in a porcelain dish, and then adding sugar solution to complete precipitation of the mercury, the end of the reaction being ascertained by placing a drop of the liquid on to a piece of the finest Swedish filter paper, covering a small beaker containing some very strong ammonic sulphide; a brown spot is observed so long as mercury remains in solution. The advantages of this method over Fehling's are, that being equally accurate, the test solution is exceedingly easy to prepare and perfectly stable, a shorter time is required for the estimation, and that the foreign bodies which mask the pure colour of the cuprous oxide are without influence on the reduction of the mercuric cyanide.—"On some isopropyl compounds," by R. D. Silva. In this notice are described isopropylic succinate, benzoate, nitrite, and nitrate, all prepared by the action of isopropylic iodide on the respective silver salts of the acids.

The *Journal of Botany, British and Foreign*, for September contains a paper by Dr. H. Trimen on Early Icelandic Botany, including an account of Rotböll's observations on the new or little-known but rare plants found in Iceland and Greenland, which appears to have been overlooked by Professor Babington in his "Revision of the Flora of Iceland." It was published in 1770, and adds a few species to the number stated by Professor Babington to be indigenous to Iceland. We have also one of Mr. J. G. Baker's careful and useful contributions to British systematic botany, an account of the British dactyloid saxifrages, which he states to form a complete series of varieties from *S. cæspitosa* to *S. hypnoides*, without any clearly marked gap at any point between the extremes; and the line of progression substantially straight, very little if at all complicated, as in the case of *Rubus*, by cross-relationships. The order of sequence is as follows: 1. *S. cæspitosa*, 2. *S. Sternbergii*, 3. *S. decipiens*,

4. *S. quinquefida*, 5. *S. hypnoides*. A table of their geographical distribution is subjoined. Two or three other short original articles and notes are also included, and the official report for 1869 of the botanical department of the British Museum.

THE *Geological Magazine* for October (No. 76) commences with a long paper, illustrated with two plates, by Mr. D. Mackintosh, on the surface-geology of the Lake district, relating chiefly to the effects of glacial conditions observable among the mountains of Cumberland and Westmoreland.—Mr. T. Davidson contributes a third series of descriptions of Italian tertiary brachiopoda, including numerous species of the genera *Rhynchonella* and *Crania*, which are figured on the accompanying plate.—In a paper on the chalk of Kent, Mr. G. Dowker, following Mr. Whitaker, distinguishes the Margate chalk as constituting the highest section of the chalk observable in that district, and gives a list of the fossils which it contains. The author proposes a division of the Kentish chalk into six sections.—A fourth and last paper is by Mr. H. B. Medlicott, on the mode of occurrence of faults in strata. The remainder of the number is, as usual, occupied by reports, reviews, &c.

SOCIETIES AND ACADEMIES

NORWICH

Norfolk and Norwich Naturalists' Society, Aug. 30.—Mr. Stevenson read a valuable paper communicated by Prof. Newton, of Cambridge, on the method adopted by his brother and himself for registering Natural History phenomena. The Register, a volume of which was on the table, was kept at Elveden, near Thetford, during a period of ten years, and its great value consists in the variety and completeness of the information with regard to each species of bird found in that neighbourhood, and the slight amount of labour required to keep up the daily record. This is effected by the use of signs extremely simple in their construction, but conveying an amount of information never before dreamed of in registers of this description: a life history from day to day of each species is given; all the rare and occasional visitors recorded, and the most striking botanical phenomena are all noted fully and explicitly, but in such a way as to occupy barely five minutes in doing. What a boon this decrease in labour alone is to the conscientious recorder, he who has had to post up his register after a hard day's work in the field will be in a position fully to appreciate. Some of the results obtained from the study of the register are highly valuable, as, for instance, the migratory habits of the song thrush, and we strongly recommend the paper, which will be published in the Transactions of the Society, to the consideration of naturalists, feeling certain that important results would be obtained by the comparison of registers kept on Prof. Newton's plan in different districts of the county. Mr. Stevenson also read a note with regard to a habit of the rook, which appears to have attracted very little attention, viz., that of throwing up the indigestible portions of its food in the form of large pellets, after the manner of hawks and owls. Several of these pellets, or "quids," picked up on the cliffs at Cromer and Sherringham, consisting mainly of the indigestible husks of barley, with a few pebbles and fragments of small beetles, were exhibited, all having been found near the edge of the cliffs, together with rooks' feathers, showing that the birds had been preening themselves during the process of digestion. A number of interesting plants found in the neighbourhood were exhibited by Mr. Bircham. At the suggestion of Mr. Southwell, a subcommittee was formed to take into consideration the formation of a list of the natural productions of the county; and it is hoped that help for this purpose will be rendered by kindred societies and naturalists resident in the county. The President announced that Mr. J. H. Gurney, jun., who has been travelling in Algeria, would read a paper on the birds of that country at the next meeting of the Society, on September 27th.

PARIS

Academy of Sciences, Sept. 5.—M. Cave presented a second note on the generative zone of the appendages in monocotyledonous plants.—M. de Saint-Venant communicated a note by M. Boussinesq, supplementary to his memoir on periodical liquid waves, and showing the general relations between the internal energy of a fluid or solid body and its pressures or elastic forces.—A note was presented by M. W. de Fonvielle on a theory of Mariotte's on barometric oscillations, relating to the rising of the mercury when the wind is from the north and north-east, and its fall when the wind is from the south and south-west.—M. Delaunay communicated a notice of the discovery of a new comet by M. Coggia, at Marseilles, on the 28th August.—A note on the composition of nadorite by M. Flajolot, was presented by M. Combes. The mineral may be regarded as a combination of oxide of lead and oxychloride of antimony, in accordance with the formula $Sb^2\ O^2\ Cl\ 2Pb\ O$.—M. Claude Bernard communicated a memoir on the venom of the scorpion, by M. Jousset. The author has experimented with the poison of *Scorpio occitanus*, by inoculating it upon tree frogs. He found that it acts directly upon the red globules of the blood, depriving them of the power of passing each other freely, and thus causing them to become agglutinated to each other, and obstruct the circulation. The extent of the action of the poison is dependent on its quantity.—M. Zaliwski noticed a battery of zinc and carbon giving a maximum of intensity for twelve hours. The zinc is immersed in a solution of hydrochlorate of ammonia, the carbon in a mixture of nitric and sulphuric acid.

THURSDAY, OCTOBER 20, 1870

ON THE COLOUR OF THE LAKE OF GENEVA AND THE MEDITERRANEAN SEA

THROUGH kindness for which I have reason to feel both proud and grateful, I have had placed in my hands two bottles of water taken from the Mediterranean Sea, off the coast of Nice. To my friend M. Soret I am also indebted for two other bottles taken from the Lake of Geneva. The friendly object in each case was to enable me to examine whether the colour of the water could in any way be connected with the scattering of light by minute foreign particles, which is found so entirely competent to produce and explain the colour of the sky. In the open Lake of Geneva, Soret himself had studied this question with considerable success,* and my desire was to apply to it other methods of examination.

The bottles, as they reached me, and with their stoppers unmoved, were placed in succession in the convergent beam of an electric lamp. Water optically homogeneous would have transmitted the beam without revealing its track. In such water the course of the light would be no more seen than in optically pure air. The cone of light, however, which traversed the liquid, was in both cases distinctly blue, the colour from the Lake of Geneva water being especially rich and pure. Something, therefore, existed in the liquid which intercepted and scattered, in excess, the shorter waves of the beam. The longer waves were also scattered, but in proportions too scanty to render the track of the beam white. The action, in fact, was identical with that of the sky. Viewed through a Nicol's prism the light was found polarised, and the polarisation along the perpendicular to the illuminating beam was a maximum. In this direction, indeed, the polarisation was sensibly perfect. A crystal of tourmaline placed with its axis perpendicular to the beam was transparent; with its axis parallel to the beam it was opaque. By shaking the liquid larger particles could be caused to float and sparkle in the beam. The delicate blue light between these particles could be quenched by the Nicol while they were left shining in the darkened field. A concave plate of selenite, placed between the Nicol and the water, showed a system of vividly coloured rings. They were most brilliant when the vision was at right angles to the beam, just as they are most brilliant when the blue sky is regarded at right angles to the rays of the sun. In no respect could I discover that the blue of the water was different from that of the firmament. The colour presented by the Mediterranean water was a good sky-blue, while that presented by the Geneva water matched a sky of exceptional purity.

My interest was long ago excited by the attempts made to account for the colour of the Lake of Geneva, and continued observation in 1857 impressed me more and more with the notion that the blue was mainly that of a turbid medium. Soon afterwards I wrote thus regarding this colour :—

"Is it not probable that this action of finely divided matter may have some influence on the colour of some of the Swiss lakes—on that of Geneva for example? This lake is simply an expansion of the river Rhone, which rushes from the end of the Rhone glacier. Numerous other streams join the Rhone right and left during its downward course, and these feeders being almost wholly derived from glaciers, carry with them the fine matter ground by the ice from the rocks over which it has passed. Particles of all sizes must be thus ground off, and I cannot help thinking that the finest of them must remain suspended in the lake throughout its entire length. Faraday has shown that a precipitate of gold may be so fine as to require a month to sink to the bottom of a bottle five inches high; and in all probability it would require *ages* of calm subsidence to bring all the particles in the Lake of Geneva to its bottom. It seems certainly worthy of examination whether such particles, suspended in the water, do not contribute to that magnificent blue which has excited the admiration of all who have seen it under favourable circumstances." *

Through the observations of Soret, and through those here recorded, the surmise of thirteen years ago has become the verity of to-day.

But though in the action of small particles we have a cause demonstrably sufficient to produce the blueness referred to, it is not the only cause operative. In the Lake of Geneva we have not only the blue of scattering by small particles, but also the blue arising from true molecular absorption. Indeed, were it not for this, the light *transmitted* by a column of the water would be yellow, orange, or red, like the light of sunrise or sunset.† Not only then is the light mainly blue from the first moment of its reflection from the minute particles, but the less refrangible elements which always accompany the blue are still further abstracted during the transmission of the scattered light. Through the action of both these causes, scattering and absorption, the intense and exceptional blueness both of the Lake of Geneva and the Mediterranean Sea I hold completely accounted for.

During the year 1869, M. Lallemand communicated to the Paris Academy of Sciences some interesting papers on the optical phenomena exhibited by certain liquids and solids when illuminated like the actinic clouds in my experiments. I also, in 1868, had examined a great number of liquids in the same manner, and a brief reference to these experiments will be found towards the end of a paper on the blue colour of the sky and the polarisation of its light, published in the Proceedings of the Royal Society for the 16th of December, 1868. M. Lallemand supposed the scattering of the light to be effected not by foreign particles but by the molecules of the liquids with which he experimented. M. Soret, on the other hand, contends against this novel view, maintaining that the scattering of the light is an affair of particles and not of molecules. While admiring the skill and learning displayed by the young French physicist, I am forced to take the side of Soret in this discussion M. Lallemand assumes a purely hypothetical cause while a true cause is at hand. He bases his case mainly on clear glass and distilled water. But the clearness is that observed in ordinary daylight, which is a very deceptive test. Glass exhibits the phenomena

* See his letter to me, Philosophical Magazine, May, 1869.

* Glaciers of the Alps (1860), p. 261.

† In fact, we have a dichroitic action of this kind exerted by glacier water when the subsidence is less complete than in the Lake of Geneva.

of scattering in every degree of intensity. Exceedingly fine examples of dichroitic action on the part of this substance are to be seen in Salviati's window in St. James's Street.* By reflected light the dishes and vases there exposed exhibit a beautiful blue—by transmitted light, a ruddy brownish yellow. The change of colour is very striking when, having seen the blue, a white cloud is regarded through the glass. Where the opalescence is strongest, the transmitted light, as might be expected, is most deeply tinged. From these examples, where the foreign ingredient is intentionally introduced, we may pass by insensible gradations to M. Lallemand's glass. The difference between them is but one of degree. Many of the bottles of our laboratory show substantially the same effect as the glass of Salviati. We can hardly ascribe to molecular action, which is constant, an effect so variable as this. It is also a significant fact that, in the case of pellucid bodies—rock salt, for example—where the powerfully cleansing force of crystallisation has come into play, M. Lallemand himself found the scattering to be *nil*. Under severe examination, rock salt itself would probably be found not altogether devoid of scattering power. I have examined many fine specimens of this substance, and have not succeeded in finding a piece of any size absolutely free from defect. A common form of turbidity exhibited by clear rock salt, when severely tested, resembles on a small scale "a mackerel sky." Nor have the specimens of Iceland spar that I have hitherto examined proved absolutely wanting in this internal scattering power.

In relation to this question, which is one of the first importance, the deportment of ice is exceedingly instructive. As a rule the concentrated beam may be readily tracked through ice, at least at this season of the year, when the substance shows signs of breaking up internally. In some cases the sparkle of motes, which are evidently spots of optical rupture, reveals the track of the beam. In other cases the track appears bluish, though rarely of a uniform blue. By causing a previously sifted beam to traverse lake ice in various directions, we are soon made aware of remarkable variations in the intensity of the scattering, and we find some places where the track of the beam wholly disappears. The convergent beam is sometimes divided by a transverse plane, one half of the cone being visible and the other invisible. In other cases the cone is divided by a plane passing from apex to base, one half shining with scattered light, and the other showing the darkness of true transparency. Now, if the scattering were molecular, it ought to occur everywhere, but it does not so occur, therefore it is not molecular. The scattering is, perhaps, in most cases due to the entanglement in the ice, when the freezing is rapid, of the ultra-microscopic particles abounding in the water. It is only by excessively slow freezing that such particles could be excluded from the ice. Purely optical ruptures of the substance itself, if minute and numerous enough, would also produce the observed effect.

The liquids which I examined in 1868 all showed in a greater or less degree the scattering of light, to which was added in many cases strong fluorescence. In no respect did the deportment of the non-fluorescent liquids which showed a blue track differ from that of the blue actinic clouds with which I was then occupied. I examined water from various sources and found it uniformly charged, not only with particles small enough to scatter blue light, but with far grosser particles. Tested by the concentrated beam, our ordinary drinking water presents a by no means agreeable appearance; some of the water with which London is supplied is exceedingly thick and muddy. Nor does distillation entirely remove the suspended matter. Soret vainly tried to get rid of it; he diminished its effect, but he did not abolish it. I was favoured a few days ago with specimens of distilled water from four of the principal London laboratories. Looked at in ordinary daylight the liquid in each case would, in ordinary parlance, be pronounced "as clear as crystal," but when placed in the concentrated beam of the electric lamp, the notion of purity became simply ludicrous. No one who had not seen it would be prepared for the change produced by the concentrated illumination. There were differences of purity among the specimens, arising, doubtless, from the different modes of distillation, but to an eye capable of seeing in ordinary light what was revealed by the concentrated beam each of the specimens would appear as muddy water. I also examined a specimen of extra purity distilled from the permanganate of potash and liquefied in a glass condenser. It contained a large amount of foreign particles; not of those which scatter blue light, but grosser ones. Such must ever be the case with water distilled in the laden air of cities and collected in vessels contaminated by such air. These facts amply justify the language applied by Mr. Huxley to the statement that solutions without particles can be obtained by the processes hitherto pursued. Such a statement could only be based upon defective observation. In the number of this journal for the 17th of March, an experiment is described in which water was obtained from the combustion of hydrogen in air, the aqueous vapour arising from the combustion being condensed by a silver surface of unimpeachable purity. In this case, though the floating particles of the air were, in the first instance, totally consumed, the water was still well laden with foreign matter. The method of obtaining water here referred to had been resorted to by M. Pouchet with a view of utterly destroying all germs, and my especial object in repeating the experiment was to reveal the dangers incident to the inquiries on which M. Pouchet and others were then engaged. But the warning was unheeded. It is not for the purpose of adding to the weight of calamities, already sufficiently heavy, that I allude to this, but rather to advertise the adventurous neophyte, who may be disposed to rush into inquiries which have taxed the skill of the greatest experimenters, of some of the snares and pitfalls that lie in his way.

NICHOLSON'S MANUAL OF ZOOLOGY

A Manual of Zoology. By H. A. Nicholson, D.Sc. Vol. I. Invertebrate Animals. (Blackwood and Sons.)

A BOOK such as this aims at being was wanted—one which should give a little more of systematic detail than is to be found in Professor Huxley's "Outlines" or

Professor Rolleston's introductory chapters of his "Forms." It required, however, a man of considerable knowledge of the subject to write such a book worthily, and we doubt whether Dr. Nicholson, though he deserves credit for enterprise, was quite the man to undertake it. He excuses himself for shortcomings in plan and execution in his preface, on the score of leading a busy life. Now is it, we would ask, for men who lead lives devoted to other objects than the pursuit of zoology, to bring out educational works on that branch of science?

Having once determined not to aim at originality, Dr. Nicholson has really performed a service in reproducing so much of Professor Huxley's lectures, both the later ones and those published in the *Medical Times and Gazette* in 1856-7, as he has here, with due acknowledgment, done; for it is not everyone who can now get at those lectures for themselves. Most of the illustrations in this book appear to come from these lectures also, but this is not acknowledged. Other figures of Turbellarians we recognise as copied from an article in the *Popular Science Review*. All figures not original should be acknowledged in a work of this kind, and if it were done in this case we should find that Dr. Nicholson has seldom gone to an original source—but has copied the copies of other people. We may make exception, however, in respect of the figure of *Rhizocrinus* on page 134 and a few others which have not before made their appearance in any handbook or manual of our acquaintance; figs. 47, 67, 68, 73, which we pick out at random, are as old as the hills. It is not only as to figures that we have to regret that the author does not quote at first-hand. On page 4 the student is told that Professor Huxley has applied the name of "protoplasm" to the physical basis of life. No one would resent more than Professor Huxley this statement, seeing that Mohl's term for vegetable "Schleim" was extended to animal "Schleim," and adopted in the broad sense of the protoplasm theory by Max Schultze and Kuhne more than seven years since. Dr. Bastian's name is quoted (p. 154) in connection with the remarkable history of *Ascaris nigrovenosa*, which we really owe to Leukart and Mecznikow. The history of a science is really of sufficient importance to render it desirable to keep to it as truly as possible, and the compiler of such a work as this should not so entirely confine himself to appropriating the gleanings of others, but should shift for himself, and give us the result of inquiries among the original writers.

The account of the Annelida is not very full, nor is it accurate. The leeches are made to form an order of the group, and the common horse leech and medicinal leech are the only members of it mentioned. Oligochæta is given as a synonym for Terricola, and is divided into Lumbricidæ and Naïdidæ. The latter group is said to include *Tubifex*, and then it is said that nonsexual reproduction characterises it. The fact is that Oligochæta includes Terricola = Lumbricidæ and Enchytrœidæ, and Limicola = Sænuridæ and Naïdidæ; *Tubifex* belonging to Sænuridæ and not to Naïdidæ, and exhibiting no reproduction by budding, which is confined to the genera *Nais*, *Chætogaster*, and *Æolosoma*. The fluid of the pseudo-hæmal system in *Aphrodite* and *Polynoë* is stated to be yellow, but Claparède's researches show these worms to be anangian, with the doubtful exception of *Aphrodite aculeata*, so that they have not this fluid at all, either yellow or of any other colour. Whilst no mention is made of Haeckel's proposal to connect sponges with Cœlenterata—perhaps a judicious omission at present—we find them actually classed as Rhizopoda, which is to us a new step in the opposite direction, and not a justifiable extension of Dujardin's class. In defining the Annuloida, Professor Allman's words, relative to the Echinodermata, only are quoted as though applying to both Echinodermata and Scolecida, into which two groups Dr. Nicholson follows Professor Huxley in dividing the sub-kingdom.

The Mollusca are treated by the aid of the late Dr. Woodward's manual, due prominence being given to the homological views of Professors Huxley and Allman. Mr. Hancock is not, however, mentioned, nor are Duthier's views on *Dentalium*, nor again are the exceedingly important facts of the resemblance of development of the nervous system and chorda dorsalis of the Tunicate larvæ and of Vertebrata, established by Kowalewsky and Kupffer, alluded to.

Perhaps a greater omission is that of all reference to the Monera of Haeckel. Whatever he thinks fit to do with them, the genera *Protamœba*, *Protogenes*, *Protomyxa*, *Myxastrum*, *Protomonas*, and *Vampyrella*, deserve recognition on Dr. Nicholson's part; so also do the Labyrinthuleæ of Cienkowski. Another omission is that of the fresh-water forms of Radiolaria, described of late years by Archer, Focke, and Greef; whilst under Myriapoda, we find no mention of Sir John Lubbock's curious aberrant form *Pauropus*; no mention of *Cecidomyia* larvæ under Insects; no mention of *Rhabdopleura* under Polyzoa, though it is alluded to in connection with Graptolites, the solid axis of the latter being supposed to resemble the chitinous rod of Prof. Allman's new order of Polyzoa (*Quarterly Journal of Microscopical Science*, January 1869)—a resemblance, if admissible, not confirmatory of Sertularian affinities, by the way. Interesting transition forms, such as *Echinoderes*, *Rhabdosoma*, *Myzostomum*, are not spoken of. The curious low forms of Arachnida, belonging to the genus *Pentastomum*, are said to occur in *some* vertebrates. It should be stated definitely that a species infests man, and that one body out of every five has been said to contain specimens.

It is not an agreeable task to point out so many deficiencies; at the same time a book destined for educational purposes can least of all be excused in these matters. For all that it contains of reference to recent zoological literature, this manual might be dated ten years back, when the same condensing process applied to the same educational books would have produced much the same result.

There is a glossary to this book which should be useful; we have only looked at its first page, and did not venture further into what promised to be a new series of mistakes. There is no Greek word "aktin," a ray—though Dr. Nicholson says there is.

As a rule, the definitions of both large and small groups are well given by Dr. Nicholson, and the most original part of his manual appears to be in those paragraphs which give the geological range of the various groups; these are well and carefully done, though there are exceptions—the geographical distribution is not given with equal care.

E. R. Lankester

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

The Evolution of Life: Professor Huxley's Address at Liverpool

BELIEVING that readers of NATURE can feel no interest in the extended personalities with which Prof. Huxley almost fills his letter this week, and believing also that such matters are little worthy of occupying your columns, I shall only allude to that part of his letter which contains statements having a scientific bearing.

The distinct issue raised in my experiments was, were *living* things to be found in the fluids of my flasks? If so, such living things must either have braved a higher degree of heat than had been hitherto thought possible, or else they had been evolved *de novo*.

The effect of the very high temperature upon pre-existing living things, which were purposely exposed thereto, was shown by their complete disorganisation in an experiment which is recorded in NATURE, No. 37, p. 219, and to this I would especially direct Prof. Huxley's attention.

Prof. Huxley advances an explanation of the mode of origin of the distinct fungi, bearing masses of fructification (NATURE, No. 36, figs. 12, 14, and 17) and of the inextricably tangled coils of spiral fibres (figs. 13 and 15) found in my flasks after exposure to temperatures at and beyond Pasteur's standard of destructive heat; his theory is entirely novel, apparently extemporised for the occasion, and is very startling. He says, and in justice to Prof. Huxley I quote the passage in full, "Any time these six months Dr. Bastian has known perfectly well that I believe that the organisms which he got out of his tubes are exactly those which he has put into them; that I believe that he has used impure materials, and that what he imagines to have been the gradual development of life and organisation in his solutions is *the very simple result of the settling together of the solid impurities, which he was not sufficiently careful to see when in their scattered condition when the solutions were made.*"

Now, although it was quite true that minute portions of *Sphagnum* leaf were found in two unpublished experiments, it seems very marvellous that on this slender foundation Prof. Huxley should hazard such a purely imaginative and unprecedented hypothesis as to the mode of production of fungi.

I have, moreover, not been able to see why the occurrence of the incident to which he refers should make him repudiate a number of experiments in which *unmistakeably living things* were found in fluids from hermetically sealed flasks after these and their contents had been exposed to temperatures higher than those which living things are known to be capable of resisting.

Following a precept more honoured in dialectics than in science, Prof. Huxley has attacked his opponent rather than the arguments which he affects to destroy. He objects to only one passage in my "Reply," and this he thinks was not worthy of the special type in which it was printed; and yet, notwithstanding its special type, I can only conclude from his reply that Prof. Huxley has failed to appreciate its meaning. My words were: "Living things may and do arise as minutest visible specks, in solutions in which, but a few hours before, no *such* specks were to be seen." The word which now alone stands in italics was ignored by Prof. Huxley. I had no wish to tell him that certain refractive particles, or foreign bodies, might not be visible in the thin film of fluid to which I referred. I alluded to the gradual and equable development of living specks throughout a fluid containing no apparent germs. His retort that some unobserved visible germs might have become centres of development is a *contre-sens*. It does not apply to the gradual appearance of myriads of *equally diffused* motionless particles in a motionless film of fluid.

The very authoritative tone which Prof. Huxley has lately assumed in his remarks concerning Brownian movements and those of living organisms, fails to impress me very much. His knowledge about these movements, as I have good reason to know, is of quite recent growth. Movements which, in the month of March of the present year, Prof. Huxley did not regard as Brownian, he now does believe to have been of this nature. If he is now right, what value is to be set upon his knowledge of Brownian movements six months ago; and what guarantee have we that in another six months Prof. Huxley may not again take a different view?

Let me assure Prof. Huxley, however, that the duty which he is "credibly informed" he owes to the public remains still undischarged. I protested against his "Address" on scientific grounds which are fully stated, and those who have read my protest will see that Prof. Huxley cannot dispose of the question really at issue by recounting any mistakes of mine, whether real or imaginary. If, as I believe, he has failed to give any worthy or serious view of the question, this could have been in no way necessitated by a disbelief, however strong, in my experiments. The labours of Profs. Wyman, Mantegazza, and Cantoni had already taken the question into regions never attained by M. Pasteur, and therefore they demanded a fair consideration. Is Prof. Huxley, in his capacity of President of the British Association, warranted in ignoring their labours, and therefore in misrepresenting the present state of science on the subject, because, owing to two errors among my many experiments, he declares himself to have altogether lost faith in my skill or capacity as an investigator? The answer cannot be doubtful. Is it, again, consistent with his high responsibilities that he should pervert the real issues, and should do a grave injustice to others, in order that he might preserve a "silence" which should be his "best kindness" to me? Let me tell Prof. Huxley that I repudiate such "kindness," as any honest man would who is simply seeking after truth, and relegate it to the same regions as I would that indescribable air of restrained omniscience whereby he endeavours to crush arguments and facts, to which he altogether fails to reply.

H. CHARLTON BASTIAN

University College, Oct. 17

Aurora Borealis

A BRILLIANT display of the Aurora Borealis was visible here on Sept. 24th. I submit the following statement of my observations, which probably may be acceptable to your readers.

About 8.30 P.M. a broad white streak of light was seen due north, extending from the horizon towards the north star. This streak was soon accompanied by several others, rising and streaming upwards from the horizon between the north-west and north-east points, and converging towards the zenith: at the same time all the northern portion of the sky became illuminated.

At 9 P.M. the coruscations of the Aurora became more brilliant and active, streaming with great rapidity towards the zenith, though none could be seen to reach that point, assuming very beautiful colours, which were generally of light pink and reddish hues.

About 10 P.M. the colouring and brilliancy of the Aurora attained its fullest effect, the coruscations varying with yellow, pink, and almost crimson hues, the intermediate spaces of the sky in the background appearing to be light green. The brightest streamers were confined to the north and north-westerly directions. The coruscations continued in rapid action with surprising grandeur up to 10.30 P.M., when a somewhat indistinct purple arch was visible, with its culminating point north and about thirty-five degrees above the horizon. Shortly after this exhibition, the display of coruscations and luminous streamers gradually ceased action, but the northern portion of the sky remained illuminated, resembling twilight after sunset.

The sky was quite clear at the commencement of the Aurora; it became partially obscure about 10 P.M.; the clouds then, especially those in the north-east, reflected very beautiful roseate tints from the Aurora, which, in combination with the varying colours of the coruscations, produced a most striking and grand spectacle.

Three shooting-stars were observed between 9 and 10 P.M., and several were seen on the previous night.

The barometer was at 30·4, and has not read below 30·3 during the past week. The temperature has been very regular for the same time; the maximum by day was 64°, and the minimum at night 51°. Winds have been constant from the east, and the sky free from cloud.

The northern region of the sky remained illuminated throughout the night, producing a strong reflection on the sea, and rendering the rocks and vegetation around me quite perceptible. Even at 3.30 A.M. the light from the northward produced all the effect of early dawn.

I must add, that during all my Arctic voyaging I never witnessed in any Aurora the same conditions of varied colouring as were displayed on this occasion.

It may also be of interest to state that on the 21st inst. I observed a bright meteor to shoot in a path from near the Pole Star to Capella, vanishing near the latter after discharging a brilliant light-green flash.

From Ilfracombe the view to the north commands an extensive range of the sea horizon.

Ilfracombe, Devon

Natural History Museums

WHILE admiring and agreeing with the main features of Dr. P. L. Sclater's plan for the exhibition of the National Natural History collections in the new Museum at Kensington, I must beg to be allowed to enter a protest with regard to the geological portion of the scheme, which was all but completely overlooked by those who took part in the discussion of his suggestions and by Dr. Sclater himself.

The only words which Dr. Sclater devoted to the subject were to the effect that the palæontological collections should be merged into the general zoological and botanical ones. This arrangement is, however, one which will not serve the purpose of the geologist. We can fancy the utter misery of the man who wishes to study the fossils of some special formation, when he finds that to do so he will have to rush from case to case, amid stuffed and spirit specimens of all kinds, all over the place. The naturalists who deplore the loss of time incurred by them under the present order of things at the British Museum, have no thought for the geologist whom their proposed arrangement would condemn to far worse wandering in the new building. But in this particular I, as a geologist, sincerely trust that the project will not be carried out without some revision, and that a palæontological collection, quite independent of any other, and arranged *stratigraphically*, will form a by no means inconspicuous part of the Museum. The advantages of this system may be seen at a glance in Jermyn Street, where the British fossils are thus arranged.

In a collection as large as that of the National Museum must be, it may very likely be found impossible to exhibit specimens of every species in the show cases, and indeed it is by no means desirable that this should be done. It would be quite sufficient, and as far as the general public is concerned infinitely better, to limit the *exhibited* specimens to those belonging to species characteristic of each formation, and to keep all others, which would interest students only, in a cabinet drawer, where they would be at once handy to the specialist and not wearying to the sight-seer. Duplicates enough could doubtless be spared to complete the zoological and botanical series in the lower galleries, but unique and rare specimens should, to my mind, most decidedly be kept for the geological series. In conjunction with the latter, it would be highly desirable to establish a lithological collection, the absence of which, with the solitary exception of the small one in the Geological Museum, is every day more and more to be wondered at in such a country as ours.

Not only should appropriate rock-specimens accompany the fossils of each fossiliferous bed, but they should be so arranged that the organisms and the matrix in which they are found embedded, could be examined side by side. Typical examples of unfossiliferous strata should be placed in their regular order of succession, including specimens of contemporaneous rocks from other parts of the world. Clear geological sketch-maps, boldly coloured and not over-burdened with names, showing the distribution (so far as it is known) of the various equivalent groups of beds, should be placed in conspicuous places at intervals in the room or gallery, and thus, or in some closely-resembling manner, could a homogeneous whole be arrived at, combining the greatest amount of instruction to the public and the greatest convenience to the student.

Of course the geological collection shadowed forth above would by no means take the place of another more detailed lithological collection, which should, if possible, be added to the mineralogical one, containing all the igneous rocks, &c., and, like the minerals, arranged *chemically*.

G. A. LEBOUR, F.G.S. &c.,
of the Geological Survey of England.

Changes of Level at Pozzuoli, referred to in the "Apocryphal Acts of Peter and Paul"

IN the well-known description which Sir Charles Lyell gives of the changes of level of the shores of the Bay of Baiæ in the 30th chapter of his "Principles of Geology," there occur at pages 172-174 (vol ii. 10th edition) the following statements.

Speaking of the so-called "Temple of Serapis," and its adornment by the Emperor Alexander Severus between A.D. 222 and 235, he says: "From that era *there is an entire dearth of historical information for a period of* 12 *centuries*, except the significant fact that Alaric and his Goths sacked Pozzuoli in 410, and that Genseric did the like in 440 A.D." Again: "The period of deep submergence was certainly antecedent to the close of the 15th century"—a statement which he goes on to prove by a quotation from Loffredo referring to the year 1530, and a reference to documents cited by A. di Joris, one of which, dated 1503, speaks of land "where the sea is drying up."

Still more recently Professor Phillips, in his interesting volume on Vesuvius, speaking (p. 244) of the "Temple of Serapis," observes that, at the time of its adornment by the Emperor, "early in the 3rd century, it must have been in its original, or else in its second stage—perhaps we may adopt the latter view—there may have been a depression of 5ft., a new floor, restoration, and adornment. Nothing is absolutely known of any further change of level till the early part of the 16th century."

Thus both the authorities cited appear to agree that from the middle of the 3rd to the end of the 15th century there is a *total* absence of information. You may therefore possibly think that the following extract from the "Apocryphal Acts of Peter and Paul" possesses some interest, even though it may be difficult to agree on the approximate date of the writer. Your columns would scarcely be the place, nor am I competent, to discuss this last point, but as one of the MSS. collected by Professor Tischendorf for his edition of the Greek original is said to be of the end of the 9th century, it appears to me that we have here not only a rather quaint explanation of the immediate cause of the changes of level of the land at Pozzuoli and in its neighbourhood, but a distinct reference *at least* to six centuries before the Italian writers already quoted, not merely to the fact, but also to the extent, of the movement in question. Notwithstanding its suspicious legendary framework, the statement that "Pontiole sunk into the sea-shore about one fathom; and *there it is until this day*, for a remembrance, under the sea," has an air of *vraisemblance*, a ring of truthfulness, about it which I hope will justify my bringing the matter under the notice of those so much more competent than I am to assign to it its true value, and to whom it may possibly be new.

I quote from the translation by Mr. A. Walker, forming a portion of Vol. xvi. of the "Ante-Nicene Library," published by Messrs. Clark of Edinburgh, pp. 257–8.

F. FOX TUCKETT

Frenchay, near Bristol, Oct. 3

"And when Paul came out of Mesina he sailed to Didymus, and remained there one night, and having sailed thence, he came to Pontiole (Puteoli) on the second day. And Dioscorus the shipmaster, who brought him to Syracuse, sympathising with Paul because he had delivered his son from death, having left his own ship in Syracuse, accompanied him to Pontiole. And some of Peter's disciples having been found there, and having received Paul, exhorted him to stay with them. And he stayed a week in hiding, because of the command of Cæsar (that he should be put to death). And all the toparchs were watching to seize and kill him. But Dioscorus the shipmaster, being himself bald, wearing his shipmaster's dress, and speaking boldly, on the first day went into the city of Pontiole. Thinking, therefore, that he was Paul, they seized him and beheaded him, and sent his head to Cæsar. . . . .

"And Paul, being in Pontiole, and having heard that Dioscorus had been beheaded, being grieved with great grief, gazing into the height of the heaven, said: 'O Lord Almighty in Heaven, who has appeared to me in every place whither I have gone on account of Thine only begotten Word, our Lord Jesus Christ, punish this city, and bring out all who have believed in God and followed His Word.' He said to them, therefore, 'Follow me.' And going forth from Pontiole with those who had believed in the Word of God, they came to a place called Baias (Baiæ), and looking up with their eyes, they all see that city called Pontiole sink into the sea-shore about one fathom, *and there it is until this day, for a remembrance, under the sea.*

"And those who had been saved out of the city of Pontiole, that had been swallowed up, reported to Cæsar in Rome that Pontiole had been swallowed up with all its multitude."

Hereditary Deformities

IN the number of NATURE for Sept. 3, a letter from Mr. William Field appears with the title "Hereditary Deformities,' commenting on certain alleged facts quoted in an ethnological article in *Cassell's Popular Educator*, from Dr. Theodor Waitz's "Introduction to Anthropology," translated by Mr. Collingwood. Mr. Field justly remarks that facts of such a character, "if substantiated, would introduce *Accidental Distortion* as a co-worker with Natural Selection in the modification of species." But he puts the question—"Do these stories rest on a good foundation?" Personally, I do not know. All I can say is, that Dr. Waitz, whose scientific authority is unimpeachable, published them without expressing any doubts of their accuracy. They may be found with some alleged facts of analogous character, at pp. 83 to 85 of his first volume, as translated by Mr. Collingwood. Speaking of animals, he says:—

"Mutilations also are sometimes transmitted. Williamson* saw in Carolina dogs which have been deficient in tails for three or four generations, in consequence of one of their ancestors having accidentally lost it. A cow, three years old, which had lost by suppuration her left horn, produced three calves, which, instead of the left horn, presented only a small protuberance on the skin. Dogs and horses whose tails or ears are clipped, as the draught dogs in Kamtschatka, often transmit these deficiencies to their offspring." (p. 83.)

Referring next to man, he considers that there are "cases in which deformities have shown themselves hereditary" (p. 84.) He says:—

"Instances of hereditary blindness and deafness, and of alternating dumbness, so that every second or third child was deaf, are given by Lucas. Harris communicates a case of hereditary blindness in one eye, and of a double thumb on the right hand."

I omit other instances. He continues again:—

"Instances are not wanting of mutilations that have been transmitted from parents to children; such, however, occur less frequently. According to Blumenbach, the children of an officer, whose little finger had been cut across and become crooked, possessed an analogous defect. Gosse cites the case of an officer wounded in the battle of Eylau, who transmitted to his offspring a scar on the forehead. Other instances of hereditary deformities are found in Wagner" (p. 85).

As Waitz, it will be perceived, quotes Blumenbach, it may be mentioned that the last-named author has a paragraph headed, "Problem proposed. Can mutilations and other artifices give commencement of native varieties of animals?" After showing that some have answered the question in the affirmative and others in the negative, he adds, "I have not at present adopted as my own either the affirmative or negative of these opinions." See p. 203 of his Anthropological Treatises, translated by Mr. Bendyside.

New facts, capable of being severely tested, would be of great value.

THE WRITER OF THE ETHNOLOGICAL PAPERS IN "CASSELL'S POPULAR EDUCATOR"

* More specific reference to the authorities on which Waitz rested may be found in the foot-notes to his work. Some of the volumes he quotes are foreign, and not to be found in the British Museum Library.

The Stability of Turret Ships

SINCE the loss of the *Captain* an opinion has rapidly gained ground, not only amongst unscientific men, but even amongst those who from their education should have acquired some of the most simple laws of statics, that that noble ship toppled over on account of her being "top-heavy"—that the *Captain*, an armour-plated ship with a low freeboard, was more "top-heavy" than a broadside ship, with more than twice as much out of water! The fact is, that her weights were lower and not higher than those of other vessels, and therefore that her fault was not "top-heaviness."

In looking at the stability of a vessel we take two points—the "centre of gravity" and the "centre of buoyancy;" the former being a certain point at which, if the attraction of gravity impressed a single force equal in intensity to the sum of all its separate actions on the component parts of the body, the ultimate effect would be the same as it is under the system of separate actions which really exists. The latter is the centre of gravity of the volume of water displaced by the ship, and may be regarded as the pivot on which she would turn on heeling over. The vessel being in a vertical position, the centre of gravity is immediately over the centre of buoyancy, and she is in a state of unstable equilibrium, *i.e.* she is in the same fix as a walking-stick standing on end. So far in favour of "top-heaviness."

Suppose now that she heels over to one side, what will the effect on our centres be? Immediately she begins to heel over the centre of buoyancy travels outwards to the side towards which she heels, and the centre of gravity being fixed, there will come a point when it will exert a force to overcome the heeling over pressure. This travelling outwards of the centre of buoyancy depends wholly on the shape of the vessel, and will appear perfectly plain by drawing sketches of a ship lying at different angles. The more a vessel heels over, the further outwards does the centre of buoyancy travel, and the greater is the resistance offered to the heeling over pressure until she approaches a certain point, then the centre of buoyancy moves out at an increasingly slower rate, and finally reaches the position corresponding to that of her maximum statical stability.

Before this, if by any disturbing cause, such as the alteration of the wave slope, the ship were inclined beyond her position of maximum stability, the resistance to heeling would become less the farther she went, until she reached a position at which her moment of stability would be the same as before the disturbing force began to act. And in this position she would remain in unstable equilibrium if the disturbing forces were removed. But if she should pass this position before the disturbing forces, and the angular velocity caused by them, cease, the ordinary movement of the heeling over force would then be greater than the resistance offered by the stability, in any position through which she would pass, and she would be turned over.

Now the difference between a high and a low freeboard ship as regards stability under sail is this:—The position of maximum stability is reached soon after the immersion of the edge of the deck; and as a high freeboard ship does not immerse her deck until she has attained a large inclination, while a ship of low freeboard will immerse hers at a very much less angle, it follows that, in the latter case, the position of maximum stability and then of unstable equilibrium is reached at a comparatively small angle of heel, and a ship of this construction is much more likely to be capsized than one with a high freeboard. Of course, in a low-sided ship, the centre of gravity may be brought so low as always to be on the right side of the centre of buoyancy, but this is not practicable in an armour-plated turret ship.

From what we have here stated it will be seen that the error in design that made the *Captain* so much heavier than was expected, and draw six feet instead of eight, was not adding so much to her stability but was in reality lessening it, and, perhaps, was the cause of her loss; and that if we are to have armour-plated turret ships, they must either be built of low freeboard, to be propelled by steam alone, or of high freeboard sufficient to give stability for sails.

The feud between naval architects and the advocates of the turret system has been going on for ten years back—the former contending that a high side was necessary in a rigged sailing ship, and the latter, that if they put their guns in turrets, they could have low-sided ships, or, in fact, ships with no sides at all, after a certain amount of inclination.

That the loss of the *Captain* has resulted from a preventible cause is quite evident, and we have shown what that cause is; it, therefore, only remains that if we are to have sailing turret ships, we must have high freeboard for the sake of stability.

T. BELL LIGHTFOOT

Newcastle-upon-Tyne

The New Postal Act

AT page 474 Mr. Reeks complains as to the working of the new Postal Act. It seems intended to obliterate the old parcel post. He says, "Herbarium specimens are not excluded." Perhaps so; but they are not included. The provisions of the new Act are limited to books, written and printed matter, genuine trade samples and patterns, so far as regards the two ounces for a halfpenny. All parcels other than books, &c., as described above, go at the letter rate of one penny for each half-ounce.

The postal card is the thin end of the wedge that will hereafter open to us a regular letter rate of a quarter of an ounce for a halfpenny. For instance: we may now send ordinary business communications up to two ounces, thus embodying the matter of twenty postal cards, for the halfpenny, if folded in a paper wrapper. An ordinary business communication of half-ounce weight goes for the halfpenny, if folded as a letter but left unsealed.

I ask, If Government will now take an open letter for a halfpenny, why not take it closed at the same rate? Common sense will hereafter equalise this disparity. The parcel post, however, is at present discontinued. P. N. Row

October 14

Science and the Government

THE reason that the Government has refused to aid "the expedition to observe the approaching eclipse" is, that it is perfectly assured that "men of science and culture" are nothing but a set of lying impostors, and would swindle the public out of thousands of pounds to take an observation which might be done for 10*l.* and much less. The nation is fast beginning to perceive that astronomy is a monstrous cheat—and the Transit of Venus has no more to do with the distance of the sun than it has with the number of fingers on my hand.

JOHN HAMPDEN

[We congratulate Mr. Lowe on his ally, merely remarking that the same Government which has refused the Eclipse Expedition has granted 20,000*l.* for observations of the Transit of Venus. Perhaps Mr. Hampden can explain the cause of this inconsistency on the part of the Government.—ED.]

Insects upon a Swallow

G. H. H. mentions in NATURE of Sept. 22 his having found on a swallow in the month of August two slate-coloured insects. On the 15th of July last, when hauling a seine net in Studland Bay, near Poole, with some fellow members of the Linnean Society Club, I picked up at the foot of the low cliff a young sand-martin, which had seven of these parasites (*Ixodes plumbea*) affixed to the skin of the head, giving it the appearance of having a slate-coloured fleshy crest. The poor little bird exhibited the symptoms described by your correspondent. I found it panting and apparently exhausted on the ground, and it remained stationary without making any effort to escape. The fishermen of our crew informed me that they often pick up martins with these ticks adhering to them.

The Waldrons, Croydon, Sept. 26 HENRY LEE

Aurora Borealis

A FINE aurora was observed here on the evening of the 14th inst., between $8^h 30^m$ and $9^h 40^m$, which, in spite of bright moonlight, nearly equalled the splendour the display of September the 24th. During the early part of the evening the eastern quarter of the sky was covered with bands of light *cirri*, which had a general direction of E.N.E. to W.S.W., or nearly at right-angles to the magnetic meridian; it was among these clouds and in the N.E. that the beams of the aurora were first seen. At $9^h 0^m$ a magnificent rose-coloured ray was noticed in the N.N.W., extending from the horizon through *Vega* towards the zenith. The three stars, ζ, ϵ, and δ, of Ursa Major were for more than ten minutes enveloped in the crimson glow of the aurora.

Bedford, Oct. 18 THOS. G. ELGER

NOTES

WE are glad to be able to state that Dr. Wyville Thomson has entirely recovered from the attack of gastric fever which prevented his taking part in the *Porcupine* expedition this summer. He is at present going over the zoological collection brought home in that vessel, at the University of London, with Dr. Carpenter, and he reports some very remarkable additions to his new group of vitreous sponges, mainly from the coast of Spain and Portugal. These, with some others procured by Mr. Saville Kent, in Dr. Marshall Hall's yacht, will nearly double the number of known forms referred to the order. They are no pigmies. One of them forms a lovely lace-like vase upwards of three feet in diameter at the lip!

WE have to add to the list of candidates for the Regius Professorship of Natural History in Edinburgh the name of John Anderson, M.D. Edin., F.L.S., director of the Imperial Museum of Natural History, Calcutta. Dr. Anderson was attached as Naturalist to a recent expedition through the north of Burmah, and he is, we understand, now on his way home, bringing with him detailed accounts of the important additions which he is known to have made to science in that expedition.

MEMBERS of the University of Cambridge, and all who are interested in the study of physical science, will hear with pleasure of the munificent offer made to the University by its Chancellor, the Duke of Devonshire, contained in the following extract of a letter to the Vice-Chancellor:—"I find in the report, dated Feb. 29, 1869, (*sic*) of the Physical Science Syndicate, recommending the establishment of a Professor and Demonstrator of Experimental Physics, that the buildings and apparatus required for this department of science are estimated to cost 6,300*l.* I am desirous to assist the University in carrying this recommendation into effect, and shall accordingly be prepared to provide the funds required for the building and apparatus, so soon as the University shall have in other respects completed its arrangements for teaching experimental physics, and shall have approved the plan of the building."

AT the Commencement held on the 12th inst. of the Queen's University in Ireland, the Most Honourable the Marquis of Kildare, the newly-appointed Chancellor of the University, presided. After expressing the deep regret of the University at the death of their first Chancellor, the Earl of Clarendon, to whom the University and Colleges were indebted for much of their prosperity, the Chancellor mentioned that the Senate had decided to establish a special curriculum, in which science should have the predominance, and that the degrees of Bachelor and Doctor in Science would be given to those who passed the examinations in the subjects to be hereafter enumerated. He also referred to the examinations for women carried on by the University—the first of these was held in June last in Belfast and Galway—and mentioned that of thirty-three candidates who presented themselves, twenty-one acquitted themselves to the satisfaction of the examiners.

MR. M. R. PRYOR has been elected to a Fellowship of Natural Science in Trinity College, Cambridge. The examination was conducted by Prof. Liveing, Prof. Michael Foster (the new Prælector of the College), Mr. Trotter, and Mr. Hort, Fellows of the College, was open to all the University, and was on a par with the examinations in classics and mathematics, held at the same time for Fellowships. It is the first occasion that this has been done, and the first time that a Fellowship has been offered in Cambridge for competition in Natural Science. We sincerely trust the plan will be continued in Trinity, and that the example will be followed in other Colleges. It would probably contribute more than any other single thing to promote the study of Natural Science in the University, and give an impetus to it in the various schools throughout the kingdom. We sometimes think the Colleges are scarcely conscious of the power they are capable of exercising in this way, and of the responsibility which necessarily attaches to such power. The questions were of a very high order, and we understand the answers evinced so much power as well as knowledge, that the examiners would gladly have elected more than one candidate. We sincerely congratulate Mr. Pryor on having thus worthily won the highest competitive reward for Natural Science hitherto given in this country.

THE Senate of the Queen's University in Ireland has conferred on William King, M.D., Professor of Geology and Mineralogy in Queen's College, Galway, the honorary degree of Doctor of Science, in consideration of his eminence as a geologist.

THE following lectures in Natural Sciences will be delivered in Trinity and St. John's Colleges, Cambridge, during the Michaelmas term, 1870. On Electricity: Mr. Trotter, Trinity. On Chemistry: Mr. Main, St. John's. Instruction in Practical Chemistry will also be given. On Geology—(1) Palæontology; (2) Lyell's Principles of Geology; (3) Elementary Lectures: Mr. Bonney, St. John's. (Students of other Colleges can be admitted to these Lectures by arrangement with their college tutor.) On Elementary Botany: Mr. Trotter, Trinity. On Physiology: The Trinity Prælector of Physiology (Dr. M. Foster) at the New Museums.

MERTON COLLEGE, Oxford, announces an open Natural Science scholarship of the value of 80*l.* for five years, and one or more exhibitions of the value of 25*l.* for three years, to be awarded in December next. The examination will be in chemistry, physics, and physiology, and an opportunity will be given for showing a knowledge of practical work in chemistry and physiology. They will be awarded either for special excellence in one subject or for excellence in two out of three subjects, but no candidate will be examined in more than two subjects. There is no limit to age, but members of the University must not be over six terms standing.

THE Natural Science Scholarship at Lincoln College, Oxford, has been awarded to Mr. Schofield, of Owens College, Manchester. The National Science Demyship of 80*l.* a year at Magdalen College, Oxford, has not been filled up, there being no candidate up to the required standard.

THE Dublin University have just published the regulations for the examinations for women for 1871. They will be held in Dublin in March 1871, one for senior and one for junior candidates. The latter must not be above eighteen years of age. Examinations will also be held at any place where a ladies' superintending committee shall be constituted, and at least twenty candidates guaranteed to present themselves.

WE understand that Dr. Schimper, the palæontologist, escaped from Strasburg the day before the final closing of the gates at the commencement of the siege. Fears are entertained as to the safety of his fine collection.

IN addition to the literary prospects of the approaching season already announced, Mr. Murray's list of forthcoming books includes the following:—"On the Descent of Man, and on Selection in Relation to Sex," by Charles Darwin; with illustrations, 2 vols. crown 8vo. "The Student's Elements of Geology," by Sir Charles Lyell; with numerous woodcuts, post 8vo. "Scrambles among the Alps, 1860–69," by Edward Whymper, including the First Ascent of the Matterhorn, with Observations on Glacier Phenomena in the Alps and in Greenland; with 100 maps and illustrations, medium 8vo. "A Visit to High Tartary, Yarkand, and Kashgar (formerly Chinese Tartary), and Return Journey over the Karakorum Pass," by Robert Shaw; with map and illustrations, 8vo. Second and cheaper edition of "The Music of the Most Ancient Nations," by Carl Engel; with 100 illustrations, 8vo. A third edition of Kerr's "The Gentleman's House; or, How to Plan English Residences, from the Parsonage to the Palace;" with illustrations, 8vo. Among Mr. Bentley's announcements are—"Travels in the Air; a Popular Account of Balloon Voyages and Ventures, with recent attempts to accomplish the navigation of the air," by J. Glaisher, of the Royal Observatory, Greenwich; royal 8vo., with 133 illustrations. "The Marvels of the Heavens," from the French of Flammarion, translated by Mrs. Lockyer; crown 8vo., with numerous illustrations. A new and cheaper edition of "The Heavens," an illustrated handbook of Popular Astronomy, by Amédée Guillemin, edited by J. N. Lockyer, F.R.S.; demy 8vo., with 200 illustrations.

MR. M. C. COOKE'S Hand-book of British Fungi will be published in the course of the ensuing season by Messrs. Macmillan and Co. Although the first volume is already printed, its issue will be delayed until the whole work is ready. It will be a complete *vade mecum* for the British Fungologist, and will contain descriptions of all the species, and illustrations of all the genera. We are glad to see that the University of St. Lawrence has recognised Mr. Cooke's services to botanical science by conferring on him the honorary degree of M.A.

MR. VAN VOORST has in preparation "The Mollusca of the European seas," by Mr. Gwyn Jeffreys, F.R.S., in continuation of his work on "British Conchology."

AN English edition of M. Taine's "De l'Intelligence," revised with additions by the author, is in preparation, and will shortly be published by L. Reeve and Co.

WE have received a prospectus of a very energetic society located in the north of London, called the Hackney Scientific Association, which is now commencing its fourth session. It numbers among its officers many men of high scientific standing, and the following is its programme of papers for the season:—Recent Progress in Astronomy—W. T. Lynn; Comets—Henry T. Vivian; Observations on Solar Eclipses—William J. Dyer; Water—C. W. Stidstone; The Predicted and Observed Meteorology of 1870, and the Probable Weather for 1871—Frederic Pratt; A Catalogue of variable Stars, with Remarks upon their Physical Constitution—Albert P. Holden; The Calendar—Henry T. Vivian; The Methods used in endeavouring to determine Man's Antiquity—William H. Davis; Infusoria—William West; The Diseases prevalent in certain Geological Formations—H. W. Emons; Micro-Photography—C. W. Stidstone; The Habitable Condition of other Worlds, as affected by Temperature—Frederic Pratt; The Origin and Constitution of the Minor Planets, called Asteroids—Albert P. Holden; Inorganic Chemistry—George C. Fearn.

WE are glad to find in the number of our able contemporary, the *Academy*, for October, an extension of the scientific department. The paper will be published in future regularly on the 15th, instead of the second Saturday in each month.

WE learn from the *American Entomologist and Botanist* that the botanists of New York have formed themselves into a club, named, after one of the most distinguished botanists of America, the Torrey Club. The club publishes a monthly *Bulletin*, the object of which is "to form a medium of communication for all those interested in the flora of this vicinity, and thus to bring together and fan into a flame the sparks of botanical enthusiasm at present too much isolated." It is many years since a similar botanical club or society has existed in London.

MR. G. P. BIDDER has written to the *Times* describing a remarkable example of parhelia or mock suns observed by him on the 7th inst. at Canterbury:—"A portion of a circular arc was seen considerably above the halo and convex to it and the sun. The centre of the circle of which it formed part was, as nearly as I could estimate, close to the zenith. This arc had all the prismatic colours pure and distinct, and about 80° or 90° of it were visible. The following rough approximation represents the general arrangement of the whole: Altitude of the sun, about 12°; radius of the halo, about 25°; interval between the nearest points of halo and rainbow arc, about 25°; radius of rainbow arc, about 25°."

THE new buildings of the Taunton College School were formally opened during the past week. After a sermon from the bishop of the diocese and the inevitable luncheon, some very good speeches were made, among which we may especially mention those of the head-master, Rev. W. Tuckwell, Mr. J. G. Fitch, and Mr. E. B. Tylor. Mr. Tuckwell thus announced the programme of the system of instruction given at the school: "I may be allowed to say one word upon the nature of the education which we are striving to carry out, because to this is chiefly due the impulse in our favour which has so greatly altered our position. All who have been concerned with us are aware that in our curriculum we have departed widely from the ancient systems. We refuse to restrict our boys, as my own contemporaries were restricted, to the exclusive study of Greek and Latin; but while we give to these only a portion of our time, and find room for the higher mathematics, for physical science, for geography and history, for French and German, and for a careful study of English literature and language, we assert that by improved methods, by dexterous timing, and by greatly increased personal labour, we teach these new subjects thoroughly, and by no means neglect the old ones."

Engineering records the death, on the 16th inst., at New York, of Mr. Thomas Ewbank, the well-known writer on hydraulics. He was born at Barnard Castle, England, in 1792, and, after being apprenticed to a tin and coppersmith, came to London, where he spent all his spare time in scientific study. In 1819, being then a member of several learned societies, he emigrated to New York, where he was engaged for seventeen years in business as a manufacturer of lead, tin, and copper tubing, which occupation he relinquished in 1836 for purely scientific work. Besides contributions to scientific journals, and labours on various Government scientific committees, Mr. Ewbank was the author of "A Descriptive and Historical Account of Hydraulic and other Machines for Raising Water, both Ancient and Modern;" "The World a Workshop, or the Physical Relation of Man to the Earth;" "Life in Brazil, or the Land of the Cocoa and the Palm;" and numerous smaller publications.

THE United States steamer *Kansas*, now fitting out at the Washington Navy Yard for duty on the Tehuantepec and Nicaragua Expedition, was, according to *Engineering*, put in commission about a fortnight ago. The *Kansas* will be the principal vessel of the expedition. The survey in Nicaragua will embrace the route for a canal advocated thirty years ago by the Emperor Napoleon. That in Mexico by the Tehuantepec river possesses less interest, owing to the length and difficulties of the route.

THE first quarterly number of the *Journal of the Iron and Steel Institute* is announced to appear with the new year.

MR. ADOLPH HUBNER read an interesting and valuable paper on scientific observation in the interior of Port Natal, at a meeting of the Natural History Association of that colony on the 20th of August.

ON the 8th August Mr. S. Vincent Erskine read a paper before the Natal Natural History Society—Mr. John Robinson in the chair—on the Tsetse Fly. Mr. Erskine severely criticised Dr. Livingstone's statements, and denied that the fly was destructive to the life of the ox, horse, or dog. He affirmed that death was to be attributed more to change of grass or climate. The same evening Mr. Morant read a paper on the Entomology of the Free State and the Trans Vaal, particularly with regard to the butterflies.

THE expedition of Yale College students, under the leadership of Prof. O. E. Marsh, to which we referred last week, spent several months in the Rocky Mountain regions, investigating its flora and fauna, and collecting for the Yale Museum as fine collections as possible of the extinct animal remains found in such abundance in the tertiaries and cretaceous deposits of Nebraska, Dakota, and Wyoming. Leaving this region they will visit California, and after investigating the geology of the Pacific coast, will return through Colorado and Kansas, reaching New Haven, if possible, in November.

COCOA

COCOA is a valuable article of food that is becoming more and more in use in this country, and judging from the increased importations during the past three or four years, and the constant average of the coffee imports during the same period, it seems that cocoa is, in a measure, displacing coffee as a popular beverage.

The plant producing the cocoa of commerce is a tree seldom growing to a greater height than 17 or 18 feet. It is known to botanists as *Theobroma Cacao*. It bears an oblong fruit, ribbed longitudinally, measuring from six to ten inches in length and four to five inches across, and, when ripe, is of a yellow colour, changing to brown in drying.

It contains from fifty to one hundred seeds, and these seeds, after being washed, thoroughly dried in the sun, and roasted, form the cocoa-nibs of commerce.

Linnæus must have had a high appreciation of cocoa when he gave to the genus the name Theobroma, which is derived from *theos*, god, and *broma*, food, signifying it as food fit for a god. Cocoa contains a large amount of nutritive matter. In this respect it differs in a marked degree from tea and coffee; for while they are taken only in infusion and are used as refreshing beverages, cocoa is usually taken more in substance, and, as such, may be considered both as food and drink.

It was used in very early times in Mexico, whence it was introduced by the Spaniards into Europe about 1520. Humboldt tells us that it was extensively cultivated in the time of Montezuma, and the seeds were commonly used as money by the Aztecs. At the present time the cocoa-tree is largely grown in the West Indies, more especially in Trinidad, and over a great part of tropical America. Numerous varieties of the cocoa tree exist, some producing longer, or broader and some thinner or thicker skinned fruits, others producing larger, longer, or broader seeds, as the case may be. The seeds also vary in quality, according to the variety producing them or the place of their growth: thus Caraccas and Trinidad seeds are considered the finest, and some manufacturers use the names of the best districts as a recommendation to their wares.

The seeds are brought into this country in a dried state, and are roasted in revolving metal cylinders, the heat causes them to shrivel slightly so that the husks or skins are left loose and are removed by fanning. It is said that large quantities of these husks are imported from Italy under the name of "Miserable," and are used in Ireland by the poorer classes. The roasted seeds, after the husks are removed, are known as cocoa-nibs, but they are never seen in commerce in their whole form. The seed naturally divides by its two cotyledons, and in the process of winnowing each cotyledon gets broken into two or more pieces. To obtain the nibs and boil them in the old-fashioned way is certainly the surest way of getting genuine cocoa.

Some trouble, however, attends the preparation of the beverage in this form, the nibs requiring to be boiled an hour or two to extract their valuable properties. To obviate this, and to supply the public with a more convenient article, powdered cocoas, which require simply mixing with cold milk, boiling water being afterwards added, were introduced. These prepared cocoas opened a wide field for wholesale adulteration, the public, by using them, sacrificing purity for convenience in the preparation for the table.

These powdered cocoas are "prepared" by reducing the seeds to a fine paste by grinding them under heavy heated rollers—starch, flour, sugar, molasses, and, in the cheaper kinds, other ingredients less wholesome being added; after which, the whole mass is reduced to powder, packed in different forms, and sold under various trade terms, such as "Homœopathic Cocoa," "Soluble Cocoa," &c. Each manufacturer's individual preparation varies perhaps in flavour, according to the proportion or character of the ingredients added. The numerous forms of cake chocolate are prepared in the same way, vanilla being largely used in the flavouring, and the pasty mass being pressed into moulds instead of being reduced to powder. Rock cocoa and Flake cocoa are likewise prepared in a similar way, but are not so highly flavoured.

Few articles are more liable to adulteration than cocoa; and so many forms or qualities are known in trade, varying in price from 6*d.* up to 4*s.* per lb., that it is not surprising that in the cheapest forms the adulterants themselves should be of the commonest and worst description. If people would only trouble themselves to think that cocoa-nibs, which are simply the roasted seeds without any preparation, are retailed at 1*s*. 4*d*. per lb., how can they expect to obtain an equally genuine article in a finely-pulverised state, and packed in tinfoil and a showy outward cover, at the same price? which is what the so-called "Homœopathic" and similarly prepared cocoas are sold at. Expensive machinery in the first place, and the constant wear and tear of the same, the consumption of fuel in the steam apparatus, and the expense of packing, have all to be paid for by the consumer, not by charging him a directly higher money price, but by increasing the bulk or weight of the article by adding foreign substances of a much cheaper description, and, which is frequently done in the commoner kinds of cocoa, bad or damaged seeds themselves. There is one thing to be said in favour of our principal cocoa manufacturers, that they seldom advertise these powdered cocoas as genuine; they either leave out that important word altogether or call them "prepared" cocoas, and this word should be borne in mind by those who wish to avoid the prepared and to obtain the real article, and are consequently ready to pay a fair price for such. If it is impossible to procure genuine powdered cocoa at 1*s*. 4*d*. per lb., still more impossible is it at 6*d*., which is the price paid by the poorer classes for an article called "Soluble Cocoa," sold in ¼ lb. packets at 1½*d*. each, and largely consumed by them. The very fact of its low price ought to be sufficient to tell us pretty plainly that a very small quantity of cocoa, and that of an inferior description, is to be found in such a packet. It contains a large amount of common fat, the presence of which can be detected by smearing a little on a piece of glass, and can be still more clearly seen on a glass slide under a microscope. The addition of fat adds to the weight, while, to increase the bulk, a very large quantity of starch is added, which is the cause of the thickening of the beverage in the cup. If a little of this so-called cocoa be placed on the tongue and rubbed against the roof of the mouth, it will be found to grate against the palate, and, moreover, to have a decidedly chalky or earthy flavour. The spoon also grates against the sediment at the bottom of the cup, clearly showing the presence of mineral matter.

FIG. 1.—Section of Cocoa-Nib as seen under the microscope

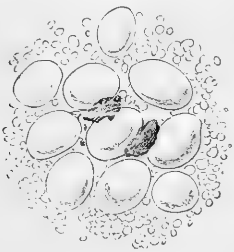

FIG. 2.—"Soluble Cocoa" as seen under the microscope

Until within the last few years, all these powdered cocoas were more or less "prepared," so that pure cocoa could not be obtained in this convenient form. An article, called "Cocoa Essence," recently introduced, has, however, dispelled this notion. We all know that the cocoa-seed naturally contains a large quantity of butter or fat (about 50 per cent.) which makes it too rich or heavy a beverage for many persons, and this more especially when we consider that other elements of nutrition, such as albumen, are also present. To deprive it entirely of its butter would be to take away one of its valuable principles; but it is possible to have too much of a good thing; therefore, by taking away about two-thirds of the butter the cocoa itself is not only improved in a dietetical point of view, but the addition of sugar, arrowroot, &c., is rendered unnecessary to take up or balance the fatty portion. Those who wish for pure cocoa in a convenient form should therefore obtain the "Cocoa Essence." It is sold in 3oz. packets at 6*d*. each. A small spoonful is sufficient for one cup, and, unlike the "Homœopathic," "Soluble," and other similar cocoas, it is not mixed with milk, but with a little boiling water, and stirred for a second or two until it is dissolved into a fine paste, the cup is then filled with boiling water, and milk and sugar added to please the taste. As no sugar is used in the manufacture of this article, it requires the addition of a larger quantity than any of the so-called prepared cocoas, and as no starch enters into its composition, the beverage is as clear as a cup of well-strained coffee. It is quite as portable as any of the packet cocoas, and as easily mixed. Its extra cost, in the first instance, is fully compensated by its purity, and by the fact that a smaller quantity is required for each cup. It is, moreover, a proof of the extensive adulteration of those kinds which are retailed at 1*s*. 4*d*. or 1*s*. 6*d*. per lb.

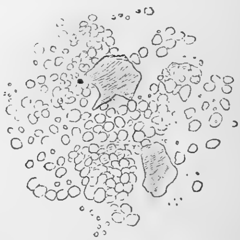

FIG. 3.—Microscopical appearance of "Cocoa Essence"

To such an extent has the public palate been led to prefer the flavour of many adulterated articles to that of the genuine, that we believe a great proportion of those who take cocoa really do prefer the thickened soup-like preparation made from the highly-flavoured and doctored sorts to an infusion of the pure seeds. If such people would think for one moment why and for what purpose they take this or that kind of food, and what are the properties and effects on the system of the articles they are supposed to consume, and what those of the articles they actually do consume, a much better state of things might be brought about, for, pending the appointment of a public analyst, the head of every household might make himself analyst to his own family, and so see that he does not get cheated either in pocket or health.

JOHN R. JACKSON

THE RECENT DEVELOPMENTS OF COSMICAL PHYSICS*

THERE are two conflicting theories with regard to education. The extreme partisans of one of these would have us believe that the great object of education is not so much to inform as to discipline the mind—the subject taught in a seminary may not in itself increase the student's real knowledge, yet if it tend to discipline his mind, it has proved its value in their eyes as a branch of education.

According to the upholders of this theory, our object in going to school is to leave it with a mind enlarged in its capacity for acquiring knowledge rather than stored with knowledge itself—having trained the soldier well, they would send him without scruple into the enemy's country, not only to fight his own way but to find his own weapons.

But there is another and opposite class of theorists who regard education not as an agent for training the mind so much as a means of storing it with knowledge. The extreme partisans of this theory would teach the student nothing but what is of apparent and immediate use; above all things they would teach him the sciences, both in their principles and also in the various details of their applications to the industrial arts of life.

The mind of the student who has undergone a training of this kind carried to its extreme, resembles the inmate of a house which is not so much well-furnished as filled full of furniture. In the accumulation of mere material, anything like plan or principle has been forgotten. It ought to be remembered that the value of a fact lies not in its existence somewhere in the mental storehouse, but in the readiness with which the mind can find it when required.

Now between these two extreme theories it is surely possible to steer a middle course—it is possible to avoid grounding on Scylla without being swallowed up in the vortex of Charybdis. In the material world, what would be said to a man who insisted upon developing bodily strength by a course of gymnastics without reference to food, or of another who insisted upon doing the same by a course of diet without reference to exercise? But is the separation more natural in the mental world? Is not that mind most perfectly disciplined which is at the same time most perfectly informed? The student who has been disciplined by only one branch of knowledge is, I venture to think, the possessor of a mind only partially disciplined, as it is only partially informed. He may not easily perceive his deficient discipline, but in after life he must often have cause to regret his deficient information. Nor is he whose mind is inordinately stored with scientific details one whit better off. Facts in education ought to be strictly subordinated to principles. A sound principle of science clearly understood will embrace a great multitude of facts, just as a simple rule of arithmetic will enable us to obtain a thousand products, each of which we should have to remember were it not for the rule. And in other branches of science, if the triumph of principle be not so apparent, it is only because we have a less accurate knowledge of its fundamental laws. It would be difficult indeed to say how many of the failures in the various walks of life are due to the neglect or ignorance of some principle which has been either omitted or dismissed from our calculations. From our leaders downwards we are a nation systematically ignoring principles, and in the minds of many a high esteem for fact is held to be quite consistent with a contempt for theory. A theory is not regarded as the very sap and life-blood of the tree of knowledge, but rather as the mildew that blights its leaves, or the worm that gnaws its root. Facts and theories are esteemed by this class of men to be sworn foes to each other, and the philosopher is supposed to live in a world of his own, rather hostile than otherwise to the world around him.

The existence of the two extreme educational theories to which I have alluded would thus seem to indicate the wisdom of a middle course. We ought to start from a platform as comprehensive as possible. Literature and science ought to go hand in hand in producing the well-trained and well-informed disciple. And while there ought to be a broad basis of instruction common to all, there should be raised upon this common basis several distinct departments, so that the student may have the opportunity of attaining proficiency in that of his choice.

Professor Stewart next touched upon the subject of energy.

If an egg be allowed to rest on its shorter axis, it will remain stationary, and any attempt to alter its position will be resisted by the egg. But the case will be different if we succeed, as perhaps we may, in causing it to stand on its longer axis, for in this position the slightest force will cause it to topple over. In the first case the egg is in stable, but in the second case it is in unstable, equilibrium.

If it stand upon its longer axis at the very edge of a table, we cannot tell whether the first slight breath of air will cause it to fall inwards upon the table or outwards over the table, to be dashed to pieces on the floor. It is a case where a very slight cause may determine a very considerable issue as far as energy is concerned. Whether the egg will retain its energy of position by falling on the table, or whether it will convert this into the energy of motion, and ultimately into heat, by falling upon the floor, is an issue that depends upon a cause too minute to come within the scope of our calculations.

Now we have two types of machines, and in one of these we take advantage of the principle of stability, while in the other we use the principle of instability. A clock is a very good instance of a machine of the first kind. When a good clock has been wound up, we are perfectly sure that at noon to-morrow both its hands will stand at twelve, and that its weight will have fallen through a distance which we can calculate with the utmost exactness, if we take the trouble, all its movements being capable of the most rigorous calculation. On the other hand, a mine that is about to be fired by means of an electric battery is a machine or combination in which advantage is taken of nature's unstable arrangements. The powder which is about to explode represents chemical instability, just as the egg on its longer axis represents mechanical instability. The slightest percussion, the smallest spark will rouse the imprisoned giant which it contains into volcanic energy. This spark has to be sent from a distance by the galvanic battery, and to do this we must complete the circuit. We cause the two wires to approach each other until they are only a very small fraction of an inch apart, but the contact is not yet complete—another touch, so slight as to be imperceptible, and the current passes, the powder is ignited, the mine explodes, and the fortress is hurled into the air. In such machines, great results, great transmission of energy, are due to the most trivial disposing causes. It depends at last upon the smallest conceivable movement of the wires conveying the current whether or not the fortress is to perish.

Nature also employs these two varieties of mechanism. In the solar system we have a clock on a large scale, only very much more accurate than any time-piece we can produce. The movements of every planet in the solar system are susceptible of the most rigorous calculation, and we have only to point our telescope properly in order to tell to the fraction of a second when a given planet will cross the field of view.

But in the living forms with which this world is so plentifully endowed, we have machines, which, viewed in their relation to matter, belong to the second order we have described. The object here is not regularity, but rather freedom of action. The motion of an animal is not like that of a planet—the latter yields to calculation, but the former defies it. Now it is probably somewhere in the mysterious brain chamber that the delicate directive touch is given which determines our movements, just as the slightest possible touch to the wire in the battery chamber explodes the distant mine. That mysterious thing we call life is not a bully who swaggers out into the open universe, upsetting the laws of energy in all directions, but rather a consummate strategist, who, sitting in his chamber before his wires, directs the movements of a great army.

While we are thus led to confine the directive action of life to the very boundary of the universe of energy, it must not, however, be supposed that we have solved the problem as to the nature of life. We have only driven the difficulty into a border land of thick darkness, into which the light of knowledge has not yet been able to penetrate. If there be truth in these statements, and if we see in a living being a machine in which great results are produced by an exceedingly small primeval impulse, are we not led to expect that the unstable forms of nature will here be largely made use of? We must not therefore be surprised that the materials of our bodily frames are eminently liable to decay, or that the very intensity of our life is to be measured by the rate of change taking place in the tissues of our bodies, so that possibly those parts which have during life the noblest and most delicate offices to perform are the very first to perish when life is extinct.

But this unstable matter, which is so wonderfully worked into

* Extracted from a Lecture delivered at Owens College, Manchester, introductory to the Session 1870-71, by Professor Balfour Stewart, LL.D., F.R.S.

our frames, is derived from the food we eat. This food does two things for us: it gives us energy in the first place, and in the second it furnishes our frames with a quantity of delicately organised tissue. But food is ultimately derived from the vegetable kingdom, and that kingdom derives it from the sun, so that we are led to regard our luminary as the ultimate material source not only of our energy, but also of our delicacy of construction.

To come now to our own luminary—very remarkable strides have lately been made in our knowledge of its physical constitution. It is difficult to say when and by whom the existence of sun spots was first remarked. Galileo, however, was the first to use them as the means of determining the elements of the sun's rotation. Besides these black spots on the sun's surface, equally mysterious forms have been seen to surround the sun on the various occasions of a total eclipse—these generally went by the name of red flames or red protuberances. Mr. Warren De La Rue was the first to prove that these phenomena were attached to the sun himself, and that the only office of the moon during an eclipse was to subdue the general light sufficiently to render them visible to the eye. While the red flames thus became objects of cosmical interest, Schwabe in Germany and Carrington in this country had both done much to increase our knowledge of sun spots. Schwabe, by a patient course of forty years' observations, had proved the existence of a well-marked periodical fluctuation in the amount and frequency of sun spots, the period of which was about eleven years. Carrington, again, had shown that the region of spots was a somewhat limited one, extending to about 20° or 30° on either side of the solar equator, so that a spot never appears at the sun's pole, and he had also detected a proper motion of spots. Schwabe and Carrington had, however, confined themselves to mapping down accurately what they saw; but De La Rue, by the introduction of celestial photography, was enabled to obtain autographs of the sun which might be studied at leisure with an absolute certainty of their being correet. A large number of such pictures has been already obtained, and they are in the process of examination by Mr. De La Rue, and those associated with him in this research.

Some of the preliminary results of this examination have already been published, and they seem to point to a connection between the behaviour and frequency of sun spots and the positions of the chief planets of the system.

Our acquaintance with the red flames has extended as rapidly as our knowledge of sun spots. It was discovered independently by Janssen and Lockyer, that these strange protuberances yield to the spectroscope under ordinary conditions of the sun, and without the necessity of waiting for a total eclipse. They exist, in fact, always round the sun, but their brightness is quenched in the diffused light which surrounds the sun's border. When, however, we apply a sufficiently powerful spectroscope, the diffused light—consisting of ordinary sun light, and therefore containing a great variety of rays—is drawn out into a long spectral ribbon, and has its brightness scattered or diffused over the various parts of this ribbon, while on the other hand the light from the red flames, consisting only of one or two kinds, appears in the spectroscope as one or two bright lines not having their intensity weakened by the scattering action of the spectroscope. They, therefore, stand out in the field of view, while the ordinary light disappears. Lockyer has found, by this means, that there is an envelope of incandescent hydrogen surrounding the glowing surface of the sun, into which there are frequent injections of heated matter from beneath, and in which there are violent huricanes often moving at the rate cf 100 miles a second. By the laboratory labours of Frankland and Lockyer, taken in connection with the solar observations of the latter, there is, I think, a probability of our ultimately ascertaining the pressure and the temperature as well as the chemical composition of the atmosphere of our luminary.

Descending now from the celestial bodies to our own earth, there is some reason to suppose that we are knit to our luminary, and possibly through him to the other members of our system by some other bond, besides that usually recognised. General Sir E. Sabine appears to have proved that disturbances of the earth's magnetism take place most frequently in those years in which there are most sun spots. This is confirmed by the experience of the present year, during which we have had a great number of sun spots, and frequent and large disturbances of the earth's magnetism.

I have already alluded to a possible connection between the behaviour of sun spots, and the positions of the planets; to which we may add, that Schwabe and other observers imagine that they have discovered traces of a periodical variation in the appearance of the planet Jupiter. All these observations would appear to indicate the existence of some unknown bond between the different members of the solar system.

But that department of cosmical physics which is of most immediate interest to ourselves, is undoubtedly the meteorology of our globe; and here it is of great importance to know whether the earth's climate and atmosphere are influenced in any way by the changes taking place in the atmosphere of the sun. Such a connection has not yet been traced, but it has hardly yet been sought for in a proper manner. Recent observations discussed by Baxendell, lead us to think there may be some connection between the daily changes in the earth's magnetism and the daily motions of the air. Coupling this with the fact that the frequency of terrestrial magnetic disturbances would appear to be connected with that of sun spots, we are led to contemplate at least the possibility of some connection between meteorology and sun spots.

If these remarks are of any value, they tend to indicate the probable union of the various branches of observational inquiry into one great cosmical research, and point to the wisdom of a very close union between the workers in the cognate fields of meteorology, terrestrial magnetism, and celestial physics.

At the present moment the prospects of meteorology are more hopeless than those of the other two branches. Our knowledge of the motions of the various components of the earth's atmosphere is extremely limited, and yet without this knowledge it is impossible to connect meteorology with the other branches of cosmical inquiry. If we endeavour to analyse the causes of this backward state of meteorological research, the first and most apparent is the magnitude of the problem.

We are too intimately associated with the earth and its atmosphere to be easily able to tell its motions. Strange to say, the meteorology of the sun is more easily studied than that of the earth, and we know already as much about the strength of solar storms as we do about that of terrestrial hurricanes.

But another cause of the backward state of Physical Meteorology arises from the fact that there are two branches of science, each of which may be furthered by meteorological observations. There is first the physiological branch of meteorology, the object of which is to trace the influence of climate upon animal and vegetable life; and there is next the physical branch, the object of which is to study the physics of the earth's surface, and more especially the motions of its atmosphere.

It is now high time that a separation should be made in the mind of the observer between these two branches of research. If he would rather pursue the physiological inquiry, let him say so definitely, but if he wish to pursue physical meteorology, let him clearly keep before his mind the object of all his labours. He should ask himself the question, what is the best system of observation, and what is the best method of reduction, to advance the great object of physical meteorology—a knowledge of the motions of the earth's atmosphere, and of the causes thereof? He should not fix upon a system of observations and a method of reduction that may possibly, but upon one that must necessarily, further this great object.

I have thus endeavoured in a few words to bring before you the recent advances in cosmical physics. Besides this, there are two other no less important branches of physical inquiry. We have the physics of organised beings, and we have also molecular physics. But there is this difference between these two branches and that of which I have now spoken:—To forward physiology or molecular physics we chiefly require experiment, but to forward cosmical physics we chiefly require observation. You are all aware that at the present moment a Royal Commission is inquiring as to the relation between Science and the State; and perhaps, therefore, you will permit me the opportunity of stating my views as to the manner in which this very necessary assistance may best be given. I think that those branches of science which demand for their extension experiments not requiring very great time may be furthered with much advantage in institutions such as Owens College. I believe it to be advantageous to bring the highest class of physical teaching into contact with research. If Government be disposed to grant pecuniary aid to such researches, an extension of the allowance made annually to the Government Grant Committee of the Royal Society would appear to be a very legitimate way of accomplishing this object.

The scientific professors of a college would thus have to state the aim of their research to a committee of the Royal Society entrusted with the disposal of Government means, and the requisite funds would be forthcoming. No one, I think, can doubt that the small sum of 1,000*l.* annually entrusted by Government to the Royal Society for miscellaneous experiments, is administered in a most praiseworthy manner; and if Government would be ready to grant, and the Royal Society willing to undertake, an extension of this trust, it would, I think, be a great point gained for this class of physical experiments. (I speak only of experiments, but the encouragement of experimenters is a point of equal importance.) But when we come to experiments and observations requiring great time, the case is very different. Certain experiments, whether from the great time they require or the great expense they demand, cannot be well performed in a college; while routine and long-continued observations such as those connected with the various branches of cosmical physics are of such a nature as to require a central establishment to superintend their organisation and reduction. There is thus, I think, the necessity for a central establishment of some kind devoted to that class of experiments and observations requiring great time, great space, and great expense for their completion.

Referring more particularly to Cosmical Physics, I feel convinced that meteorology should be pursued in connection with terrestrial magnetism and solar observations; and were a well-considered scheme for solving this great problem fairly introduced, I am sure that scientific institutions and individuals throughout the country would do all that they possibly could to promote this most important branch of physical research.

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE

Barometric Predictions of Weather.—Mr. F. Galton, F.R.S. It has long been an established custom to consult the barometer to learn what the weather is likely to be. Now, I propose to investigate the value of this form of barometric authority by showing that it is possible to make strict use of the rules of prediction, notwithstanding the vagueness with which they are enunciated, and then, by comparing a series of carefully-made predictions with facts, to measure the degree to which they correspond. There is another form of barometric authority about which I do not propose to say anything here, namely, where the barometer is consulted in connection with the daily Weather Report. Owing to the new data thereby introduced, an inquiry into the value of those predictions would have to be conducted along an altogether different line to that which I am about to follow.

My comparisons between predictions and facts will be based upon the tracings of the continuously self-recording instruments at Falmouth, established by the Meteorological Committee appointed by the Royal Society, which have been published for the first quarter of the year 1869. It is, however, right to add, that some years ago I made an elaborate inquiry into the Dublin observations during a much longer time, which led, so far as it went, to the same conclusions as now.

I did not publish those inquiries, because I had a misgiving which was never wholly removed until I had the opportunity now afforded by the above-mentioned publication of studying the *continuous* records of instruments in large numbers. It is said that instrumental changes commonly occur in sweeps so large and steady that future changes in them may be to some extent predicted by a knowledge of what has occurred. An analysis of the Dublin observations, made at intervals of three hours, contradicted this assertion, but I felt they might be held insufficient to dispose of it. It might fairly be said that three hours was too long an interval between the observations, and that if the instruments had been read off more frequently, I should have been led to different conclusions. It was necessary to settle this doubt, because, as there is certainly some correspondence between the barometer and the weather, it followed that if it be possible to predict the movements of the former, we shall also, as a matter of course, be able in some degree to predict the latter. I therefore examined the tracings which represent the continuous records of the barometer and other instruments with great interest and care, and soon convinced myself that the irregularities of the barogram and thermogram were far too great to enable us to predict their course from moment to moment. We have only to place a paper upon them, so as to hide what follows any given instant, and to expose what precedes it, and to move the paper forward, step by step, guessing beforehand what we are to see, to be convinced of the vanity of our expectations. This basis of weather prediction is so manifestly unsound, that I shall not take any further notice of it.

We all know that the weather with which the barometer sympathises, is considered to consist of three independent variables—the velocity of the wind, its temperature, and its dampness. It is a question how far the direction of the wind need be reckoned as a fourth distinct influence. We also know that the velocity of the wind is the most important; it is said that when the two other variables are unchanged, and the velocity of the wind alone varies, the barometer may range through two inches, but that it can only range through a quarter as much when either the temperature or the damp are the sole variables. I therefore feel at liberty to begin by simply comparing the changes of the wind's velocity with those of the barometer, in order to obtain a provisional idea of the manner in which they go together.

Two things are very clear at first sight—the one is that the wind's velocity passes through numberless tumultuous variations of which the barometer takes no cognizance, and the other is that a connection decidedly exists between periods of storm and of fine weather, with barometric falls and rises. What, then, do we mean by *periods* of storm? How long is the period during which the velocity of the wind should be summed up and averaged, in order to be made to accord most closely with the barometer?

I made several trials, and protracted the results on the same time-scale as the corresponding barograms. The ordinates of the different points whose position I calculated represented the average velocity of the wind during a definite period at the moment indicated by the point; then I connected the points by a line drawn with a free hand. In this way I constructed a curve, every point of which represented the average velocity of the wind during the space of one hour, being half an hour before and half an hour after the instant corresponding to that point. In another curve, a three-hour period was adopted, and so on. Below all these I copied the barogram.

There could be no doubt, on inspecting those lines, that a one-hour period is far too short, that a three-hour is better, a six-hour better still, and that a twelve-hour is as good as can be obtained. Any period between twelve and sixteen hours seemed equally suitable for adoption, some parts of the curve improving in correspondence as the period was lengthened, and others falling off; but, after a sixteen-hour period, the curve of wind velocity became less varied than the barogram, and the maximum of correspondence was passed. Finding the twelve-hour system the most convenient to employ, I have adopted it here, leaving it to be understood that a different period might be taken within the limits named, without sensibly affecting the results.

The correspondence between the wind curves thus obtained and the barograms is respectably close, there being hardly a dip or rise in the one which has not a counterpart in the other; but they are far from being exactly alike. Neither do the changes, of course, in the two curves, bear an invariable relation in point of time to one another; but, as neither of them lags habitually behind, they must be considered *on the average* simultaneous.

I do not find the correspondence sensibly affected by making broad allowances for the neglected variables. Thus, on marking the epochs of cold and dry polar winds in one way and those of warm and moist equatorial winds in another way, little or no new light was thrown on the reason of the want of coincidence of the two curves. It seemed to me, from this trial, that the influence of temperature, damp, and wind's direction, is considerably less than was commonly believed.

The parallelism of the curves was as close in extreme positions as in mean ones, which confirms the common statement that we must look to differences of barometric height and not to the absolute height for signs of changing weather.

All this is easily compressed into a formula: h_1 h_2 are two successive barometric heights a few hours apart; v_1 (12) v_2 (12) are the corresponding twelve-hour averages of wind velocity; m is a simple factor to be determined by trial, then

$$h_1 - h_2 = m\left\{v_1(12) - v_2(12)\right\}$$

+ a function of temperature and another of damp, neither of which is of much importance.

m is strictly constant only for the same season, because the range of the barometer is wider in winter than in summer, for the same latitude because its range is smallest at the equator, and for the same locality because the wind's velocity may be checked by geographical conditions. Bearing this in mind, the value of m for the first quarter of the year, at Falmouth, as derived from about 100 selected equations of the form $\frac{h_1 - h_2}{v_1 - v_2}$ is -2, when the barometer is reckoned in hundredths of an inch and the velocity in miles per hour. In selecting the equations, I omitted all cases of abrupt change in any of the variables. Consequently our equation becomes

$$h_1 - h_2 = 2 \left\{ v_2 (12) - v_1 (12) \right\}$$

+ the functions of temperature and damp.

It may now be very reasonably asked how it is possible for the barometer to be affected by past and coming conditions of wind. Its sympathy with such considerable periods as six hours before and six hours after the moment of observation, cannot be accounted for on the hypothesis of each new phase of weather regularly making its first appearance high in the atmosphere, because, if it did so, each phase would necessarily disappear from above before it disappeared from the earth's surface, and, consequently, the barometric change would invariably precede the change of average wind velocity, which, we have already seen, it does not. What, then, is the explanation of the curious phenomenon, of the barogram corresponding with the average velocity of the wind, according to the system of twelve-hour periods?

The answer to this question will best be conveyed by a consideration of what we should expect the movements of the mercurial column to be if a suitably made barometer were plunged into troubled water. Its movements would not correspond to each ripple that passed vertically above its cistern, because it would be affected by all the disturbances in an area of surface water whose radius is a function of the depth of immersion. If it were plunged to the depth of many fathoms the mercury would wholly cease to oscillate, because the average level of the large area with which it sympathised would be constant, however much its surface might be broken up into undulations. If it were immersed to a suitable depth, the mercury would foretell the advent of each wave of exceptional size, before an exceptional height of water had arrived vertically above the barometer. It is easy and interesting to make an experiment to the same effect, by dipping a glass tube, open at both ends, straight into a pan of water, and disturbing the water with the hand. When the tube is dipped but a short way in, the water it encloses harmonises in its oscillations with the water that surrounds it, but this harmony is diminished, and the oscillations in the tube become more sluggish, as the tube is immersed more deeply, and at length they disappear altogether. In precisely the same way I believe the mercury in the barometer sympathises with atmospheric disturbances throughout a wide circle. Its height represents the average value of them at the moment of observation, and when a great atmospheric disturbance sets in, as is wont, from the westward, the barometer is affected some time before the arrival of the locus of greatest disturbance. The diameter of the circle which affects the barometer may admit of being determined in more than one way, but I am not now concerned with its linear measurement. What I am immediately in search of is, what the diagrams have already told me, that its diameter in relation to its usual rate of movement is such, that it is commonly twelve hours in passing over an observatory.

It appears to follow that the twelve-hour period for averages must apply not only to the wind but to all other elements of atmospheric disturbance, such as temperature and damp. Therefore the undetermined portion of our equation will be functions of t (12) and of d (12).

Without professing to decide the precise nature of those functions, we may be sure that it does not differ materially from a simple proportion, within the limits of meteorological records. The inferior importance of these functions makes a small error of still less consequence. I therefore assume the undermentioned portion of the equation to be

$$p \left\{ t_1 (12) - t_2 (12) \right\} + q \left\{ d_1 (12) - d_2 (12) \right\}$$

Calculating on the basis of the already quoted statement, that temperature and damp, unaided, may respectively affect the barometer to the amount of half an inch, p and q may both of them be considered equal to -1, when t is reckoned in degrees Fahr., and d is the vapour tension expressed in hundredths of an inch. For reasons already mentioned, I disregard the direction of the wind. Consequently the formula becomes

$$h_1 - h_2 = 2 \left\{ v_2 (12) - v_1 (12) \right\} + \left\{ t_2 (12) - t_1 (12) \right\} + \left\{ d_2 (12) - d_1 (12) \right\}$$

and I now proceed to utilise it, in making a series of predictions for comparison with facts.

Let h_1, h_2, be separated by an interval of six hours, which I will distinguish by the letter b; similarly let a represent the six hours that preceed h_1, and c the six hours that succeed h_2.

Now the average wind velocity during the twelve-hour period $a + b$ is half the sum of the average velocity during the six-hour periods a and b,

or $$v_1 (12) = \tfrac{1}{2} \left\{ v (a) + v (b) \right\}$$

also $$v_2 (12) = \tfrac{1}{2} \left\{ v (b) + v (c) \right\}$$

$$v_2 (12) - v_1 (12) = \tfrac{1}{2} \left\{ v (c) - v (a) \right\}$$

similarly for t and d.

Therefore our equation becomes

$$h_1 - h_2 = v (c) - v (a) + \tfrac{1}{2} \left\{ t (c) - t (a) \right\} + \tfrac{1}{2} \left\{ d (c) - d (a) \right\}$$

and

$$v (c) = h_1 - h_2 + v (a) + \tfrac{1}{2} \left\{ t (a) - t (c) \right\} + \tfrac{1}{2} \left\{ d (c) - d (a) \right\}$$

Using this simple formula, I selected all the periods during which the changes of the barometer had been abrupt or otherwise characteristically marked, and I calculated the values of v (c) during those periods, obtaining in this way a total of 106 predictions. Comparing these with the actual facts, I obtained a mean error of ten miles per hour. Next, in order to procure a standard whereby to ascertain the importance of this error, I obtained and took the mean of a series of differences between the same observed values of v (c) and v (b); in other words, I calculated what the mean error would be supposing it was invariably asserted that the average wind velocity for the next six hours would be the same as during the six hours just elapsed. The mean error in this case was only 7·7 miles per hour. This extraordinary result made me curious to learn whether the co-efficients of t and d might not be altered with advantage; so I first made them both $= 0$, in fact, ignoring the influences of temperature and damp altogether. The mean error again came out ten miles per hour, the gains and losses due to the correction having balanced one another. Secondly, I made the co-efficients each $= -2$, that is to say, I doubled the importance originally given to temperature and damp, and the mean error rose to 11·3 miles per hour.

The result of all this is, that, judging by the experience of 106 well-marked instances of change occurring at Falmouth during the first quarter of 1869, it is more unwise in the ratio of 10·0 to 7·7 to be guided by the barometer, than to say off-hand that the weather will continue as it has been. Also that there can be no gain and may be further loss, if the wet and dry thermometers be consulted as well.

It is, no doubt, possible that the errors I have assigned may be qualified in a trifling degree by other calculators. They may adopt periods of average and numerical co-efficients, somewhat differing from my own; also, their data as measured off from the instrumental tracings, may be more accurate than those that I made, but I feel satisfied there is no mistake in the broad truth of my results. After more tentative analysis than I care to describe, I believe it impossible to substantially improve these predictions, and the experience I gained from the Dublin observations makes me doubt whether a more extended examination would lead to different conclusions. The barometer, when consulted by itself, without a knowledge of the weather at adjacent stations, can claim but one merit, namely, to guide us in a form of storm which does not occur once a year in the British Isles, of a fall in the mercury outstripping in an extraordinary degree the increasing severity of the weather; and I believe it to be on account of this rare phenomenon here, and of the reports of sailors from hurricane latitudes, where it is much more frequent, that the fame of the instrument has been so widely spread. But for use in ordinary English gales, and still less in ordinary English weather, this inquiry shows the barometer to be one-third worse than no guide at all. It is better to base our expectations upon what has occurred, than also to take the barometer into our counsel. We easily see the reason of this to be, that the theory of prediction involves many postulates, every one of which must be strictly fulfilled in order that the result may be correct. But they are only true on the *average* and not in the individual case. The area with which the barometer sympathises is never exactly twelve hours in passing over us; the six-hour radius of that area, which has already gone by, is not an accurate sample of the demi-area of which it forms the central strip; neither is it at the moment of observation in the same condition as when it passed over us. Precisely the same may be added in respect to the six hours of weather which are the subject of prediction. It must also be especially borne in mind that whatever error may affect the twelve-hour average is necessarily doubled in the six-hourly prediction, because the difference between what was expected of the whole twelve hours, and what has been fulfilled in the first half of it, must be heaped on to the second half, which has therefore to bear an additional load of error, equal in amount to its rightful share. Thus, if 100 miles of wind had been expected, and eighty miles really came, in the twelve hours, the error of the expectation would be one in four; but if forty miles of wind had come in the first six hours, the prediction would assign sixty miles to the next six hours, whereas the fact would show forty miles, making an error in the prediction of two in four, or double the original error of expectation for the whole twelve hours.

Section B.—Chemical Science

On the Utilisation of Sewage, with Special Reference to the Phosphate Process.—Mr. David Forbes, F.R.S. &c. The processes at present employed for the treatment of sewage were classed under two heads: the purely mechanical and the mechanico-chemical. The former, which at best only effected a mere filtration of the sewage, have everywhere failed to effect any such purification of the sewage water as was necessary in order that it might be allowed to flow directly into the streams. Sewage irrigation was included in the latter class, not because any direct chemical treatment was employed, but for the reason that, whilst the soil acted mechanically as a filter to separate the solids, the chemical action exerted by the vegetation decomposed and assimilated the organic matter, ammonia, and other available substances in the liquids also. The more purely chemical processes, such as the treatment by lime alone, or in combination with chloride of iron, alum, sulphate of alumina, and, lastly, the so-called A B C process, were next alluded to, but regarded as failures, since the evidence brought forward not only proved that the affluent water had not been sufficiently purified, but also that the sewage manure obtained was, by the admixture of the materials employed in these processes, rendered of so low an agricultural value as to preclude its employment elsewhere than in the immediate neighbourhood of the sewage works.

Admitting that sewage irrigation was to be recommended wherever the local circumstances were favourable to its employment, it was maintained that under many circumstances it was neither applicable nor advantageous, and that in these cases it was preferable to employ a chemical treatment, which had the advantage of not requiring any large outlay for pumping or distributing machinery, or the purchase of large areas of ground for sewage farms. For this purpose an entirely new process was recommended, called the phosphate process, based on the property which hydrated phosphates have of combining with organic matter, whilst the ammonia also can be precipitated in the condition of the double phosphate of ammonia and magnesia.

The process was shown experimentally with Liverpool sewage, and consisted merely of adding a solution of certain phosphates, chiefly of alumina, in sulphuric or hydrochloric acid to the sewage, and afterwards a little milk of lime barely sufficient to neutralise the acid and give a faint alkaline reaction to the sewage; even if tinctorial matters of great intensity (ink was added in the experiments) were present, the liquor became immediately discoloured, the supernatant liquor resting quite clear above a precipitate of the phosphates along with all the insoluble matter and a large portion of the soluble organic matter and ammonia originally contained in the sewage. The authors of this process, Messrs. A. Price and D. Forbes, although they did not pretend to have extracted the entire amount of the ammonia and other matter valuable for agriculture from the sewage, or to effect an absolute purification of the affluent water, believed that, as the water so purified was free from any nauseous taste, so that it could be drunk without repugnance, was devoid of smell, and did not putrefy or emit any disagreeable odour even when left standing in an open vessel during the whole of the preceding hot summer, that it had been sufficently purified by the phosphate process as to permit of its being directly run off into rivers without detriment to the fish in them or the health of the inhabitants on their banks.

A most particular feature of this process when compared with the other processes of precipitation was, that the substances employed in effecting this purification were not detrimental to the agricultural value of the precipitated manure, but, on the contrary, added so much to its value as to enable it to bear the cost of transport to distant parts of the country, and thus showed some hope that the value of the manure might be sufficient to pay for the expense of treating the sewage.

Section C.—Geology

Remarks on newer Tertiary Fossils in Sicily and Calabria. Mr. J. Gwyn Jeffreys, F.R.S. In the last deep-sea exploring expedition in H.M.S. *Porcupine*, in the Bay of Biscay, and along the Atlantic coasts of Spain and Portugal, Mr. Jeffreys procured at considerable depths, and especially from 994 fathoms, many species of mollusca in a living or recent state, some of which had previously been regarded as fossil only, and extinct, and all as belonging to the newer tertiaries of Sicily and Calabria; and he believed that a record of the fact might lead to the further discovery of the geological phenomena which had caused the fossilisation of such species in that limited area. Several of these species inhabit northern, and even Arctic, seas; such are *Terebratula cranium*, &c. Other species now found in a living or recent state, are *Terebratula spheroidea*, &c. One of the last species, in the last list or category (*Fiparesepla papillesa*) was also dredged by Mr. Jeffreys last autumn, at Dröbak, in Norway; and he was of opinion that our knowledge of the Arctic marine fauna was very imperfect. The newer Tertiary fossils of Sicily and Calabria had been to a great extent investigated by Dr. Philippi, formerly of Cassel, Professor Seguera of Messina, the Abbé Brognone of Palermo, and Dr. Tiberi of Resina near Naples; and their collections had been examined by Mr. Jeffreys. Two suggestions or questions were submitted by the author of the present paper. 1. Have not all the deep-sea species of European mollusca originated in the north, and spread southwards in consequence of the great Arctic current? 2. Inasmuch as the pliocene division of the Tertiary formation is now ascertained to contain scarcely any extinct species, and the future explorations may reduce the percentage of such species to *nil*, may not that artificial division hereafter merge in the quaternary formation, and the tertiaries be restricted to eocene, miocene, and pliocene?

The President and Sir Roderick Murchison spoke of the great importance of this communication, and the latter hoped Mr. Jeffreys did not share the opinion of his colleague Dr. Carpenter, that their discoveries tended to upset modern geology.

Professor Duncan confirmed Mr. Jeffreys' statement with respect to the specific identity of corals from deep-water with those of the South-Italian tertiaries.

The Rev. H. W. Crosskey also addressed the Section as to the glacial fossils of Scotland being quaternary and not tertiary.

Mr. Jeffreys, in reply, begged to assure Sir Roderick, as one of the parents of English geology, that he need not be under any apprehension for his offspring, so far as the deep-sea explorations were concerned.

Modern and Ancient Beaches of Portland.—Mr. W. Pengelly. The Chesil Bank having been described, the author stated that he had found amongst the flints of which it was chiefly composed, specimens of Budleigh Salterton pebbles, some containing the fossils occurring in these pebbles. Some granite pebbles were probably from the valley of the Teign. From these specimens it was concluded that the transportation along the coasts of South Devon and South-west Dorset is up Channel, that is, in the direction of the prevalent winds. The Raised Beach of Portland Bill consists of 7 feet of yellow clay, the same of pebbles, sand and shells from the Raised Beach, and 50 feet of rock resting at sea-level on a shingle beach. The shells are species now living on the shore. The beach was held to indicate an elevation of the coast of not less than 50 feet; and the pebbles showed that at the time of their deposition the direction of transportation was the same as now. Portland was then an island.

On the Occurrence of Seams of Hard Sandstone in Middle Drift of East Anglia.—Mr. J. E. Taylor. This sandstone was composed of 66 per cent. of siliceous sand, cemented by 33 per cent. of carbonate of lime. It occurs immediately below the upper or chalky boulder-clay. Formerly it was employed at Norwich in building, the Castle being built of it. Even in beds later than the boulder-clay, specimens of indurated sandstones had been found by the author, proving, as he believed, that the older rocks owed their compactness more to the cementing material than to heat or pressure.

On the Palæontological Aspects of the Middle Glacial Formation of the East of England, and on their bearing upon the Age of the Middle Sands of Lancashire.—Messrs. Searles V. Wood, and F. Harmer. The authors gave a list of 65 species of shells obtained from the middle glacial sand in the neighbourhood of Yarmouth, of which a large proportion, about 20 per cent., are not now known to be living, and one of them, *Erycinella ovalis*, a coralline crag form, being almost generically extinct; among which they had found five or six shells apparently new. The formation altogether presents a decidedly southern aspect, with strong affinities to the crag, only two species (with the exception of the new forms) being unknown to the crag beds. On the other hand, the middle sand of Lancashire, as at present described, did not appear to have yielded any shell not now to be found in the seas of the immediate neighbourhood. They pointed out that the mere fact of the middle glacial sands of the east of England, and the middle sands of Lancashire being both of them underlaid and overlaid by boulder-clay, was altogether inconclusive, and urged that all the evidence we had at present before us would relegate the latter to a much more recent position in the glacial sequence. They suggested tentatively that the Lancashire sands might possibly prove to belong to the Hessle series, as there seemed to be a close resemblance between the list of shells from Kelsey Hill, believed by them to belong to the Hessle series, and those from Blackpool.

In the discussion which followed, Sir Charles Lyell was understood to say that he was inclined to accept the conclusion of the authors.

Mr. Hughes did not think there were as yet sufficient data to correlate the drifts of the East and West of England. But little was known of the relations of the drifts of the West to one another. We must first trace the included fragments to their origin in the mountains, and not form any theory to account for the origin and succession of the wide-spread drift of the lower country, which will not also account for the phenomena observed in the hills. As the result of his own observations, he described three drifts occurring in the district north of Liverpool, which might be roughly distinguished from one another.

1. A stiff blue clay with included fragments of the rocks of the immediate neighbourhood. This drift occurs at the highest levels up to 2,100 feet. The fragments are striated when the rock is of such a character as to preserve the scratches.

2. The ordinary stony clay drift which occurs along the valleys and runs up the hill-sides to about 1,800 feet. In the *Fell-top drift*, No. 1, the matrix is a very uniform stiff lead-coloured clay, no matter what it rests on; while the included fragments may have come from rocks about the same level and close at hand. In the *Hill-side drift*, No. 2, the matrix varies more according to the rock on which it rests; while the included fragments, which are more numerous than in the *Fell-top drift*, No. 1, are derived from higher up in the same drainage area; and, where different kinds of rock occur on opposite sides of the valleys, the drift on either side is chiefly derived from the rocks on the same side, as if it were the lateral moraine of a glacier coming down the valley.

3. In the lower valleys false-bedded sands and gravel, such as might be produced by the action of the sea at the end of the receding glaciers, overlap the clay drift No. 2, and are almost continuous with the great mass of gravel drift which is so largely developed on the lower ground of North Lancashire. But while these divisions are tolerably clear in a large way, in detail it is difficult to draw a line between them; and when we try to group all the drifts in and around the mountain districts of Wales and the North of England under one of these heads, or to fit all the observed phenomena into any scheme of regular increase and decrease of cold—any uniform submergence or elevation, we find many exceptions and complications. The false-bedded sands and gravels usually occur along the larger valleys at low levels, but sometimes we find similar sand gravel dovetailing into the boulder clay at various heights; in another place occurring along terraces 1,000 feet above sea-level. In the absence of organic remains, we cannot yet say which of these should be referred to marine action and which to fresh-water streams and ponds in and near the melting ice. Flints commonly occur in the lower gravels, but once a large unworn flint, about eight inches in diameter, was found in the re-sorted surface of the highest drift at about 1,900 feet above the sea. In the case of the Shap granite boulders, to the mode of distribution of which Professor Harkness has devoted much attention, the difficulties are more obvious, as the rock is so marked. Boulders cannot be formed except when the rock from which they are derived is above the ice and water. This limits the submergence and depth of the ice as to the maximum. But according to the view that the boulders were transported over Stainmore into East Yorkshire on floating ice, the south end of the Pennine range must have been submerged. This limits the submergence as to minimum. What was the line of transport of the Shap boulders *before* the submergence of Stainmore? Again, in the drifts on the top of Stainmore, we find not only boulders of Shap granite, but also fragments of the Permian brecciated conglomerate which can have come only from the bottom of the valley more than 1,000 feet below. Can we believe that these have been lifted by shore ice from time to time throughout that long submergence, or have we evidence of older drifts of very different origin being washed, sifted, and sorted by the encroaching sea. Again we find, even on the north side of steep mountain ranges, where we should have expected the glaciers to have lingered longest and to have ploughed out the old drift, that even boulder-clay has travelled up the hill from the lower ground, and must therefore be referred to a period when its transport was irrespective of the present valleys and mountain slopes.

In fact, there is much evidence to show that the land ice has often ploughed across and transported marine deposits, and the sea has often washed and re-sorted the *debris* brought down by land ice, and thus the drift has been used up over and over again. That might be the reason why we so often find fragmentary and rolled shells associated with perfect though delicate shells, which seem to be of the age of the deposit in which they are found. He quite agreed with Mr. Searles Wood as to the derivative character of some of the shells in the gravel drift recently described by Mr. Jamieson.

But even frequent oscillations of level would not alone be sufficient to account for the manner of occurrence of the marine drifts, especially when the palæontological evidence is considered. The agencies which produce the warm Western Ocean currents must have been in operation throughout the long period under notice, but the circumstances which determined the direction of those currents must have varied with the changes of level. He asked what would be the effect upon the Gulf Stream of a submergence or an elevation of a large part of the bed of the Atlantic to the amount of 2,000 feet or more? The shells of Moel Tryfaen, though of less Arctic character, might well be referred to the period of greatest general cold, provided the form of the sea-bed and distribution of land turned a warm ocean current on that part of the western coast.

He would, therefore, urge the expediency of adopting the method always taught by Professor Sedgwick to his pupils—first, to establish clearly the relation of the beds in each separate area, and to avoid obscuring an already complicated question by adopting prematurely in the West the local nomenclature of the East of England.

On Certain Glacial Phenomena in the Central District of England.—Rev. H. W. Crosskey. The author had determined the existence of glacial striæ in the central plateaux of England, and covering these markings on true boulder-clay, physically corresponding to the older "till" of Scotland. The clay with granite boulders in the midland counties was of marine origin. A succession of drift beds was established from an actual section showing a boulder-clay resting on the Bunter sandstone; second, sands and gravels with false bedding; third, a clay with pebbles; fourth, a bed of sand mixed with clay.

On some Thermal Springs in the Fens of Cambridgeshire.—Mr. F. W. Harmer. In several farm-yard wells near Chatteris, of the depth of about ten feet, the author had found water of the temperature of $74\frac{1}{2}°$ Fahr. on the 14th March, the air being but 37°; and in June of $79\frac{3}{4}°$, the air being then 70°. An analysis of the water by Mr. F. Sutton showed that the heat was not due to chemical causes. The fens being below the sea-level, and therefore permanently saturated with water at the depth of ten feet, and the phenomenon described being apparently continuous over an area of ten miles, and no doubt further, the cause producing the heat would not be an insignificant one. Mr. Judd, of the Ordnance Survey, affirms that the secondary rocks of this neighbourhood are extensively faulted, and may thus afford a communication with the central heat of the earth.

On the Matrix of the Gold in the Scottish Gold Fields.—Dr. Bryce. The author had found gold in the fragments of granite, and tracing it to the native rock, he obtained the crushing of a sufficient portion to prove that it was distinctly, though not remuneratively, auriferous.

Some Remarks on the Denudation of the Oolites of Bath.—Mr. W. S. Mitchell. The author held that there was no proof establishing the continuity of the Oolites. He thought they were accumulated locally, and, as it were, in patches, with currents sweeping in between. The sedimentary matter which followed filled in the spaces forming the Bradford clay. Denudation subsequently came into play, and the ready-yielding clay formed the valley.

On an Antholite discovered by Mr. C. P. Peach.—Mr. W. Carruthers. Various estimates of the position and of the structure of this fossil had been formed, but the specimens found by Mr. Peach established that the bud sprang out of the axil of a bract, and consisted of several scales supporting three or four flowers, having fruits which had been described as species of *Cardiocarpum.*

On the Sporangia of Ferns from the Coal Measures.—Mr. W. Carruthers. These organs were found in what were called coal-balls, from the beds of coal at Bradford and Halifax. They exhibited the structure, form, and attachment of the sporangia of some recent hymenophyllaceous genera.

Section D.—Biology

Department of Zoology and Botany

On the Larval State of Molgula, with description of several new species of simple Ascidians.—Mr. A. Hancock. The author described the tadpole larvæ of *Molgula complanata*, and referred to the Amœba-like form of larva described by Lacaze Duthiers, as found in *M. tubulosa*; but it may be doubted whether this species is a *Molgula*, and reasons for believing it to belong to a new genus *Eugyra* were given. Many new species were described belonging to the genera *Ascidia* (11), *Carella* gen. nov. (2), *Ciona* (1), *Molgula* (3), *Eugyra* (1). Many of these species were sent to Mr. Hancock by Dr. Bowerbank, Rev. A. Norman, and Mr. A. G. More.

On the Structure of the Shell in the Pearly Nautilus.—Mr. H. Woodward. After referring to the great interest attaching to the *Nautilidæ* on account of their vast geological and geographical range, the author proceeded to describe the structure of the shell with its septa and siphuncle, the latter structure being only found in the Cephalopoda and nearly confined to the Tetrabranchiate division of the class. The camerated structure, however, is found both among the Bivalves and Gasteropoda, and the author suggested that if any incipient character could be found leading up as it were to the siphuncle, we might fairly infer that that structure was only a more highly-differentiated form of shell-growth. Such incipient structure occurs in the *Ostreadæ* and *Spondylus*, in which the shell-muscle dips down from layer to layer, offering a rough similarity to the siphuncle in *Aturia* and some other *Nautili.* Mr. Woodward described the structure of the shell, and showed by actual dissection that no vascular system exists between the shell and the animal by means of the siphuncle. The siphuncle proves only to be a pearly tube, within which is another composed of an extension of the periostracum, and quite destitute of vascular or cellular structure. Shell structure proves, when once formed, to be dead matter, destitute of change, and can only be repaired when in contact with the mantle of the shell.

On a New Species of Coral.—Mr. W. S. Kent. In 1869, when examining the collection of Madrepores in the Paris Museum, the author found a worn specimen having a close general resemblance to *Alveopora fenestrata*, Dana. A superficial examination at once showed it to be quite distinct from that species, and the presence of numerous irregularly-disposed but perfect and well-developed tabulæ demonstrated its close relationship to the ancient genus *Favosites*; the cretaceous genus *Koninckia* forming the immediate connecting link. To this remarkable form he gave the name *Favositipora deshayesana.* Diagrams were exhibited showing the structure of this new coral, as also photographs of the original specimen.

The Secretary read a letter from Dr. J. E. Gray, of the British Museum, in which he described a new genus, *Callisphæra*, for the beautiful sponge from Setubal, described by Mr. Kent as *Pheronema grayi*, and which he believed differed in several particulars from the genus *Pheronema.* He also provisionally referred the *Holtenia pourtalesii* of Schmidt to the genus *Vazella*, and the same author's *Tetilla polyura* to the genus *Polyurella.*

Mr. J. Gwyn Jeffreys, who had just returned from the south of Europe, after having accomplished his part of this year's deep-sea exploring expedition in H.M.S. *Porcupine*, stated that in this cruise he had dredged across the Bay of Biscay, and along the coasts of Spain and Portugal to Gibraltar. The weather had not been favourable; but the depth reached was 1,095 fathoms. A large collection of Mollusca, Echinoderms, Corals, Sponges, and Hydrozoa, had been made. Half-a-dozen specimens of a beautiful new *Pentacrinus* (*P. wyville-thomsoni*) had been taken in 795 fathoms depth, between Vigo and Lisbon. Both Northern and Mediterranean species of shells were met with.

On the Vegetable Products of Central Africa.—Colonel Grant.

On the Parasitic Habits of Pyrola rotundifolia.—Mr. Gibson. In the discussion which followed this paper, the opinion was expressed that the parasitism of this species was not yet proved.

On the Desert Flora of North America.—Dr. C. Parry.

Note on Ribes spicatum.—Professor Lawson.

Mr. E. Birchall exhibited a beautiful collection of Hybrid Sphingidæ and other Lepidoptera.

Department of Ethnology and Anthropology.

Account of the Exploration of the Victoria Cave, Settle, Yorkshire.—Mr. Boyd Dawkins.

Account of certain remarkable Earth Works at Wainfleet, Lincolnshire.—Rev. C. Sewell.

On Ancient Sculptures and Works of Art from Irish Cairns.—Dr. Conwell. The author gave a brief account of his discoveries and researches during the summer of 1865, among the ruined remains of thirty-one cairns, extending along "the Loughcrew Hills," in the county of Meath, about two miles south-east of the town of Oldcastle. So far had these ancient remains escaped all public attention previously, that it was only during his investigation of them that an officer was sent from the Ordnance Department to insert them upon a map, which is now zincographed and sold by the Ordnance publishers. Revered and sacred in former ages as must have been these resting-places of departed splendour, standing out conspicuously on the peaks of a range of hills rising to the height of nearly a thousand feet above the level of the sea, in the proverbially flat country of Meath, it is very remarkable that the site has not yet been identified with any description, reference, or allusion, in the ancient annals of the country. The unroofed chambers, and the fragments of broken urns, afforded practical evidence that these ancient tombs had been plundered at some previous period, and this fact gives additional interest to the miscellaneous collection of articles of stone, bronze, iron, amber, glass, bone, &c., found in them.

In the remains of fourteen of the cairns, the large upright stones, to the number of 115, which formed the interior chambers of the cairns, were found inscribed with devices, almost entirely novel, sometimes *punched*, and at other times *engraved*, the diversity of which may be inferred from the fact, that out of all this number there are not two alike. No key has yet been found for reading or interpreting these devices. A series of drawings were exhibited of the symbols on thirty-one stones from *a single cairn* at Loughcrew, being exactly the number of inscribed stones in the two well-known cairns of Dowth and New Grange, taken together in the same county.

The following are some of the more remarkable objects of art which were found:—Several small stone balls of various colours, one of syenite beautifully polished, and nearly three inches in diameter, and another somewhat larger, of brownish red hæmatite or iron-stone; an oval object of jet-like appearance and polished; two pendants and a bead, all of different colours, evidently portions of a necklace of stone; a ring; probably part of an ear-ring, made of jade, and nearly worn across in one place; one polished flint nodule; one leaf-shaped flint arrow-head.

Of bronze, were found several small open rings, and a very perfect bronze pin, with ornamented head.

Of iron, as might be expected, in a much corroded state, some fragments of uncertain use, two small iron rings, a piece of iron resembling one leg of a compass; another an iron chisel or punch.

Of amber, some small beads of different shapes and sizes.

Of plain glass, some small beads differing in shape and colour; and one "*double bead*," imperforated, and of a soft green hue, and some glass fragments.

Of bone, were obtained two bone beads, some bone pins—one with ornamented shaft and a metallic rivet, apparently for attaching a bead; a collection of the remains of nearly 5,000 worked bone flakes of various sizes and patterns, in a few instances preserving their original polish, as if quite modern; and upwards of 100 of these ornamented in a very high order of art, with various circles, curves, ornamental puncturings, &c., of which no description could give an adequate idea. On one was found the representation of an antlered stag: but what may have been the uses to which these bone flakes were applied, Dr. Conwell expressed himself unable to come to any conclusion. As the accounts are very meagre of any articles of "historical value," having ever been extracted from cairns, the collection now brought under notice is probably the most curious and remarkable which has ever been found joined together under similar circumstances.

On some forms of Ancient Interment in County Antrim.—Dr. Sinclair Holden.

On a Discovery of Platycnemic Men in Denbighshire.—Mr. Boyd Dawkins and Prof. Busk. Mr. Dawkins explained that the remains to which he referred were found at a place in Denbighshire which rejoiced in the name of Perthi Chwaren. They were in a cave in the mountain limestone, and the explorers found from twenty to twenty-five human skeletons, and a large quantity of the remains of animals. The skeletons were interred differently from those of modern times, in that they were lying in confused heaps, which clearly showed that the people had been buried in a sitting posture. The cave (he said) was inadequate to contain such a large number of human corpses at one time, so it followed that it was used at different times, probably as a family mausoleum. There were also found bear's bones, fragments of mussel shell, a specimen of cockle, and a tusk, one of the largest he (Mr. Dawkins) had ever seen. There was likewise discovered some pottery, fragments of coal, and a splinter of iron which was not oxydised. The only evidence as to the antiquity of the cave was a fragment of flint. Flint was used by the Romans and Egyptians, and the discovery pointed to the fact that at one time flint was the only material in use, but it did not show that this deposit was of the date when no metals were known. Mr. Dawkins thought all the evidence went to show that the cave was of the Neolithic age.—Prof. Busk next gave his conclusions with regard to the skulls which were found in the cave. He said that the people whose remains had been discovered were of low stature, the skeletons being only from 5 feet to 5 feet 6 inches in height.

On Carved Stones recently Discovered at Nithsdale, Scotland.—Dr. Grierson.

On a Quartz Implement from St. George's Sound. — Mr. H. Woodward. This crystal of quartz (having its terminal planes preserved at both ends) was found by his colleague, Mr. Davis, among a number of other minerals in the British Museum, forming part of the Old Sloane Collection. On examination it was found to have written on it in ink, "St. George's Sound, N.W. coast of America, Captain Cook." The crystal had been used as a flint implement, one end being sharp and the other notched. It had an attachment for a wooden handle, which would admirably fit it for picking holes in the ice, through which the Esquimaux might fish.

On a Flint-flake Core from the River-gravel of the Irwell, Salford, Manchester.—Mr. John Plant. The upper valley of the Irwell, the author said, was overspread with silt and sandy layers. Terraces of above 200 feet in elevation were very distinct in places. The river now flowed over the beds of New Red sandstone, having contracted its bed for at least a mile to about sixty yards. The upper terrace was composed of sand and gravel of older age than the silts which fringe the banks. The pebbles of gravel were mainly derived from the pebble beds and eroded silt, others were flattened pebbles from the coal measures. Throughout these pebbles there were no flints, but bits of chert only from mountain limestone. The weapons of Lancashire were neolithic in character, so that the occurrence of a flint-flake was remarkable from its site in the barren desert of gravel and sand in the Irwell. Mr. Plant thought the specimen he exhibited belonged to the time when the east of England was in the occupation of the early palæolithic people of Europe.

Remarks on Stone Implements from Western Africa.—Sir John Lubbock, Bart.

Section E.—Geography

The Lines for Ship Canals across the Isthmus of Panama.—Gen. W. Heine. The author said that in his various explorations, extending over twenty years, he had often found the reports made by other explorers differed from existing facts. In cases where elevations of only 150 feet had been reported, 900 feet were found to exist; and few explorers seemed to have taken into consideration the geological formation, which often consisted entirely of porphyry and basalt, and was almost as hard as cast steel. After giving an account of the line proposed across the Isthmus of Tehuantepec, Honduras, Nicaragua, and nine lines proposed across the Isthmus of Darien, he came to the conclusion that only two lines were of a kind to deserve consideration, because the expense of constructing and working the canal would not be out of proportion to the benefit derived from it.

These two lines are—1. From Aspinwall along the line of the railway to Panama, with an extreme elevation of 269 feet, a length of thirty-five miles, through rocks of porphyry and basalt, and with but middling ports of entry. 2. From the Gulf of Darien through the rivers Atrato, Casarica, Paya, and Tingra, to the Gulf of San Miguel, with an extreme elevation of 186 feet, length 52 miles, through a soil composed of alluvial deposit with some thin ranges of greyish sandstone or schist, and with very good ports of entry.

The survey of the first line was very perfect, that of the second line less so, and a more exact level was desirable. Of the nineteen expeditions undertaken, twelve were of American origin, four were undertaken by Frenchmen, one by a native Columbian, and only two by Englishmen. Considering the vast interests England had at stake in shortening a marine passage to Australia, the west coast of America, the islands of the Pacific Ocean, including Japan, he was astonished at the lack of energy, especially as the very moderate expense of 1,000*l.* to 1,500*l.* would suffice for all necessary exploring purposes.

Section G.—Mechanical Science

Hydraulic Bucketting Engine for Graving Docks and Sewerage.—Mr. Percy Westmacott, C.E. This was a short paper describing the mechanical appliances devised by Mr. Westmacott, at the suggestion of Mr. George Fosbery Lyster, dock engineer, for the purpose of emptying the Herculaneum Graving Docks, Liverpool. They were devised with the view of working in conjunction with the system that the dock engineer had resolved to adopt for working the gates, capstans, &c., and thus save the erection of another steam engine and plant for the special purpose of emptying the docks. The system adopted was the hydraulic system. The essential feature of Mr. Westmacott's engine is a scoop-shaped bucket, constructed of wrought iron, and capable of lifting 14½ tons of water. It is undesirable to give the constructive details of the engine without the drawings by which the paper was illustrated; but the following facts may be mentioned:—The minimum lift at the high level discharge is 7 feet, and the maximum 23 feet, and about 5 feet more stroke is required for tipping up the bucket. About 3 feet per second is the usual average speed of the bucket in plunging or lifting. The filling is effected in 5 seconds, but the emptying occupies from about 12 to 15 seconds, owing to a contraction that had to be made at the front end of the bucket to suit the existing masonry in the well. This latter operation, with a free mouth to the bucket, should not require any more time than the filling, if even so much. The coefficient of effect obtained by this engine is as follows:—At 7 feet (minimum) lift, ·4; at 23 feet (minimum) lift, ·6—average, ·54; which will be found to compare not unfavourably with other appliances under the same conditions of working; but the loss occasioned by the choking of passages and gagging of valves or paddles is altogether avoided by this system, which, for this reason, is peculiarly well adapted for sewerage purposes.

The President, Mr. R. B. Grantham, C.E., and Mr. Oldham expressed approval of the engine. Mr. J. F. Bramwell, C.E., F.R.S., said that for short lifts the engine would be economical, but for very high lifts he thought it would be inapplicable. In reply Mr. Westmacott said there would be no difficulty in making a 40-feet lift, while beyond that height there might be two or three buckets each above the other.

On Appliances for the Production of Heavy Forgings.—Lieut.-Colonel Clay. In this short paper the author mentioned, under the following three heads, the improvements recently introduced into the manufacture of large forgings, as illustrated by his experience at the Birkenhead Forge:—1. Improved heating by the use of Siemens's regenerative gas furnaces. 2. Facilities for handling and removing large masses of wrought iron from the furnace to the hammer, and for moving them when under the hammer. 3. Improved hammers, with a clear unfettered fall, and with such width of standards as to give the workmen all the comfort and convenience possible in executing the necessary operations of shaping, forging, and cutting the material to the required form.

On Hammering and Stone-Dressing Machinery.—Dr. J. H. Lloyd. The author claimed to have devised machinery which was particularly applicable for cutting, sawing, chiselling, drilling, and dressing stone and other substances, for forging and hammering metals, and for working the tools in general by motive power, so as to supersede hand-labour. The invention has not yet been applied; indeed, the improved machinery as yet only exists in the state of a model. The paper was illustrated by numerous drawings.

REPORTS OF COMMITTEES

REPORT OF THE RAINFALL COMMITTEE

This report was read by Mr. G. J. Symons, the secretary of the committee. It commenced by referring to the steps taken last year to secure uniformity in the registration of rain by the observers throughout the country, and to the acceptance by the General Committee of the recommendation of the Rainfall Committee that additional observers should be obtained in parts of the country where at present such observers are far from one another. Dartmoor was last year quoted as an illustration; thither after last meeting Mr. Symons proceeded, and the result is that the number of stations in that district has been doubled. There are, however, still two parts of the moor where no one lives, and no one has yet been found willing to superintend a gauge. Reference is next made to other steps taken by the committee to secure returns from various other districts, and to the success of these efforts. The committee close this portion of their report by pointing out that to keep up an amateur staff adequate to the requirements of the subject, say from 1,500 to 2,000 observers, it is indispensable that a number of new ones be enlisted each year to supply vacancies caused by deaths and removals, and they therefore intimate their desire to receive through their secretary (Mr. G. J. Symons, 62, Camden Square, London) offers of assistance from parties willing to provide themselves with the inexpensive and simple gauge now generally in use. The report then proceeded to mention that the secretary has during the past year visited and examined the gauges in use at upwards of one hundred stations. By this personal intercourse greatly improved accuracy and uniformity of procedure is secured. The committee regret that through want of funds they have been unable to make any progress with the collection of old returns during the past year. The report then proceeds to describe certain experiments carried out at Calne, in Wiltshire, by Colonel Ward, with a view to determining the difference in the amount of rain collected at various heights above the ground, not so much with a view to determining the cause of this variation as its amount, and therefrom the possibility or otherwise of reducing observations made with gauges at different heights above the ground to what they would have been at some uniform datum. This portion of the report commences by a brief notice of the experiments made by Prof. Phillips at York in the years 1832-35, then pass on to illustrate the necessity for the determination of these corrections; thence to a description of the instruments employed, and their position; and then follow a heavy batch of tables of the calculations and the results which it is impossible to abbreviate. Part of the conclusions were exhibited in the form of diagrams representing the total rainfall on the surface of the ground, and its decrease at various altitudes above it, one diagram giving the mean annual decrease, and a series of twelve others the monthly curves; from these it was perfectly obvious that the difference between a gauge on the ground and one 20ft. high is in winter nearly three times as great as in summer, and hence it becomes evident that the mean annual correction is applicable to the total fall in one or more years only, and not to individual months, for each of which separate corrections are given. The report then proceeds to consider the most suitable height for the orifice of gauges to be above ground, and gives various reasons *pro* and *con*, finally concluding that 1ft., as hitherto adopted, be still recommended. The report next refers to the tables in an appendix giving the monthly fall of rain at about 300 stations during the years 1868-69, and to various calculations in different states of progress. The report concludes by pointing out the great work being done by the voluntary and entirely gratuitous services of nearly 2,000 observers, and suggests that it would be alike graceful and an economical act on the part of the Government were they to offer to relieve the observers from the cost of reducing and publishing the observations which are now by their accuracy and completeness accepted as a type by foreign countries and our own colonies, and which are found yearly more and more useful in relation to our manufacturing and commercial interests. The committee conclude with the following words:—"A few hundreds annually would probably suffice to hold together a body of practised observers which has no equal in the world, and which once broken up, could not be replaced, since, irrespective of the difficulty of training the new observers, the continuity of the observations would be destroyed."

SCIENTIFIC SERIALS

THE *Geological Magazine* for September (No. 75) opens with an important article by Mr. E. Ray Lankester, describing a new species of *Cephalaspis* (*C. dawsoni*) from the Devonian sandstones of Gaspé, in Canada. This fish is figured, as also a spim, *Machairacanthus sulcatus*, which was found associated with it. Mr. Lankester also describes the characters of *Scaphaspis knerii.*—Mr. Davidson continues his descriptions of Italian tertiary Brachiopoda, which he illustrates with two fine plates containing a great number of figures.—Mr. Alfred Marston contributes a paper on the transition beds between the Silurian and Devonian rocks; and Mr. Lankester describes and figures a supposed new species of *Terebratula* (*T. rex*), obtained from East Anglian drifts, but probably derived from beds of Portlandian age. The remaining articles in the number are a catalogue of mammalian fossils which have been discovered in Ireland, by Mr. R. H. Scott, and a reply by Archdeacon Pratt to some remarks by M. Delaunay on Mr. Hopkins's method of determining the thickness of the earth's crust.

THE *Journal of Botany* for October commences with some Observations on Willows, by the Rev. J. E. Leefe. Dr. Hance contributes some carpological notes on Chinese plants; and Mr. A. W. Bennett his paper on the relative period of maturity of the male and female organs in hermaphrodite plants, read at the Liverpool meeting of the British Association, of which an abstract has already appeared in our columns. Dr. Ferdinand von Müller has a note on some interesting plants gathered near Lake Barlee during Mr. Forrest's recent expedition; and among the borrowed abstracts is one of Mr. Bailey's useful paper on the natural ropes used for packing cotton bales in the Brazils, read before the Literary and Philosophical Society of Manchester.

THE two longest articles in the *American Naturalist* for September are a reprint of Mr. Darwin's memoir on the movements and habits of Climbing Plants, and a highly favourable review of Wallace's "Contributions to the Theory of Natural Selection." Prof. Cope contributes an article on the Fauna of the Southern Alleghanies, and Dr. C. C. Abbott one on Mud-living Fishes. One of the most interesting papers in the number is a very short one by Dr. William Stimpson on the Deep-water Fauna of Lake Michigan, containing a short account of a series of dredging operations which has been undertaken in this lake during the present year by the Chicago Academy of Sciences. At a distance of eighteen miles from Chicago, where the depth was fourteen fathoms, the sandy or gravelly bottom was found to be nearly barren of life. Between the distances of twelve and twenty-two miles from off Racine, the average depth was forty-five fathoms, and the bottom generally a reddish or brownish sandy mud. This bottom was found to be rather densely inhabited; the captures including a *Mysis* allied to Arctic forms, which led the author to refer its original entry into the lake to the cold period of the quaternary epoch, two species of *Gammarus*, a small white *Planaria*, and a new species of *Pisidium*. The investigation of the materials obtained by the dredging parties of the Academy is now in progress, and the results will be published in full with illustrations at an early period.

SOCIETIES AND ACADEMIES

BRISTOL

The Observing Astronomical Society.—Report of Observations made during the period from Aug. 7 to Sept. 6, 1870, inclusive.—*Solar Phenomena*:—Mr. T. G. E. Elger, of Bedford, writes: "Observers of solar phenomena have seldom an opportunity of witnessing such a fine outbreak of spots as that which took place during the last fortnight of August. After the disappearance of the large group observed in the S. hemisphere (about July 31), a comparative lull in solar activity ensued, lasting thirteen days; the spots which appeared during this interval presented no remarkable features, and were mostly confined to the S. hemisphere. On the 17th, in the N. hemisphere, a large scattered group was observed, which a few days before had consisted of a congeries of minute specks; on the 18th it was 2′ 55″ in diameter, and was followed by another group, 2′ 26″ in length; both these groups diminished very rapidly after the 19th. On the 20th the two largest groups on the disc were nearly central; one of them 36″, the other 54″, in diameter. Cloudy days intervened between the 21st and 24th. On the latter date the first indications of the approaching outburst were remarked. At $4^h\ 30^m$ there were three immense groups in the N. hemisphere, extending from the centre of the disc to the E. limb; the preceding group, which was made up of very light and ill-defined penumbræ, enclosing upwards of sixty separate black spots, measured 3′ 10″ × 1′ 49″. The second group was 1′ 20″ in length, the third was too near the line to be satisfactorily measured. From the 26th to the end of the month the north maculose zone was completely crowded with groups and isolated spots, while the corresponding S. zone contained only punctures and small clusters. The following are the lengths of the three largest groups observed on the 29th: 3′ 6″, 2′ 26″, and 1′ 57″. The spotted zone could be seen with the naked eye, protected by an ordinary dark glass at noon on the 28th; it had the appearance of a dusky belt parallel to the sun's equator. Fresh groups observed in the sun's N. hemisphere during August = 11; ditto observed in the sun's S. hempishere = 15. Maximum number of groups on disc = 13 (Aug. 29, $21^h\ 18^m$); minimum number = 4 (Aug. 20, $4^h\ 15^m$).—Mr. William F. Denning, of Bristol, observed the sun with his 3in. refractor, on Aug. 28, and reports that on this date four large groups of spots were visible in the northern hemisphere. In the N.E. quadrant two large groups were perceptible lying just above the equator. In the N.W. quadrant an irregular scattered group was seen near the limb, and another group near the centre of the disc was very conspicuous. The S.E. quadrant contained three small groups, while the S.W. quadrant was entirely free from visible spots.

Aurora Borealis.—Mr. H. Michell Whitley writes that on August 20 he observed a brilliant aurora. From $11^h\ 30^m$ to 12^h it was very well defined. Straight beams of light shot up from the N. horizon to an altitude of about 35°. "These streamers faded and reappeared in other places." Mr. Henry Ormesher, of Manchester, also witnessed this phenomenon. He says, "I first observed it at $11^h\ 40^m$, but from its appearance it must have been visible for some time previous. I determined the extent of its base to be as far as W. by N. to N.E. by N. From between these points streamers shot forth in rapid succession, to a very considerable altitude, a great many of them reaching to the zenith of my place of observation. Some of these streamers were very brilliant, particularly one which at $11^h\ 50^m$ shot forth from a point just beneath the Pointers in a direction towards the polar star, and onwards to the zenith. I should think this stream of light to have been of about five minutes' duration, during which time its colour changed from a dark straw to a yellowish tinge. At $12^h\ 10^m$ there was quite an auroral arch, whose centre was towards the magnetic pole, and extending from the before-mentioned points to an altitude of at least 40°. The brightness of this arch increased until about $12^h\ 14^m$, when it was exceedingly brilliant. During the whole of the time the sky was very clear, with the exception of a reddish glow, of which the aurora was the cause.

Meteors.—Very few meteors appear to have been observed on about August 10. Mr. Edmund Heison saw nine on the 10th, three on the 11th, and two on the 12th. The Rev. S. J. Johnson watched the sky from $10^h\ 45^m$ to $11^h\ 46^m$ on the same date, and only detected one. Mr. H. Michell Whitley, of Penarth, witnessed the appearance of two meteors on the evening of August 29. The first was visible at $10^h\ 25^m$, and was accompanied with a faint train. It passed downwards below Corona Borealis. The second was seen at $10^h\ 30^m$ to the W. of Aquarius. Both were equal to a first magnitude star. On the 30th the Rev. S. J. Johnson observed the train of a very brilliant meteor. From the appearance of this train it was evident that the meteor must have become visible a degree or so to the W. of *k* Draconis and have ended a degree or two to the E. of *a* Draconis.

NEW ZEALAND

Wellington Philosophical Society, July 10.—The value of the New Zealand Flax was fully discussed, and Dr. Hector exhibited the operation of the machine he is employing in testing the strength of the various fibres for the Commissioners who have been appointed to investigate the subject. The result, as far as yet obtained, tends to prove, that while the flax of the *Phormium tenax* dressed in the native manner greatly exceeds in strength either Russian hemp or Manilla; yet, when dressed by the machines in ordinary use, it is much inferior. The few samples of the fibre prepared by retting or carefully applied chemical processes, however, gave much better results.

July 17.—Mr. T. H. Potts described an egg of the Great Auk which is in his possession.

New Zealand Institute, July 23.—Anniversary meeting, his Excellency Sir G. F. Bowen, G.C.M.G., in the chair. The president, in adverting to the transactions of the Institute and affiliated societies during the past year, drew attention to the number of contributors on a great variety of subjects to the last issued volume, as proving that a large amount of intellectual activity and practical zeal exist among the associates, although debarred by the geographical circumstances of the colony from achieving frequent meetings. The address was chiefly directed to the necessity for practical scientific instruction; and he stated that the Board of the Institute, having been applied to, the Government had recommended that a course of lectures shall be established in connection with the Museum and Laboratory, on natural history, geology, chemistry, and mineralogy. In proposing the thanks of the meeting to the president, the Hon. Mr. Fox, Premier, stated that the scheme which his Excellency had propounded would be favourably entertained by the Government, who were very desirous of assisting the diffusion of sound scientific instruction, as it was an essential step towards developing the resources of the Colony.

THURSDAY, OCTOBER 27, 1870

THE REPRESENTATION OF SCIENCE AT THE SCHOOL BOARD

AN impression seems to prevail that only those persons should be placed on the Metropolitan School Board who are already acquainted with the details of education. Against this principle we protest. We hope the new schools will be great improvements upon those which already exist. When we are told by the Bishop of Manchester that a third of these schools only are efficient, that a third are inefficient, and that a third are wholly useless, if not pernicious, it is high time that the whole system should be looked into by those who will come fresh to the inquiry, unencumbered with the ideas that have led to such disastrous results. We think, then, the public should look to that instructed body of men who are known as cultivators of science to represent them on the London School Board. Already we are glad to see signs that the class of persons we have named have found favour in the eyes of London electors. The selection of Professor Huxley and Dr. Elizabeth Garrett, as candidates for Marylebone, is highly creditable to that district of the metropolis; but their hands must be upheld by a very much larger number of candidates, if common sense and intelligence are to prevail at the councils of the School Board.

The points to which we think the earliest attention of the School Board ought to be directed, and in which men of science are likely to give the greatest assistance, are the following:—

1. *The sanitary condition of the schools.*—It is well known that in many cases our schools are foci of contagion, and the means of spreading contagious diseases. Children are frequently sent to school, not only from families where contagious diseases are present, but actually with disease upon them. No trouble should be spared to prevent this, and if necessary a short clause should be added by Act of Parliament to the Education Act, in order to punish those who in this way are the means of spreading around the destructive diseases. Nor is this all that is required. The school-rooms should be well ventilated, clean, and not overcrowded. Every Government school should be placed under the superintendence of the medical officer of health of the district in which it is placed, and he should report periodically to the School Board on the state of the school and on any departure from sanitary rules. Cleanliness should especially be encouraged and insisted on amongst the children attending the school, and if no means exist at home, baths and lavatories should be provided at the schools.

2. *The times of study.*—It is a fact well known to the physiologist, that the attention of the human mind can only be given with success to a particular subject for a limited time. The younger the brain is, the less the time during which knowledge can be taken in or retained. In opposition to these obvious facts, children are kept at their studies or in school for much longer periods than they can successfully learn. The consequence is that they remain in the close school-room whilst they ought to have been in the yard at play. This system is doubly wasteful, for both health and learning are sacrificed. The whole system of hours of study, and of play or of work, requires to be revised in our primary schools. The importance of play-grounds in the open air can hardly be overrated. It is only the practical physiologist who can appreciate the real value of muscular exercise, and the influence of fresh air from time to time during the day, to enable children to pursue their studies with success.

3. *The course of studies to be pursued.*—Here is where the Augean stable of a past education needs to be purified. The notion that when a child has learned to read, write, and cipher, he is educated, must be eradicated. These are at best but means, and are only the instruments by which education is conducted. It will be for the man of science to show his colleagues on the School Board that perhaps the better half of a liberal education may be obtained without books at all. This is the error that lies at the foundation of all our systems of education, whether conducted in our highest, middle-class, or national schools. The education of the senses by which the man is to get his living and to perform his duties in life is entirely neglected. Where attempts have been made to introduce the study of the natural sciences, it has been done solely by the aid of books, and not with that demonstration of the facts to the senses which is the only way in which such knowledge can be made useful. In a word, henceforward there must be a portion of every day taken up with teaching children by objects, specimens, or experiments, the nature of the great laws by which the universe is governed. We cannot argue here on the necessity for this knowledge. Look at that great German army, recently spoken of as the most wonderful military engine ever seen on the face of the earth. What makes it so? The intelligence of each individual of which it is composed. It is the same with wheels and pistons, spindles, hammers, chisels, and ploughs, as with guns and bayonets: the more intelligent the man is who wields or superintends them, the more successfully and prosperously will they do their work. Ten years ago Mr. Whitworth astonished the Manchester manufacturers with the account of the machines he had seen in America. "Why should we not have such machines here?" said the Manchester men. "Because," said Mr. Whitworth, "you have not intelligent hands to work them." And for these long ten years we have gone on talking about educating our working classes, and allowing priceless treasures to pass out of our hands. Every portion of Europe, as well as the United States of America, is stealing something of our rightful wealth and increasing our pauperism, because of our stolid indifference to the introduction of those branches of human knowledge which alone can properly develop the powers of industry and application, of which the English people are so wonderfully capable.

This great question of the introduction of Natural Science into all schools must be taken up by our School Boards throughout the kingdom. To delay it is to shelve it, and to commit an irretrievable error. It is now or never. If the present opportunity is neglected, all is lost. Let no heed be given to the cry that it is impossible to find teachers. If teachers cannot be found they must be made, and all old teachers must be told that unless they qualify in this respect they will be of no use. The cry of the example of our Universities must not be listened to.

We have nothing to do here with their failure to teach Natural Science, and thus to mislead where they ought to have led. What we now ask the people of England, and especially the people of London, is to put Men of Science on their School Boards.

E. LANKESTER

THE GLACIATION OF BRAZIL

Thayer Expedition: Scientific Results of a Journey in Brazil, by Louis Agassiz and his travelling Companions. Geology and Physical Geography of Brazil. By Ch. Fred. Hartt, Professor of Geology in Cornell University. With Illustrations and Maps. (Trübner and Co.)

THIS thick volume of 620 pages is the result of two visits to Brazil, the first with the Thayer Expedition, the second during a vacation holiday of "some months." The author has proposed to combine with his own personal observations all the information on this subject obtainable from other sources, and thus give a complete view of the present state of our knowledge of the geology and physical geography of this vast and interesting region. The design is an admirable one, but the execution of it is, in some respects, disappointing.

The first great fault of the book is, that it has been swelled by the introduction of much irrelevant matter. Mr. Hartt's own journeys were mainly along the coast, from Rio Janeiro to the Amazon, with occasional trips of a hundred miles or so into the interior, and he inflicts upon us pages of unimportant detail on the topography of small rivers, creeks, and harbours, which have no bearing on the geology or physical geography of the country. Detailed descriptions of the marine animals and fossils collected would also have been better in an appendix than in the body of the work where they are given. The arrangement of the book, too, is faulty, since it treats of the provinces of Brazil in succession, and makes no attempt to indicate the great physical divisions of the country, and there is not a single geological or physical map of Brazil, or of any part of it; the maps alluded to in the title-page being mere outline or sketch maps of small districts, or plans of harbours and mouths of rivers. Another strange defect is the absence of all measurement of heights. The author travelled without barometer or aneroid; he, consequently, everywhere roughly estimates his heights, and gives no sections, but a few "ideal" ones. Notwithstanding the bulk of this volume, it does not complete the geology of the voyage, for we are informed that Mr. St. John, another geologist attached to the expedition, who travelled more in the interior of the country, will give the results of his observations in a separate work.

But although we have thus plainly indicated the defects of the book, there is much valuable matter to be found in it. The author has been very diligent in examining all the chief authorities on Brazil, and has extracted from them most of their geological matter; and among the extracts from Spix and Martius, Prince NeuWied, Darwin, Gardner, Halfield, and others, are to be found many interesting passages desciiptive of the peculiarities of the scenery and geology of the country. The chapters on the coral reefs of the Abrolhos and on the gold mines of Brazil, the account of the exploration of the bone-caves by Lund, and the appendix on the Botocudos Indians, will furnish some interesting matter for the general reader, while the student of science will obtain (though with some difficulty) a notion of the general physical and geological characteristics of an almost unexplored region.

The most striking geological feature of tropical South America east of the Andes is the enormous extension of gneissic rocks, which appear to form the whole foundation and much of the surface of the country, from the cataracts of the Orinooko to Paraguay and the southern frontier of Brazil. All the great mountain tracts of Brazil and Guiana, as well as the low plain which separates the watersheds of the Orinooko and Amazon, are of this rock, which is considered to be of Laurentian age. Its characteristic features are the great dome-like masses and the conical peaks or pillars, generally of more or less smooth and rounded outlines, a peculiarity dependent on the decomposition of all exposed surfaces, which fall away in concentric flakes. Great hemispherical domes up to a thousand feet in diameter are one of the results of this decomposition wherever a more resisting mass has occurred. Still more extraordinary are the vertical pillars of rock, that rise up at intervals out of the forest to some hundreds, or, in the case of the Pedra lisa, in the province of Rio de Janeiro, to more than three thousand feet high. Similarly formed peaks or pillars in Fernando, Noronha, and St. Helena have been formed by injections of fluid felspathic lava. What an enormous amount of denudation do these isolated pillars indicate!

In South Brazil a few tracts of Silurian and Carboniferous rocks occur, but the next formation of any extent is the Cretaceous, which consists of sandstones, generally upheaved and fractured. Other sandstones, which cover an immense extent of country, and form the ranges of flat-topped hills from one to nearly three thousand feet high, called *taboleiros*, are in perfectly horizontal strata, and as these lie unconformably on the cretaceous rocks they are presumed to be tertiary, although no fossils have yet been found in them.

We now come to a very wide-spread, yet recent and superficial deposit, which is at once the most puzzling and the most interesting feature in Brazilian geology. This is a layer of clay or loam, varying in thickness from a few feet to one hundred, and wrapping in its folds hill and valley, over vast tracts of country, including the steep slopes and summits of some of the highest mountains. All Rio de Janeiro, and all the coast provinces visited by our author, were thus covered. It has been described in Minaes Geraes and San Paulo, and Prof. Agassiz has observed it in all the northern provinces as far as the Amazon valley. It covers alike the gneiss and the tertiary formations. This clay is of a red colour, and is evidently formed of the materials of the adjacent and under-lying rocks, but ground up and thoroughly mixed. There is never the least sign of stratification throughout its mass, although it very frequently rests on a thin layer of quartz pebbles. It contains, scattered through it, rounded and angular boulders of quartz, gneiss, and other rocks, and the surfaces upon which it rests are always more or less smooth and rounded. Our author always speaks of this formation as "drift," and he agrees with

Prof. Agassiz that its peculiarities are such as unmistakeably to indicate its glacial origin.

This is truly a startling conclusion, and one which has hitherto been received in this country with some incredulity. Prof. Agassiz was thought to be glacier-mad; but if we separate his theories from his facts, and if we carefully consider the additional facts and arguments adduced by Mr. Hartt in this volume, we shall be bound to conclude that, however startling, the theory of the glaciation of Brazil is supported by a mass of evidence which no unprejudiced man of science will ignore merely because it runs counter to all his preconceived opinions.

Mr. Hartt's facts and deductions have the more weight, because he is evidently not very enthusiastic on the subject, and because he fairly states the sources of error in observation, and fully discusses such other modes of explaining the facts as have been proposed. He acknowledges that in some cases the decomposed gneiss cannot be distinguished from the "drift;" but he shows that in the former the materials remain *in situ*, especially the quartz veins, while in the latter all are mixed and ground up together; and wherever the two are seen in contact for any distance, the sudden cutting off of the quartz veins at the drift, and other well-marked characters, render it impossible to confound them. He also adduces several other phenomena which are strongly indicative of a glacial origin. Both in the Orang Mountains and in Bahia there are valleys with no outlet, and in Alagoas there are many deep lakes in rock-basins. In the province of Bahia there are extensive bare, elevated, rocky plains thickly strewn with angular blocks of stone, some of which are erratics, and *exactly resembling the drift-covered plains of the north.* On similar elevated plains, far removed from any higher land, Mr. J. A. Allen (another member of the Thayer Expedition) found numerous deep and smooth pot-holes worn in solid gneiss. They were of various sizes, the largest seen being elliptical, eighteen feet long by ten wide, and twenty-seven feet deep. Similar pot-holes are known to be formed by glacial waterfalls, and they are found over the glaciated regions of New Brunswick and Nova Scotia. Heaps of débris, exactly resembling glacial moraines, have also been found both in the south and north of Brazil. Mr. Hartt is satisfied of their resemblance to true moraines in the valley of Tijuca near Rio, and Prof. Agassiz has described others still more perfect in Ceara, only four or five degrees south of the equator. After describing these in detail, he concludes: "I may say that in the whole valley of Hasli there are no accumulations of morainic materials more characteristic than those I have found here, not even about the Kirchet; neither are there any remains of the kind more striking about the valleys of Mount Desert in Maine, where the glacial phenomena are so remarkable; nor in the valleys of Loch Fine, Loch Awe, and Loch Long, in Scotland, where the traces of ancient glaciers are so distinct." It can hardly be maintained that the discoverer of glacial phenomena in our own country, and who has since lived in such a pre-eminently glaciated district as the Northern United States, is not a competent observer; and if the whole series of phenomena here alluded to have been produced without the aid of ice, we must lose all confidence in the method of reasoning from similar effects to similar causes which is the very foundation of modern geology. The only objection of any weight that has been made to this interpretation of the phenomena, is the fact of the absence of glacial striæ; but Mr. Hartt states that no striæ or polished surfaces have yet been found even in the extreme south of the continent where the glacial phenomena are undisputed. It is at best a negative argument, and as such cannot neutralise those of a positive nature. We must also remember that we have no indication of the age of the Brazilian or southern glacial epoch. It may have occurred much earlier than that of the northern hemisphere, and the greater lapse of time, combined with the powerful decomposing and denuding agency of tropical rains, may have obliterated most of such marks.

The physical difficulty of the conception of tropical glaciers may be resolved into the question of whether a subsidence to the extent of ten or twelve thousand feet may not have subsequently occurred; since a greatly increased elevation at a time when a severe glacial epoch reigned in the south temperature zone, would probably lead to the glaciation of the southern tropics down to what is now the sea-level.

A much more serious objection seems to be the biological one. If the whole surface of what is now Brazil was recently covered with a sheet of ice, whence has arisen the wonderfully rich and varied, and, in many respects, peculiar flora and fauna that now inhabit it? Judging from the map of the Atlantic given in Maury's "Physical Geography of the Sea," a rise of twelve thousand feet would only add a belt of about four hundred miles in width to tropical America; but a great part of this might have enjoyed a truly tropical climate, just as the valleys of Switzerland have a warm summer though in the immediate vicinity of glaciers. It seems probable, also, that the glaciation was a southern one, and did not extend far north of the equator, if it even reached so far, so that the whole of Venezuela and Guiana, with the additional belt of land due to elevation, might have been even more luxuriant and more densely populated than at present. There would thus have been an ample surface to support the ancestors of the existing fauna and flora of Brazil during the glacial epoch, just as there was sufficient land in Europe to support the ancestors of the existing European fauna and flora even when so much of the present surface was covered by a thick mantle of ice.

It must be stated that Mr. Hartt does not accept Prof. Agassiz's extraordinary hypothesis (which rests on a very slender basis of fact) of a great Amazonian glacier. He believes that the wide-spread beds of clays and sandstones, which Prof. Agassiz classes as glacial, are marine, and states that they agree perfectly with the tertiary beds in other parts of Brazil. The patches of drift, with erratics in the Amazon valley, may well have been produced by detached masses from the glaciers of the Andean and Brazilian highlands, which melted and deposited their load of drift in the warm waters of the ancient Amazon.

We have devoted so much of our space to this question of the Glaciation of Brazil, in the hope of attracting the attention of geologists to a country which offers such an interesting subject of inquiry, and which it is so easy and agreeable to explore. The facts, as stated by two careful observers, both thoroughly experienced in glacial phenomena, are undoubtedly such as to warrant the main conclusion drawn by them; and it is to be hoped that geologists will not ignore the facts because the conclusions seem improbable, as they so long ignored facts proving the antiquity of man for no other reason.

A. R. WALLACE

MODERN ANGLING

The Modern Practical Angler. A complete Guide to Fly-Fishing, Bottom-Fishing, and Trolling. By H. Cholmondeley-Pennell, Inspector of Fisheries. Illustrated by Fifty Engravings of Fish and Tackle. 16mo, pp. 286. (London: Fred. Warne and Co., 1870)

TO those readers of NATURE who are not acquainted with Mr. Pennell, the following quotation may serve as an introduction: "Fishing has been in a special sense my mistress—the fairest and most loving wife—in many a wild and lonely spot where, but for her gentle companionship and solace, I should have felt myself in every sense of the word alone;" whilst those of us who have for some time had an acquaintance with his writings, know that in making this confession he is perfectly sincere, and that he is one of the most devoted disciples of Izaak Walton; so that we cannot help wishing he were an "Inspector of Fisheries" (as he describes himself on the title-page), instead of being appointed by the Government to investigate the causes of failure and possibilities of improvement of our *oyster* fisheries. His book has only a partial resemblance to Walton's "Complete Angler." Those passages of pleasing simple eloquence, those fine sentiments, those virtuous precepts, in short, all those characteristics which have rendered Walton's book immortal, must not be looked for in Mr. Pennell's "Modern Angler." To imitate Walton successfully, would, indeed, require a genius of no common order; and Mr. Pennell has contented himself with giving a mere manual of the piscatorial "art" and "science" (we must not be too severe with enthusiasts about terms); and judging of it as such, we can sincerely say that it is the best and most useful handbook we have yet seen.

The book is divided into four parts, treating minutely of tackle, fly-fishing, trolling or pike-fishing, and bottom-fishing. The author takes credit for several inventions or improvements. Thus, for instance, he describes or figures the "Pennell-hook," in which "the medium between theoretical and practical requirements" is believed to be hit. We are glad to see him advocating a reduction in the number of artificial flies used at present; he proposes to substitute six typical flies, three for salmon and grilse, and three for trout, grayling, &c. We feel sure that these flies, together with those which are especially used at certain localities, will be quite sufficient for all purposes. Mr. Pennell has thought a great deal at the river-side; he is never satisfied with simply describing what, according to his experience, has proved to be the most successful method or the deadliest instrument; he always gives the reasons. Thus, in one of the chapters, we find expounded the "true theory of trout-flies," in a seconn the "theory of salmon-flies," and in a third, of white trout-flies; however, we are afraid that in expounding theories he will not be more successful in convincing his readers than the majority of theorists. For instance, to the question, For what does the salmon take the artificial fly? he gives the answer, "For its beauty and tempting appearance; probably it has an appetising effect." Let Mr. Pennell once watch a prawn (one of the principal articles of food of salmon in the sea) swimming in jerks through the water, and he will at once perceive that by means of our rod we impart to the fly the peculiar motion of the prawn, whilst the iridescence of the real creature is reproduced by the colours of the fly, which must vary according to the physical changes of the sky and water. No two things can be more unlike than a prawn and a dry artificial fly; no two things are more alike than a swimming prawn and that same fly in the water worked by a skilful hand.

But we must conclude our notice of this book, welcome and useful to every class of anglers. It is illustrated by numerous well-executed woodcuts, which are more instructive than the best descriptions. Lithographic plates of some of the more common freshwater fishes are evidently reproductions from the *Fisherman's Magazine.*

A. GÜNTHER

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

The Government and the Eclipse Expedition

WE are now within two months of the date fixed by Nature, whose name you so worthily wear, for a total Eclipse of the Sun, and it is not probable that she will postpone her appointment for a period sufficient to enable the joint committee of the Royal and Astronomical Societies to renew and succeed in their endeavour to teach the Government what such a phenomenon may, if duly observed, contribute to human knowledge. It may be taken for granted that no encouragement will be afforded by our thrifty rulers to an expedition of sixty-eight astronomers, projected for the quixotic purpose of collecting intelligence not calculated to increase the revenue.

This well-timed and praiseworthy frugality reminds me of some imputations which were, not long ago, cast at the Government by two eminent men of science, one of whom, the Astronomer Royal, lives to repent his injustice; the other, the late Dr. W. A. Miller, alas! can speak no more.

On the 31st March last, I read at a Society of Arts' conference, by request of the Council, a paper on the subject of the Relations of the State to Science. A discusssion followed, in the course of which the Astronomer Royal remarked that "having had a somewhat long connection with the Government, he was quite competent to say that there had never been any unwillingness, as far as instances occurred to him, to promote liberally the purpose of speculative science when brought before the Government, with a good cause shown, and upon the responsibility of some person in whom they placed confidence."

Here Mr. Airy lays down, with his usual clearness, the conditions necessary to induce our Government to promote liberally speculative science, namely, "a good cause shown, and on the responsibility of some person in whom they placed confidence." Our failure, then, to obtain aid on the occasion in question must have been due to one of three things—either a good cause was not shown, or the Government had no confidence in the persons showing it, or the Government differs considerably from Mr. Airy's portrait of it. Who were the persons whose worthiness of confidence is thus doubtful? The Astronomer Royal himself, the President of the Royal Society, and the President of the Astronomical Society; and these untrustworthy beguilers of our too liberal guardians of the public purse were the accredited representatives of a select joint committee of the two first scientific societies in the kingdom. As to the goodness of the cause, that is to be inferred from the character, requirements, and position of the three personages above indicated, who had the presumption to advocate it. To these two causes it is evident that the failure is due, and not to any want of liberality in statesmen, for whose readiness to promote speculative science Mr. Airy himself, one of the unsuccessful petitioners, has vouched.

The late Dr. Miller spoke as follows on the occasion above referred to:—"Gentlemen," he observed, "representing great branches of science, like the Astronomer Royal, were met by the Government with liberality; and scientific bodies, such as the Royal Society, when they made an application, after careful consideration of the objects they had in view, were also listened to with respect, and, in the majority of instances, their applications were granted. It appeared, therefore, that the great difficulty on the part of the Government was to be sure that what they expended was wisely laid out."

Dr. Miller, as Treasurer of the Royal Society, spoke with authority; he shared with the Astronomer Royal the error of imputing to Government a liberality towards science utterly inconsistent with that true economy for which they have, in so many other matters, earned high renown.

The whole transaction, considered as the latest notion in civilisation, is so ludicrous that it is difficult in speaking of it to do so seriously. It may be argued that Mr. Airy and Dr. Miller were perfectly correct in their picture of former Governments, but that our present Ministry act on different principles, and refuse to promote what their predecessors would have thought worthy objects. This hypothesis is so extremely disparaging to the Ministers of to-day, that I for one cannot adopt it. When the speeches I have cited were made I offered no reply, but I was far from assenting to the estimates of Government liberality to science in England given by Mr. Airy and Dr. Miller. I do not now for the first time say that, not only have English Governments, past and present, been backward in promoting science, but that no English Government has ever shown that it understood the value of science—how it should be promoted, or what were their duties respecting it. This inability to realise the requirements of Science is not confined to Governments—it largely pervades the most intelligent portion of the community—the whole governing class. For one man of high position and culture who comprehends the mode of advancing science, and the certain effects of advancing it, there are, not hundreds, but thousands, who have clear views regarding art, literature, and general education. Every man of wealth covers his walls with pictures and books, but how many equip a laboratory or an observatory? The knowledge of science which most educated men possess has been acquired by reading only, and their notions of what is needed to advance science, of the extent of field remaining still unoccupied, of the means requisite for cultivating it, and of the value of the produce, are, we find from every-day experience, exceedingly hazy.

The true explanation of the difference between the distinguished speakers and those who think with me I believe to be this—that the demands made upon the State by scientific men and bodies have hitherto been so moderate, so desultory, and so infrequent, that few of them could, with decency, be denied by men not utter barbarians. I am of opinion that the moderation of scientific men has been exceedingly detrimental to the nation, and utterly opposed to true economy. For it has led to the waste of the two most valuable gifts of Providence—the human intellect and the forces of nature. This moderation has encouraged the comfortable creed of English statesmen that private enterprise will do all that is needful, and that the utilisation of those two gifts forms no part of their national duties But suddenly those who have suffered Government to hug itself in its inaction, and live in a fool's paradise of indifference to duties which they do not understand, are startled by their own teachings recoiling on themselves in a rebuff unequalled for its narrowmindedness since the time of Galileo.

But a new school of scientific men is now astir, and this rebuff will quicken its energies and so do good. A Royal Commission on Science now sits, and at such a tribunal this wrong to Astronomy must be heard and judged. Let us hope that when next the sun is eclipsed, the darkness on the minds of men may not equal the darkness on the earth's face.

ALEX. STRANGE, Lieut.-Col.

The Geological Bearings of Recent Deep-Sea Explorations

YOUR report of the Proceedings of the Geological Section of the British Association (No. 51, p. 503) makes Sir Roderick Murchison say that "he hoped Mr. Jeffreys did not share the opinion of his colleague Dr. Carpenter, that their discoveries tended to upset modern geology." I have the authority of Sir Roderick to state, that he did not accuse me of any such absurdity; and that I should find what he did say on that occasion, in dissent from some of the views put forth by Prof. Wyville Thomson and myself, fully expressed in his introductory address, of which he has given me a copy. As, however, he there attributes to a passage in a lecture which I delivered eighteen months since at the Royal Institution, a sense which I never meant it to convey, I shall be obliged by your allowing me to give a precise explanation of my meaning.

The passage cited by Sir Roderick is as follows:—"The facts I have now brought before you, still more the speculations which I have ventured to connect with them, may seem to unsettle much that has been generally accredited in Geological Science; and thus to diminish rather than to augment our stock of positive knowledge; but this is the necessary result of the introduction of a new idea into any department of scientific inquiry."

Now I gave not the remotest hint of impugning those great doctrines of Stratigraphical and Palæontological succession, to which Sir Roderick refers as accepted by Uniformitarians, Catastrophists, and Evolutionists alike; my chief heresy being the indorsement of the doctrine of which my colleague, Prof. Wyville Thomson (himself a sound and accomplished Geologist), was the originator, "that we may be said to be still living in the Cretaceous Epoch." Our meaning was this:—There can now be no question that a formation, corresponding with the Chalk of the Cretaceous Epoch, alike in its material, and in the general character of its Fauna, is at present going on over a large part of the North Atlantic Sea-bed. This similarity is marked, not by the occurrence of a few types of life (like the Lingulæ and Terebratulidæ of the older formations, referred to by Sir Roderick Murchison), but by the persistence of those which constitute the formation itself, viz., the Globigerinæ, the Coccoliths and the Coccospheres; as also of numerous types of Echinodermata that were formerly considered as essentially Cretaceous, and of a great variety of those Sponges (including Xanthidia), and Foraminifera, whose abundance in the White Chalk is one of its most important features. The explorations carried on by the United States Coast Survey in the Gulf of Mexico have furnished results entirely coinciding with our own in many of these particulars.

Now it is, of course, quite open to any geologist to maintain that this Formation is a mere repetition of the Cretaceous, at a later date, under generally similar conditions. Such was, I presume, the idea of those who, several years before our researches began, had pointed out the conformity of the material of the Atlantic deposit with that of the old Chalk; and such had been my own belief, until Prof. Wyville Thomson suggested to me the probability of a continuity between the past and the present deposits, on the following ground:—The oscillations of the earth's crust, in the Northern part of the Northern Hemisphere,* during the whole Tertiary period, have not been shown anywhere to exceed 1,500, or at the most 1,800 feet, or 300 fathoms; and as the general depth of the North Atlantic Sea-bed ranges from twice to ten times that amount, there is no reason to suppose that the formation and accumulation of Globigerina-mud have been interrupted in any part of its duration. Now the termination of the Cretaceous Epoch is commonly regarded as having been marked by the elevation of the Cretaceous deposits of the European area into dry land; but there is no evidence that this change of level stopped the formation of Chalk in the deep sea elsewhere. On the contrary, according to the received doctrine of Geology, it is highly probable that coincidently with the elevation of the European area, there was a gradual subsidence of what is now the North Atlantic Sea-bed; so that the Globigerinæ and Coccoliths of the former area, with such accompanying types of animal life as could accommodate themselves to the change of conditions, would progressively spread themselves over the latter.

Now there is nothing more heterodox in this view than in M. Barrande's doctrine of "colonies," which is now, I believe, universally accepted as the explanation of a large and very important series of geological facts—the persistence, in certain outlying localities, of a Fauna characteristic of a formation stratigraphically inferior to that in which it presents itself. The only difference here is in the relative extent of the existing Cretaceous deposit in the North Atlantic, which may hold to that of Europe somewhat the relation that the English-speaking race which has colonised America does to that of the mother country, instead of

* This statement has been recently met by our friend Mr. J. Gwyn Jeffreys, who adverts to the well-known fact of the elevation of Tertiary strata in the South of Euaope to 11,000 feet. But there is no evidence, so far as we know, of any such elevation in the latitude of Great Britain, or north of it.

that which the Norse-speaking Icelanders hold to the modern Scandinavians.

If the facts be as I have now stated them, the *onus probandi* seems to me to lie upon those who affirm that a complete stop was put to the formation of Chalk before the commencement of the Tertiary period. If, on the other hand, the continuity of the existing Chalk-deposit with that which formed the Chalk of Dover Cliffs be admitted, the question, whether we can be rightly said to be "still living in the Cretaceous Epoch" seems to me one of terms rather than of essentials.

That we could not expect to find the Cretaceous Fauna *as a whole* in our modern Chalk, is evident from the considerations admirably set forth in a parallel case by the President of the Linnean Society, in his last Annual Address.

The difference is undoubtedly most marked in the *Mollusca;* only one shell, the *Terebratula caput-serpentis,* having at present been shown to be common to the Cretaceous and the Modern period. But the positive evidence of continuity afforded by the persistency of all the types which *make* the chalk, as well as of numerous forms of Echinoderms, Sponges, and Foraminifera which are among its characteristic inhabitants, appears to us to outweigh the negative evidence afforded by the larger amount of change that has taken place in the Molluscan Fauna, for which it would not be difficult to assign probable reasons.

Further, it is to be borne in mind that the successive beds of the Cretaceous formation differ from each other in a very marked manner; so that we could not expect to find, in any one deposit, more than a small part of that *ensemble* which is commonly spoken of as "the Cretaceous Fauna." What we mean by the expression to which Sir Roderick Murchison has taken exception, is simply that the facts and deductions we have brought together justify the assumption of the continuous prevalence of the same general Physical and Biological conditions, in the deep sea that separates the northern parts of the European and American continents, from the time when the Chalk of those continents was raised into dry land to the present date. This is perfectly compatible with those changes in the conditions of the shallower portions, which have given origin to the long succession of Tertiary deposits.

Passing from this topic, I now proceed to other points on which the researches of Prof. Wyville Thomson and myself appear to us to invalidate Geological doctrines that have gained general currency.

Up to the commencement of the recent exploration of the Deep Sea bottom by means of the Dredge, the doctrine propounded by Prof. Edward Forbes as to the limitation of Animal Life to a depth of 300 or 400 fathoms, and the consequently *azoic* character of all deposits formed at depths exceeding that amount, was generally accepted by Geologists; partly on account of the deservedly high authority of its originator, and partly because it appeared to afford a simple explanation of phenomena which had long perplexed Geologists and Palæontologists, viz., the occurrence at various epochs of vast accumulations of sedimentary strata apparently altogether devoid of organic remains. The indications obtained by the Sounding apparatus, of the existence, not merely of humble Foraminifera, but of Annelids, Echinoderms and Crustacea, at depths far exceeding Edward Forbes's limits, were not generally accepted, either by Zoologists or Palæontologists, as indicating the presence of a varied and abundant Fauna on the ocean bottom; for although Dr. Wallich, with a sagacity to which I have uniformly endeavoured to do full justice, had argued that they should be, it was specially noticed that these researches gave no evidence of the existence, at great depths, either of Mollusks or of Zoophytes—the two groups whose fossil remains are usually of the highest Palæontological significance.

Now the Dredgings which were carried down in the *Lightning* Expedition of 1869 to 650 fathoms, and in the *Porcupine* Expedition of 1869 to 2,435 fathoms, have established beyond all reasonable question that a varied and abundant Fauna may exist on the sea-bottom without any limit as to *depth* and *pressure;* and they have further rendered it probable that, putting aside those Animals which are necessarily restricted by the nature of their food to the depth to which living Vegetation extends, a large proportion may accommodate themselves by gradual modification to any amount of *change* in depth and pressure; so that the assumption that the occurrence of particular types is significant of the depth at which a formation was deposited, can no longer be upheld, except in the case of animals essentially littoral. For example, no doctrine has been more generally accepted than that of the limitation of the Pedunculate Crinoids to comparatively shallow water; the large West Indian representatives of that group being found growing on coral reefs, and a like *habitat* having obviously been peopled by them in the Carboniferous epoch. Yet, in the *Porcupine* dredgings of the present year, a large Pentacrinus, closely allied to the West Indian species, has been obtained near the coast of Portugal from a depth of about 800 fathoms; and the little Rhizocrinus, with another small Apiocrinoid, which I hope soon to describe under the name of Wyvillocrinus, were found last year, the former at 862 fathoms, the latter at 2,435.

Further, the *Lightning* and the *Porcupine* dredgings have fully established the position that the distribution of marine life is much more closely related to the *temperature* of the ocean-bottom, than to its depth. This is most clearly evidenced by the results of the careful exploration of the Channel of from 500 to 650 fathoms depth, which separates the plateau that supports the northern extremity of Scotland from the Faroe Banks. For we have shown that, whilst the *surface*-temperature of this Channel is everywhere nearly the same, and indicates a derivation of its upper stratum from a warmer source, a considerable part of the deeper portion of this Channel is covered by *a frigid stream,* bringing a temperature as low as 29·5° from the Arctic Ocean; this stream having in some places a depth of 2,000 feet. Thus the bottom of this Channel is divided into a *warm area,* on which the bottom-temperature at depths of from 500 to 600 fathoms is about 45°, and a *cold area* on which the bottom-temperature at like depths is 30°, or even lower. We have traced these two areas at corresponding depths within about twenty miles of each other; and where the bottom was unequal,—the slope of the plateau at the edge of the cold area, or of a bank in its midst, raising its bottom out of the *cold* stream into the *warm* which overlies it—a difference of 18·5° was found within *eight miles.* No contrast could well be more striking than that which presented itself between the Faunæ of these two areas. The Globigerina-mud was rigorously limited to the *warm;* and of the animals living on its surface a large proportion were characteristic of the warmer-temperate seas. The bottom of the *cold* area consisted of sand and stones; and of the animals which were abundantly distributed over it, a large proportion were essentially Boreal. In the shallower portions of the cold area, where an intermediate bottom temperature prevailed, an intermixture of the two Faunæ, corresponding with the border position of this area between the Temperate and the Boreal provinces, was readily traceable.

Here, then, we have the remarkable fact that two deposits may be taking place within a few miles of each other, at the same depth and on the same Geological horizon (the area of one penetrating, so to speak, the area of the other), of which not only the Mineral character but the Fauna are alike different;—that difference being due on the one hand to the direction of the current which has furnished their materials, and on the other to the temperature of the water brought by that current. If the *cold* area were to be raised above the surface, so that the deposit at present in progress upon its bottom should become the subject of examination, by some Geologist of the future, he would find this to consist of a Sandstone formed by the disintegration of older rocks, the Fauna of which would in great degree bear a Boreal character: whilst if a portion of the *warm* area were elevated at the same time, the Geologist would be perplexed by the stratigraphical continuity with the preceding of a Cretaceous formation, the production of which entirely depends upon the extensive development of the humblest forms of animal life under the influence of a higher temperature, and which includes not only an extraordinary abundance of Sponges, but a great variety of other animal remains, several of them belonging to the warmer-temperate regions. He would naturally suppose these widely different climatic conditions to have prevailed at different periods, and would probably have had recourse to the hypothesis of a "fault" to account for the phenomenon. And yet these Formations have been shown to be going on together, at corresponding depths, over wide contiguous areas of the sea-bottom; in virtue solely of the fact that one area is traversed by an Equatorial, and the other by a Polar current. Further, in the midst of the land formed by the elevation of the Cold area, our Geologist would find hills some 1,800 feet high, covered with a Sandstone continuous with that of the land from which they rise, but rich in remains of animals belonging to a more temperate province; and might easily fall into the mistake of supposing that two such different Faunæ occurring at different levels must indicate two distinct climates separated in time; instead of indicating, as they have been shown to do, two contemporaneous but dissimilar climates, separated only by a few miles horizontally and by 300 fathoms vertically.

But further: the Temperature-soundings taken in the *Porcupine* Expeditions of 1869 and 1870 have conclusively shown that a temperature as low as 36·5° prevails over the deeper parts of the North Atlantic sea-bed; this reduction being due to the pervasion of Arctic and Antarctic waters, which come to replace the superficial flow of Equatorial water (as in the Gulf Stream and other currents) towards the Polar areas. In conformity with this depression of temperature, many species of Mollusca, Crustacea, and Echinodermata, formerly supposed to be purely Arctic, have been found to range southwards in deep water as far as the Straits of Gibraltar; and we have shown it to be highly probable that an extension of the same mode of exploration would bring them up from the abysses of even intertropical seas, over which a similar climate prevails, and that an actual continuity may thus be found to exist between the Arctic and the Antarctic Faunæ. This idea was well put forth some years since by our excellent friend Prof. Lovén, of Stockholm, in his discussion of the results of the deep-sea dredgings executed by the Swedish Spitzbergen Expedition of 1861, under Torell. "Considering," he says, "the power of endurance in these lower marine animals, and recollecting the facts that properly Arctic species which live also on the coast of Europe, are generally found there at greater depths than in their proper home, and that certain Antarctic species very closely agree with Arctic species, the idea occurs that, while in our own seas and those of warm climates, the surface, the coast line, and the lesser depths are peopled with a rich and varied Fauna, there exists in the great Atlantic depression, perhaps in all the abysses of our globe, and continued from Pole to Pole, a Fauna of the same general character, thriving under severe conditions, and approaching the surface where none but such exist in the coldest seas."

But whilst the question of Deep-sea Temperature is one of the greatest Biological interest, its determination is of even greater importance to the Geologist, as affecting his interpretation of the phenomena on which his belief in a former general prevalence of a Glacial climate is founded. For if a Glacial temperature should be found now to prevail, and types of Animal life conformable thereto should prove to be diffused, over the deeper portion of the *existing* Sea-bed in all parts of the globe, it is obvious that the same may have been the case at *any* Geological epoch; for there must have been deep seas in all periods, and the Physical forces which maintain the oceanic circulation at the present time must have been always in operation, though modified in their local action by the distribution of land and water existing at any particular date. And as the elevation of the present deep-sea bed of even the Intertropical oceanic area would (if we have correctly interpreted the results of our own and others' observations) offer to the study of the Geologist of the future a deposit characterised by the presence of Polar types, so must the Geologist of the present hesitate in regarding the occurrence of Boreal types in any marine deposit as adequate evidence *per se* of the general extension of Glacial action into temperate or tropical regions. At any rate, it may be considered as having been now placed beyond reasonable doubt, that a Glacial Submarine climate may prevail over any area, without having any relation whatever to the Terrestrial climate of that area.

These views are offered by us with the more confidence, since they are in harmony with the deductions already drawn by Geologists of eminence from facts observed by them. Thus I find on my return from the Mediterranean a letter from Principal Dawson, of Montreal, from which I am sure he would permit me to make public the following extract:—

". . . In reading your recent interesting publications on the Life of the Deep Sea, it occurred to me to mention to you that the fact which you have proved on the European coast, as to the existence and action of cold Arctic currents on the bottom of the ocean, was affirmed by me years ago for the American coast, on geological and geographical evidence, and was applied to the explanation of the Post-pliocene climate. On the American coast we have the cold currents in shallower water than you have now; though in the Post-pliocene you had them in shallow water also. It is true that the Glacial theories of Agassiz and others have prevented the proper amount of attention to these facts; but I have insisted on them again and again, and fully believe that the varying distribution of the cold and warm currents, depending on the elevation and depression of the sea bottom, will account for most of the differences of climate indicated by fossils and boulders from the Laurentian to the Modern period. I have some new and unpublished facts on this subject, which I intend to bring out in connection with the work I am now doing with the help of your brother, in the Post-pliocene geology of Canada."

In conclusion, I venture to anticipate that the words with which I concluded my lecture at the Royal Institution, "On the Results obtained in the *Lightning* Expedition of 1868," will be found to have been fully justified by those of the "*Porcupine* Expeditions" of 1869 and 1870; and that whatever may be thought of the notion that "we are still living in the Cretaceous epoch," we have furnished adequate proof that the formation of Glacial beds was not limited to any special Geological period, but that they are now, and have been through all time, in course of deposition:—"The facts I have now brought before you, still more the speculations which I have ventured to connect with them, may seem to unsettle much that has been generally accredited in Geological Science, and thus to diminish rather than to augment our stock of positive knowledge; but this is the necessary result of the introduction of a new idea into any department of scientific inquiry. Like the flood which tests the security of every foundation that stands in the way of its onward rush, overthrowing the house built only on the sand, but leaving unharmed the edifice which rests secure on the solid rock, so does a new method of research, a new series of facts, or a new application of facts previously known, come to bear with impetuous force on a whole fabric of doctrine, and subject it to an undermining power which nothing can resist, save that which rests on the solid rock of Truth. And it is here that the Moral value of Scientific study, pursued in a spirit worthy of its elevated aims, pre-eminently shows itself. For, as was grandly said by Schiller in his admirable contrast between the Trader in Science and the true Philosopher, 'New discoveries in the field of his activity which depress the one, enrapture the other. Perhaps they fill a chasm which the growth of his ideas had rendered more wide and unseemly; or they place the last stone, the only one wanting, to the completion of the structure of his ideas. But even should they shiver it into ruins, should a new series of ideas, a new aspect of nature, a newly-discovered law in the physical world, overthrow the whole fabric of his knowledge, *he has always loved truth better than his system*, and gladly will he exchange her old and defective form for a new and fairer one.'"

WILLIAM B. CARPENTER

On a Method of Ascertaining the Rate of Ascent of Fluid in Plants

WHEN conducting a series of physiological experiments on the transpiration of fluid by leaves, it became a matter of importance to determine the rapidity of ascent of fluid. My colleague, Prof. Church, had suggested for another series of experiments the use of lithium citrate, a salt easily taken up by plants, and one which can be detected with the greatest readiness by means of the spectroscope. Preference was given to the citrate, because of its containing an organic acid, and on this account not likely to meet with any obstruction to its passage from the tissues. This method I have used with great success. In one experiment the fluid had risen nine inches in thirty minutes, in another five and a half inches in ten minutes. This method is greatly superior to the use of colouring matters, which seem to experience considerable resistance in their passage through the vessels. Full particulars of these and numerous other experiments in the same direction will shortly be published. W. R. M'NAB, M.D.

Royal Agricultural College, Cirencester, Oct. 20

The Aurora Borealis

HAVING read the two accounts of Aurora Borealis in this week's number of NATURE, I hope the following brief account of the very beautiful one that occurred here may not prove uninteresting. On Friday, the 14th Oct. at 8.15 p.m., I noticed a bright appearance towards the north-west, somewhat resembling the moon rising, and on going to the front of the house which faced the north, saw that the whole of the horizon from west to south-east was lit up with a bluish white light. Gradually long streaks of the same colour stretched themselves up almost to the zenith, and then a blood-coloured light formed the higher portions, while the lower kept the bluish white colour already noticed.

Then appeared in the west a long broad band reaching to the zenith, consisting of a number of narrower bands, alternately red and bluish white, and through this the stars could be seen in their natural colour. At 9.30 the blood-red colour of the higher parts had almost disappeared, and long narrow streaks of yellowish white light extended up from the horizon.

At the lower part of the whiter light, in a northerly direction, appeared shadows having a somewhat rectangular form. (The town lies just in front of where I was standing, so that these shadows may have been caused by the ascending smoke.)

At 10.30 the red colour remained only in the west, and a narrow arc of bluish white light extended from north to about north-west, at about 25° above the horizon. The air was very calm, there being but a slight movement from the north-west. The moon was shining brightly all the time. Not having access to magnetic instruments I am unable to state how they were affected. On the 12th the barometer had fallen suddenly to 28·5°, and a violent westerly wind prevailed all day.

Dublin, Oct 18 T. W. PHILIPS

THIS evening, October 24, occurred one of the grandest displays of auroral lights which has probably ever been witnessed in these latitudes.

As I was, at a few minutes after seven o'clock, passing through the Observatory with the intention of observing with the heliometer, my attention was attracted by the brightness of the northern portion of the sky. On going out into the North Garden, I perceived that this was due to a general illumination of the sky of about that intensity which is produced by the rising of the full moon on the sky immediately above it, the moon itself not being visible. The contrast between this white illuminated sky, and the deep ordinary blue on the south side of the zenith, was very striking, the two portions being with moderate accuracy separated by the prime vertical.

On the south side of the zenith was observed what appeared to be an illuminated cloud, extending nearly from the zenith in a south-easterly direction for about forty degrees. Finally, there was at this time a well-defined arch of light, corresponding pretty accurately in position with the equator, and visible from east to west nearly to the horizon; and, beneath this arch, the sky was unusually dark, the darkness not being due to cloud or mist, as the stars were seen with their usual distinctness.

There was a small tendency at intervals to a display of streamers, but they were not conspicuous. From these phenomena I was led to expect, in the course of the evening, a grand display of aurora, and I was quite prepared for the summons, which I received from Mr. Keating, the assistant on duty, at eight o'clock, to come down and witness it.

The spectacle at this time was most magnificent. The northern portion of the heavens was nearly covered with crimson light of great intensity, and the sight was so fine that, for a few moments, I was occupied only with the admiration which it excited.

On proceeding to observe it more particularly, I saw that it consisted mainly of two large sheets of crimson light, one chiefly on the east side of the sky and the other on the west.

The eastern sheet extended generally from Polaris to Capella towards the zenith, which it did not, however, at this time quite reach. The most brilliant sets of streamers had their centres passing through these stars, and, after a few minutes, the extreme eastern portion was tolerably well defined by Perseus and Cassiopeia.

The western sheet was equally well defined, as lying between α Lyræ and α Aquilæ, but its brilliancy and the rapid change produced by the streamers were inferior to those exhibited in the other portion at the time when I observed it.

It is also worthy of remark, that the two portions seemed to be connected by an illuminated fleecy or cirrus cloud a little south of the zenith. This apparent cloud was, I believe, also a portion of auroral light, as I examined it a few minutes afterwards when it exhibited more of the auroral character.

At this time the portion of the eastern sheet, which had passed through Polaris, became separated from its more eastern portion passing through Capella, and formed a distinct sheet, while the western sheet was apparently drifting still more towards the south-west.

In a few minutes the intensity of the light diminished rapidly, and, as it was fading, my attention was attracted to a very beautiful feature in the phenomena exhibited. Just below the red light of the most western position, was a most brilliant bluish white light vaguely defined but very intense. It was most probably pure white, the bluish appearance being the effect of contrast with the red. The arch which I had observed earlier in the evening was now much brighter, and extended in the direction of the equator to the eastern portion of the heavens, where there was soon a similar effulgence of white light, but not quite so intense.

The darkness of the sky (perfectly free from cloud) beneath the bright arch was now much more conspicuous than it had been in the earlier part of the evening.

In a few minutes the whole faded away, and, excepting some small remains of the phenomena in the north, nothing unusual was visible. The grandest part of the phenomena continued for about half an hour, that is, from eight till half-past eight o'clock. Later in the evening a tolerably bright bank of auroral light was visible above the Northern horizon, and another brilliant display occurred, as described by Mr. Lucas.

For a considerable time during the first display, Mr. Lucas was watching from the tower of the Observatory, where he commanded a full view of the northern half of the heavens, and saw, at about $8^h\ 15^m$ to $8^h\ 20^m$, an ill-defined dark segment along the north horizon, from which white streamers issued through the whole extent, very much resembling an ordinary aurora, but which might be easily passed over in the grandeur of the display.

Mr. Lucas watched from 10 o'clock, but saw nothing except the white light extending under the Great Bear, till $10^h\ 30^m$, at which time white streamers shot up to Polaris and Beta Cephei, changing to intense red. At $11^h\ 10^m$ two sets of streamers appeared, one near Alpha and Beta Ursæ Majoris, and the other a little to the east of Beta Draconis, the former going eastward to *h* Ursæ Majoris, and the latter westward past Gamma Draconis. These were succeeded by some at Alpha Lyræ, combining with the last mentioned, and the mass, of an intense red colour, travelled slowly to Alpha Aquilæ, where it remained for a considerable time, as did that of Ursa Major, while the part of the heavens appeared perfectly clear. At $11^h\ 30^m$ streamers again shot up at Beta Ursæ Minoris, and between Gamma Draconis and Alpha Lyræ for a short time, and a few faint indications were visible till a little after 12, when the sky appeared to have regained its usual appearance.

From the relation of others it appears that another brilliant display took place still later in the night.

R. MAIN,
Oxford, Oct. 26 Radcliffe Observer

HAVING occasion to leave my house at 6.40 (the time given is Greenwich mean time throughout, and the bearings and directions were estimated from the pole-star, not compass) this evening, I was immediately struck with an unusual amount of uniformly diffused white light in the west and north-west. In a very few minutes a band of the same colour, but brighter, appeared, extending continuously across the sky, from W.S.W. to E.N.E. It was sharply defined, somewhat variable in breadth, but commonly about 6°. It lasted for nearly a quarter of an hour, and gradually disappeared, from the east westward. The diffused light, previously mentioned, remained unaffected. There were a few clouds in the south, but none elsewhere.

From 7.15 I went out of doors at intervals of a quarter of an hour to observe, but saw nothing but the diffused light already spoken of, which seemed to have acquired a greenish tinge, until 8 o'clock; when there was a band, broader than that first noticed, and of fiery rose colour, which extended from due east or not more than a degree or two north of it, towards the west, becoming gradually fainter in the latter direction. In a very few minutes the band became continuous from east to west, from 10 to 12° broad, and at the meridian, where it culminated, about 54° above the horizon at its upper edge, as estimated from the immersion of the pole-star within it, and which was occasionally much obscured by it. The red colour was equally pronounced in the east and in the west, but less so at the meridian and for about 15° on each side of it. Below the band, from N.W. to N.E. the sky was free from the red colour, but still retained the greenish diffused light. Soon after the formation of the complete band, streamers, varying from white to various degrees of red, shot up from every part of the northern half of the horizon towards the zenith, beyond which some of them extended. Those from the north, chiefly of white light, crossed the band at right angles, whilst the others cut it more and more obliquely according as they were nearer to the east and west. I watched it continuously with a large party of friends until something after half-past eight, and then left it in full vigour. Before nine it had in great measure disappeared, but the diffused white light still lingered, gradually becoming more and more limited in extent, though remaining equally pronounced, until 10.30; when it occupied the small segment of the sky comprised within about 5° on each side of the north point of the horizon, and from 6° to 7° above it.

Lamorna, Torquay, Oct. 24 W. PENGELLY

THE AMERICAN GOVERNMENT ECLIPSE EXPEDITION

AT the last session of the Congress of the United States of America, an appropriation of 6,000*l.* was made for the observation of the Total Eclipse of the Sun, under the direction of Professor Benjamin Peirce, the Superintendent of the U.S. Coast Survey. This generous act of legislation was suggested by one of the ablest statesmen of America, the Hon. John A. Bingham, of Ohio, and passed both houses unanimously.

An officer was immediately sent to examine the various places, and obtain all the local information which might be required to select the most favourable positions for observation. The expedition has been divided into two parties, each of which consists of about twelve persons. One party is under the immediate direction of Prof. Peirce, and will observe in Sicily; and the other is under the direction of Prof. Winlock, the director of the Observatory of Harvard University, and will observe in Spain. Almost all the astronomers of the expedition were upon the central path of the great eclipse which occurred in America in August 1869, so that they have already been under fire, and are prepared for the sudden outburst of the total obscuration.

The observations for precision will be entrusted in each party to an experienced officer of the survey, who will be upon the ground at least a fortnight before the eclipse. He will have the instruments all properly mounted and protected, the time well observed, and the arrangements made so that the principal observers of the physical phenomena may find everything in readiness when they arrive. Their presence will not, therefore, be required till within a few days of the eclipse. The officers upon whom this duty has devolved are Mr. Schott and Mr. Dean, assistants of the Coast Survey.

The spectroscopic observations have been chiefly arranged by Professor Winlock, assisted by Professors Young and Morton. New and peculiar methods have been prepared for preserving a record of the lines of the spectrum for subsequent measurement and discussion.

The photographic preparations are varied and original. The party of Prof. Peirce will have photographic apparatus prepared by Mr. Rutherford of New York, with lenses especially ground for the purpose under his direction by Fitz of New York, and young Fitz will himself superintend this portion of the observations. The party of Prof. Winlock will have its photographic apparatus prepared, under the directions of the Professor, by Clarke, of Cambridge, and will use lenses ground by Clarke. Alvan Clarke, Jun., will also assist in these observations. Prof. Winlock's new method of photographing the sun through a long tube will be used in a portion of this class of observations. In both parties arrangements are made for long and short exposures in different instruments during the period of totality.

The polariscopic observations will be made by Prof. Pickering in the party of Prof. Winlock.

General observations of the corona will be made by as many of the party as possible, and it is hoped that Steinheil's hand comet-seekers will be especially available for this class of observation. Hand spectroscopes will also be used by several of the party, and it is hoped that in the preparations for this portion of the service material assistance will be derived from Mr. Lockyer's suggestions.

It is worthy of notice that two of the ablest officers of Engineers of the United States' Army have been detailed by the War Department to accompany the Expedition. They are Major Abbott, whose name is familiar to hydraulic engineers through his connection with General Humphrey's Monograph upon the Mississippi river, and Captain Ernst. B. P.

DR. W. ALLEN MILLER

WE have already referred to the lamented death of Dr. W. A. Miller, and now give a short sketch of his life. Dr. Miller was born at Ipswich in 1817, and received part of his education in Merchant Taylors' School. He obtained, however, his first insight into chemistry in a school belonging to the Society of Friends, at Ackworth, in Yorkshire. At the age of fifteen he was apprenticed to his uncle, who was surgeon to the General Hospital at Birmingham, and at the age of twenty he entered King's College, where (we quote from an obituary notice in the *Chemical News*) his knowledge of chemistry attracted the attention of Professor Daniell, who, during the illness of the laboratory assistant, engaged his services. In 1840 he visited Germany, and passed some time in Liebig's laboratory at Giessen. In the same year he was appointed to the post of Demonstrator in the Laboratory of King's College. In 1841 he became Assistant Lecturer to Professor Daniell, and also took his degree of M.D. in the University of London. He also assisted Professor Daniell in various scientific inquiries, and conducted the experiments on the electrolysis of saline compounds, his name being associated with that of Daniell in the paper that appeared in the *Philosophical Transactions* for 1844, In the following year he became a Fellow of the Royal Society, and on the death of Professor Daniell succeeded to the vacant chair. At this period he became greatly interested in the subject of spectrum analysis, in which he worked with great activity as an observer of the various phenomena which were then attracting the attention of the scientific world. He was a member of the Council of the Royal Society from 1848 to 1850 and from 1855 to 1857, being elected treasurer in November 1861, thereby becoming vice-president of the society. About this time his highly-trained mind and great knowledge were utilised to the highest degree in a joint research with Mr. Huggins on the spectra of stars and nebulæ, and in this class of researches his loss will be as severely felt as it will be at King's College, the Council Board of the Royal Society, and other places where his calm and sound judgment was conspicuous.

Professor Miller received the degree of LL.D., Edinburgh; of D.C.L., Oxford; and of LL.D., Cambridge. He also received the gold medal of the Astronomical Society, in conjunction with Mr. Huggins. At the time of his death he was a member of the Royal Commission which is now considering the whole question of scientific instruction and the advancement of science. His contributions to scientific knowledge, beyond those we have mentioned, were not large, his time being much taken up, as is the case with too many of our best scientific men, with teaching. His "Elements of Chemistry" is a valuable work which has long been favourably known, and has gone through several editions.

AUGUSTUS MATTHIESSEN

THE sad death of Dr. Augustus Matthiessen, which we briefly referred to in a previous number, has bereft English chemical and physical science of one of the most arduous and successful workers who ever entered her ranks. Born January 1831, in London, he from early youth upwards, manifested a great liking for chemistry, but it was not until he came of age that he entered upon its study in earnest at the University of Giessen, where he subsequently took his doctor's degree, and afterwards at Heidelberg, where, for nearly four years, he worked under the guidance of Bunsen and Kirchhoff. His first paper, "On the Preparation of the Metals of the Alkalies and Alkaline Earths by Electrolysis," appeared in the *Annalen der Chemie und Pharmacie* for March 1855, and was devoted to a description of the preparation and properties of the metals calcium and strontium, then isolated for the first time. Calcium he found to be a metal of the colour and glance of bell metal, exceedingly ductile and malleable; using water as the exciting fluid, he found it to be electropositive to magnesium, and electronegative to sodium and potassium, which at once explained why it could not be obtained from its chloride by the action of sodium or potassium at high temperatures. Next in order is a paper of his in Poggendorf's *Annalen* for 1857, communicated by Kirchhoff, in whose laboratory the results were worked out, entitled, "On the Electric Conductivity of Potassium, Sodium, Lithium, Magnesium, Calcium, and Strontium." Following this, appear in Poggendorf's *Annalen* for 1858 two communications from him "On the Electric Conductivity of Metals," and "On the Thermo-electric Series." On his return to London he worked some time at the Royal College of Chemistry under Hofmann, and published a paper "On the Action of Nitrous Acid on Aniline." Hunt had described phenol, free nitrogen and water as the products of this reaction, but he found that an intermediate reaction took place, by which ammonia was formed; extending his experiments to ethyl and diethylaniline, he obtained ethylamine and diethylamine. It was this reaction which first led him to the study of narcotine, which afterwards in his hands yielded such splendid results. After working diligently several years in a laboratory which he fitted up for himself in Torrington Square, he was appointed Professor of Chemistry to St. Mary's Hospital in 1862. It was about this period that his most important researches were carried out in conjunction with Dr. Vogt, Von Bose, Holzmann, &c., and published in a series of papers in the Philosophical Transactions of the Royal Society, to which he was admitted a Fellow in 1861. Some of the most important of these papers are those "On the Influence of Temperature on the Electric Conducting Power of Metals." It was this research which proved the important fact, that the conducting power of the pure metals decreased to the same extent between 0° and 100° C.; two remarkable exceptions, however, to this law, Iron and Thallium were the subject of a later paper; "On the Specific Gravity of Metals and Alloys;" "On the Chemical Nature of Alloys," in which he showed that nearly all the two-metal alloys may be considered as solidified solutions of the one metal in the other. Also a long series of determinations of the influence of temperature on the conducting power of alloys. He also made a most careful redetermination of the expansion of water and mercury, and found that Kopp's coefficients were slightly too low. He was a very active member of the committee appointed by the British Association "On the Standards of Electrical Resistance," and it was one of the alloys discovered by him which was finally adopted for the reproduction of the now well known B A unit of electrical resistance. His later chemical work is embodied in a series of papers in the *Philosophical Transactions*—"On the Chemical Constitution of Narcotine"—published partly in conjunction with Prof. Foster, and partly with Dr. Wright. In these he shows that one, two, and three atoms of methyl can be successively removed from narcotine, and also describes a large number of interesting derivatives of the same. In 1869 he was appointed Professor of Chemistry in St. Bartholomew's Hospital, and in the same year received the Royal Society's Gold Medal for his published researches on the metals and the opium alkaloids. One of the most important results of his last investigation is the discovery of the relation between morphia and codeia, the latter simply containing one of methyl more than the former; although, however, he succeeded in obtaining apomorphia from codeia, he was never able to reconvert apomorphia into morphia, and thus form morphia direct from codeia. At the time of his death he was occupied with the experiments on the chemical nature of pure cast-iron, of the Committee appointed to inquire into which he was a member, and also with experiments with a view to determine whether the specific heat of platinum was constant at high temperatures, and if so, to employ it in the construction of a standard pyrometer. He was also prosecuting his researches on the opium bases, and had already arrived at interesting results, which we believe will shortly be published. All the beforementioned researches display an enormous amount of manipulative skill, and there is little doubt that his success was mainly due to the wonderful acuteness of his powers of observation, and also to his great perseverance; but it is indeed surprising that, labouring under the physical disadvantages he did, he should have been able to attain such ends.

At a time when England can least afford it, she has lost one who had not only done a vast amount of valuable work, but who, there was every prospect, would do as much more in the future.

BRITISH EDIBLE FUNGI

MUSHROOMS and their congeners seem never have been in good repute since Agrippina employed one of the tribe to poison her husband, and Nero with villanous pleasantry called it the "food of the gods." With proverbial tenacity the bad name thus incurred has clung to the whole family of agarics, and what within certain limits might be called a wholesome dread has become a deep-rooted and irrational prejudice, excluding from popular use a really valuable class of vegetable esculents. We cannot altogether go along with those enthusiastic mycophagists who recognise a substitute for meat in every edible fungus, and dilate on the ozmazome and other nutritious properties of the tribe; but we readily acknowledge that their merits as secondary sources of food-supply have hitherto been unduly neglected. The great difficulty always felt in advocating the claims of the class to more extensive use has arisen from the want of some definite rules, some formula at once simple in expression and universal in application, by which to distinguish the noxious from the innocent members. Pliny, in his Natural History, goes so far as to say that the first place amongst those things which are eaten with peril must be assigned to agarics, and he expresses his surprise at the pleasure which men take "in so doubtful and dangerous a meat." But his observations show that fungi of all sorts, including even such growths as the *Fistulina hepatica*, were known to his countrymen and eaten by them without scruple. Indeed, in one particular the wisdom of the ancient Romans seems to have been superior to that of their descendants, for, while Horace lays down the rule—

> Pratensibus optima fungi
> Natura est; aliis male creditur—

the modern Ædiles of the Roman market condemn to instant destruction every specimen of the meadow mushroom (*A. campestris*) which comes within their reach. Although, however, it is not always easy to distinguish the wholesome from the unwholesome fungus, and the organs of sight and smell require some training before they can be wholly trusted in the matter, yet the dangers have been greatly exaggerated, and, as a matter of fact, hogweed is more often mistaken for parsnip and aconite for horse-radish than are *Boletus sátanas* and *Amanita verna* for their innocent brethren. No better opportunity for engaging in the study of this branch of natural history could be found than that which the present season affords; and if the treatises of Mr. Berkeley, Dr. Badham, or Mr. Worthington Smith be not at hand, the following notes on the chief edible fungi which are now to be met with may prove acceptable to some of our readers.*

With the ordinary meadow mushroon *(A. campestris)* and its near relative the horse mushroon (*A. arvensis*), every one is familiar, and both of them have occurred in profusion this autumn. Against the latter an unfounded prejudice prevails in some districts, but its larger size and coarser texture require only a little extra cooking to develop the flavour and correct indigestibility. In spite of all that has been said to the contrary, we maintain that these agarics are entitled to the first place, and for the second much rivalry exists between the orange-milk mushroom (*Lactarius deliciosus*) and the Parasol Agaric (*Agaricus procerus*). Both are readily distinguishable, and may be eaten with equal impunity. The former is chiefly found in plantations of Scotch fir and larch, is of an orange-brown colour, and firm flesh, and yields, when bruised, an exudation of orange-red milk, which turns green after a few minutes' exposure. The latter is common in pastures, and may be recognised by its tall habit, the stalk gradually enlarging at the base, the umbo of a brownish colour with spots or patches, and the gills white and unconnected with the stem. The plum

FIG. 1.—*Lactarius deliciosus* (Orange-milk Mushroom). Under fir-trees, in autumn; colour, brown-orange; milk at first orange, then green; diameter, 3 to 10 inches.

mushroom (*A. prunulus*) is for the autumn months what the St. George's mushroom (*A. gambosus*) is for the spring —a large fleshy fungus, delicate in flavour, though not so choice as the *Orcella*, for which it is often mistaken. It is to be found in shady places pretty generally throughout England, and is conspicuous from its whiteness. The gills are close together and of a pale rosy hue, and the smell of the plant has been compared to that of fresh meal.

We must mention two other fungi, common enough and easily recognised, but of their culinary virtues we do not entertain a very high opinion. These are the puff-ball, and the maned agaric (*Coprinus comatus*). The former needs no description, and perhaps others may be more fortunate than we have been in detecting the latent flavour of omelette which it is said to possess. The latter is called by Dr. Bull the "agaric of civilisation." We have met with it in farmyards, on lawns, on railway-cuttings, and, in fact, in nearly every waste place. It looks like an attenuated cocoon, snow-white at first, but gradually changing in colour and splitting upwards in a dozen places. The gills, white at first, become pink and then black; the last stage, which is very quickly reached, presaging the immediate dissolution of the plant, which gradually deliquesces into an inky-black fluid.

It would be easy to amplify this list, but we desire to avoid all risk of confusing the tyro's mind with too many details, and have purposely confined our remarks to those fungi which belong to the autumn season.

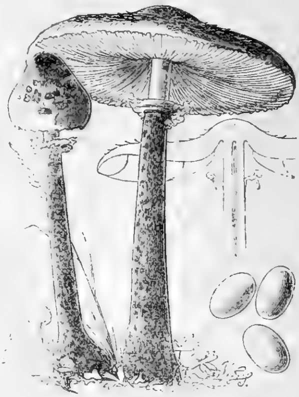

FIG. 2.—*Agaricus procerus* (Scaly Mushroom). Pastures, &c., in autumn colour, pale brownish buff; diameter, 5 to 12 inches.

One caution must be added. All agarics are more wholesome fresh than stale, and with some the neglect of this rule may lead to unpleasant consequences. It is rigidly enforced in the Roman market, where all specimens which are "muffi, guasti," or "verminosi" are seized and thrown into the Tiber, and it should be distinctly understood in every English kitchen into which even the common mushroom is allowed to enter. The fungus which to-day successfully simulates a sweetbread, may tomorrow simulate with equal success a handful of snuff.

FIG. 3.—(1) *Agaricus orcella* and (2) *Agaricus prunulus* (Plum Mushroom Woody places, in autumn; colour, snow white, with pale rose gills; diameter, 2 to 4 inches.

Our illustrations are taken from Mr. W. Robinson's admirable little manual, to which we have already alluded, and are from the facile pencil of Mr. Worthington Smith. Here will be found also instructions for cooking all the most common edible species.

C. J. ROBINSON

* At the conclusion of "Mushroom Culture, its Extension and Improvement" (London: Warne, 1870), Mr. W. Robinson gives some useful information, derived chiefly from the above authorities, and from the Proceedings of the Woolhope Field Club.

NOTES

DESIROUS of aiding the English Eclipse Expedition, Prof. Peirce has addressed the following letter to Mr. Lockyer. It is to be hoped that observers will take advantage of the opportunity so magnificently afforded them :—

"Fenton's Hotel

"MY DEAR SIR,—I have been directed by the Government of the United States to have the best possible observations made of the total eclipse of next December. If I could aid the cause of Astronomy by assisting the observers of England in their investigation of this phenomenon I should be greatly pleased. I take the liberty therefore to invite your attendance, and also that of other eminent physicists of England, with either of the parties of my expedition, one of which will go to Spain and the other to Sicily.—Yours very respectfully and faithfully,

"BENJAMIN PEIRCE

"J. Norman Lockyer, Esq., F.R.S."

Of course it would have been better had English observers, who have devoted their attention to solar physics, gone out under the English flag; but science is of no country, and they may well be proud to join such a distinguished corps as that with which they are asked to associate themselves.

WE are also informed that arrangements are being made for a deputation to urge on Mr. Gladstone, as a last resource, the importance of not abandoning the Eclipse Expedition, and to point out the especial inopportuneness of such a course at a time when neither France nor Germany can send out expeditions, and when, if we withdraw, the whole burden of observation will fall upon America. It will be remembered that the reason given by the Admiralty for refusing the loan of a Government ship was "that Parliament did not place money at the disposal of the Naval Department for such purposes." If this should be the only difficulty with the Admiralty, it will not be hard for the Deputation to find precedents, from the time of Captain Cook downwards, for sending out such expeditions. It is to be hoped that Mr. Gladstone may take a more liberal view of the subject than the Lords of the Admiralty have done, and that the leaders of science in this country will show themselves less supine in the matter than they have hitherto done.

WE are informed that the work done by Dr. Carpenter in the *Porcupine* expedition of the present year has satisfied him of the justice of the views advanced in his reply to Prof. Wyville Thomson's lecture, as to the over-estimation of the heating and moving action of the real Gulf-stream. It is Dr. Carpenter's intention to bring his views on this subject before the Royal Geographical Society.

THE Science and Art Department of the Committee of Council on Education have published a second edition of their Directory, with regulations for establishing and conducting Science Schools and Classes, superseding those previously printed.

THE amount of interest shown in Natural Science at Oxford cannot be better illustrated than by noticing the long list of lectures which are to be given this term. These, exclusive of the purely mathematical, are as follows :—1. University Lectures: Professor Phillips, F.R.S., "On the Composition and Structure of the External Parts of the Earth." Professor Lawson, "On the Minute Anatomy of Plants." Professor Rolleston, F.R.S., "On Anatomy and Physiology." Professor Pritchard, F.R.S., "On Astronomy." Professor Clifton, F.R.S., "On Elementary Statics," and a continuation of his lectures "On Heat." Mr. Wyndham, for the Professor of Chemistry, "On Elementary Principles of Chemistry." The Professor of Zoology will give assistance to all who are working at the Articulata, the collection of which he is arranging. All these are free public lectures, and are illustrated by experiments, and are all largely attended. 2. College Lectures, &c. : Mr. A. V. Harcourt, F.R.S., Lees Reader in Chemistry, "On the Chemistry of the Metals," at Christ Church. Mr. A. W. Reinold, Lees Reader in Physics, "On Hydromechanics and Heat," at Christ Church. Mr. J. B. Thompson, Lees Reader in Anatomy, "On Comparative Osteology," at Christ Church. Mr. Heathcote Wyndham, "On Chemical Philosophy," at Merton. Mr. Abbay, "On Elementary Physics," at Merton. Mr. Chapman, "On Anatomy and Physiology," at Magdalen. These lectures are open to all other Colleges on payment of a small fee.

MAGNIFICENT displays of the Aurora Borealis have been witnessed in London on two nights of the present week, Monday the 24th, and Tuesday the 25th inst. It will be interesting to hear from distant subscribers the extent of the area over which the phenomenon was visible. In addition to the letters printed this week, we have received others describing the display from C. Pocklington, Poole; E. C. Walker and T. H. Waller, York; E. Dukinfield Jones, Fermoy, Co. Cork, and others. *Apropos* of one of these displays, a correspondent of the *Pall Mall Gazette* thus states the view taken of it by the inhabitants of a little village through which he passed :—"They were all standing outside their houses gazing at the heavens. 'There is France for you,' said one of them to me as I approached him. I requested an explanation, and found that not only he but all his neighbours attributed the blood-red light in the sky to the burning of Paris. 'Gad, how it blazes!' I heard a man remark. 'They're a gettin' it hunder now,' said another; and so on through all the village. At a garden gate of nearly the last house I observed a respectable-looking man with a telescope, with which he was rolling the sky: 'It is rum,' he said to me, 'and very sublime; but the d——d asses, I can't make 'em believe it is only the Southern Cross.' I rather think he was the schoolmaster of the parish."

PROF. PETERS, of Clinton, New York, announces the discovery of a new planet (No. 112) on September 19th, of the eleventh magnitude, to which he gives the name Iphigenia. The following are given as the elements of planet No. 111 (Até) :—

Epoch, 1870, Sept. 0, 0 mean Berlin time

M	=	205°	17′	21″·0	
π	=	122	53	7·3	mean eq. 1870
Ω	=	306	26	28·4	mean eq. 1870
i	=	5	1	21·4	mean eq. 1870
ϕ	=	5	49	10·6	
μ	=			858·392	
log. a	=	0·4108808			

The planet is now nearly stationary, and is of the twelfth magnitude.

PROFESSOR LUTHER, of the Königsberg Observatory, records in the *Astronomische Nachrichten* the death, at the early age of 26, of Dr. F. Tischler, Observer in the same Observatory. Dr. Tischler was born at Breslau in 1844, and after pursuing his studies at Königsberg and Bonn, and publishing a treatise on the path of Tuttle's comet, was appointed Observer at the former place in 1867. At the outbreak of the Franco-German war, he obeyed a summons to serve in the Prussian infantry, and was seriously wounded in the battle before Metz, on August 14th, and succumbed to his injuries on September 30th.

THE first meeting of the Zoological Society for the session will take place on Tuesday, the 1st of November, when the following papers will be read :—1. The Secretary: "On Additions to the Society's Menagerie." 2. Prof. W. Peters, F.M.Z.S.: "Contributions to the knowledge of *Pectinator*, a genus of Rodent Mammalia from North-Eastern Africa." 3. Mr. C. Darwin, F.R.S.: "Note on the Habits of the *Chrysoptilus campestris*."

THE first meeting for the session of the Chemical Society will be held on Thursday evening, Nov. 3, when Mr. A. H. Elliott will read a paper "On the Analysis of Cast-iron."

THE first meeting of the Linnæan Society will be held on Thursday evening, November 3, when papers will be read by Dr. Mansel Weale "On the Fertilisation of Orchids and Asclepiads," and "On a Solitary Bee from South Africa."

THE forthcoming exhibition of the Photographic Society of London will be inaugurated by a *Conversazione* open to members and their friends, to be held at the Architectural Gallery, 9, Conduit Street, on Thursday evening, Nov. 8, at seven o'clock. The Exhibition will remain open during the remainder of November from 9 A.M. till dusk daily. Intending exhibitors are requested to send in their works not earlier than Nov. 1, nor later than Nov. 3.

WE shall be happy, in accordance with a suggestion from a correspondent, to insert (gratuitously) in our advertisement columns, a list of "Scientific books wanted" by any of our subscribers who are unable to obtain them through the ordinary channels.

THE following lectures will be delivered during the ensuing season at the London Institution, Finsbury Circus. Educational Courses—Mondays, at Four. Eight lectures on Chemical Action, by Professor Odling; Oct. 31; Nov. 7, 14, 21, 28; Dec. 5, 12, 19, 1870. Six lectures on the First Principles of Biology, by Professor Huxley, Jan. 23, 30; Feb. 6, 13, 20, 27, 1871. Eight lectures on Astronomy, by R. A. Proctor; March 6, 13, 20, 27; April 3, 17, 24; May 1, 1871. Conversazione lectures —Wednesdays, at half-past seven, On Dust and Disease, by Professor Tyndall, Dec. 21, 1870. On Alizarine and other Colouring Matters, by W. H. Perkin, Feb. 15, 1871. Stained Glass æsthetically considered with reference to Modern Art, by Henry Holiday, March 15, 1871. Evening courses—Thursdays, at half-past seven. Two lectures (with instrumental music) on the Acoustics of the Orchestra, by Dr. W. H. Stone, Nov. 10, 17, 1870. Two lectures on Precious Metals and Precious Stones, by Professor Morris, Nov. 24; Dec. 1, 1870. Two lectures on Count Romford and his Philosophical Work, by W. Mattieu Williams, Dec. 8, 15, 1870. Two lectures on Music, Characteristic and Descriptive, by John Ella, Jan. 12, 19, 1871. Four lectures on the Action, Nature, and Detection of Poisons, by F. S. Barff, Jan. 26; Feb. 2, 9, 23, 1871. Six lectures on Economic Botany, or Vegetable Substances used for Food, and in the Arts and Manufactures, by Professor Bentley, March 23, 30; April 6, 20, 27; May 4, 1871.

A COURSE of three lectures (on Nov. 4th, 7th, and 8th) will be delivered at the Gresham College, Basinghall Street, by Dr. E. Symes Thompson, on the Organs of Respiration in Health, on Hay Fever, and on the Respiratory Organs in Disease. The lectures, which are illustrated by diagrams and chemical experiments, are free to the public, and commence each evening at 7 o'clock.

MR. VAN VOORST announces the following works in preparation:—"The Natural History of the British Diatomaceæ," by Arthur Scott Donkin, M.D. "Heads of Lectures on Geology and Mineralogy," delivered at the Royal Military College, Sandhurst, by Prof. Rupert Jones. "The Ornithology of Shakespeare," by J. E. Harting. "The Natural History of the Azores," by F. DuCane Godman, F.L.S. A fourth edition of "Yarrell's British Birds," edited by Prof. Alfred Newton. A fourth edition of Prof. Rymer Jones's "Organisation of the Animal Kingdom." "Dr. Bevan on the Honey Bee," a revised and enlarged edition, by W. Augustus Munn. "Prof. Frankland's Lecture Notes for Chemical Students." Vol. 2 (Organic Chemistry).

THREE hundred bags of a remarkable-looking seed, new to British commerce, have recently been brought into this country as an oil seed; they were shipped from Lisbon to Liverpool, but are believed by the Liverpool merchants into whose hands they have been delivered to have come originally from the east coast of Africa. Mozambique is, in all probability, the port from whence they were first shipped, seeing that they are the seeds of *Telfairia pedata*, a tall climbing cucurbitaceous plant, native of the coast opposite Zanzibar. These seeds have somewhat the colour and appearance of almonds, but they are flat, nearly circular, and about 1½ inches across; they are covered with a very closely reticulated net-work of woody fibre, and the kernel is about the colour and hardness of that of a Brazil nut and contains a large quantity of oil, which is probably intended for use in this country as a culinary oil. The kernels, however, are of a rank, bitter taste, though they are stated in books to be as sweet as almonds. The fruit is very large, and is said frequently to contain as many as 250 seeds. Two species only are known of the genus, the one under consideration and *T. occidentalis*, native of the opposite or West Coast of Africa.

WE are glad to call attention to the fact that the *American Journal of Science and Arts*, which has from its commencement been the leading vehicle for the original papers of the scientific men of America, will be continued after the close of the present year as a monthly journal. This increased frequency of publication will, it is believed, meet a wish often expressed by authors for a more rapid interchange of views, and an earlier knowledge of the progress of research; and the editors hope that the friends and patrons of science will aid in promoting its wider circulation. We believe that there are many public and private libraries, and reading-rooms, throughout the country, which are not yet supplied with this journal, which is certainly one of the most important of existing scientific publications.

THE bastion in front of Fort Bicêtre, known as Bastion No. 87, is manned by the members of the Ecole Polytechnique. The professors of the college have consented to serve under their former pupils, wherever these have been selected as lieutenants. In this bastion may be seen MM. Bertrand, Bonnet, Langier, Frémy, Tissot, Laguerre—all members of the Institute, professors at either the College de France or at the Sorbonne—daily at their posts in the bastion, which has already acquired the reputation of being one of the best mounted among the fortifications of Paris.

THE Council of the Institution of Civil Engineers print a list of 38 subjects, respecting which they invite communications, as well as upon others; such as (1) Authentic Details of the Progress of any Work in Civil Engineering, as far as absolutely executed (Smeaton's Account of the Eddystone Lighthouse may be taken as an example); (2) Descriptions of Engines and Machines of various kinds; or (3) Practical Essays on Subjects connected with Engineering, as, for instance, Metallurgy. For approved Original Communications, the Council will be prepared to award the Premiums arising out of special funds devoted for the purpose.

THE shock of an earthquake was felt last Thursday at 11·30 A.M. both in the United States and in Canada. The motion, accompanied by a loud rumbling noise, was felt at Boston, New York, Montreal, Toronto, and St. Katherine, and throughout the provinces of Ontario and Quebec. The shock lasted twenty seconds, and appeared to travel eastward.

THE towns of Reading and Maidstone have been among the earliest to throw themselves into the new movement in favour of Technical Education. Classes in various departments of Natural Science are being formed at both places.

PROF. ZOELLNER ON THE SUN'S TEMPERATURE AND PHYSICAL CONSTITUTION *

AMONG the characteristic forms of the protuberances † the observation of which the spectroscope with widened slit has rendered possible at all times, is to be found a not inconsiderable number of such, whose appearance at once conveys the conviction to every impartial observer that we have here to deal with vast eruptions of incandescent hydrogen masses.

It is probably impossible, without quitting the range of known analogous occurrences and at the same time the conditions explanatory of cosmical phenomena, to assume any other cause of these eruptions than the *difference of pressure* of the issuing gas in the interior and on the surface of the sun. The possibility of such a difference of pressure presupposes, necessarily, the existence of a separating layer between the inner and outer masses of hydrogen, the latter of which, as is known, form an essential constituent of the sun's atmosphere.

The assumption of the existence of such a separating layer is, at first sight of the above-mentioned protuberance phenomena, so cogent that it even forces itself as undeniable upon observers who, like Respighi, do not hold it to be improbable that electrical forces could be the cause of such eruptions.

Keeping, however, to the more simple and therefore more natural assumption of a difference of pressure, we have to deal with a phenomenon which, on the application of the mechanical theory of heat and gases, is capable of yielding most important information as to the temperature and physical constitution of the sun.

For perfect gases the mechanical theory infers from its premises,—firstly, the law of Mariotte and Gay-Lussac; secondly, the constancy of the relation of the specific heats at constant volume and constant pressure.

This constant, therefore, when determined according to known methods for a definite gas, must, from the point of view of the mechanical theory of gases, be considered, similarly to the atomic weight of a body, as invariable, and must on no account be placed in the category of other empirical constants, such as the conducting power of bodies for heat, or the co-efficient of expansion of solid and liquid bodies, &c. These constants only hold good within those limits within which they are determined by observation, and lose their significance when employed far beyond those limits.

Under this supposition I consider the eruptive protuberances as a phenomenon of the efflux of a gas from one space into another, the pressure in both spaces during the discharge being assumed constant, and neither a communication nor an abstraction of heat as taking place.

Let A be the heat-equivalent of the unit of work,
- v the velocity of efflux of the gas in the plane of the opening,
- g the intensity of gravity on the sun,
- x the relation of the specific heats of the gas at constant pressure and constant volume,
- c the specific heat of the gas at constant volume referred to an equal weight of water,
- t_i the absolute temperature of the gas in the inner space, from which the efflux takes place,
- t_a the absolute temperature of the issuing gas in the plane of the discharge opening,
- p_i the pressure of the gas in the inner space,
- p_a the pressure in the plane of the discharge opening.

Then, according to the dynamical theory of heat, we have, under the assumptions which have been made, the following two relations‡ between these nine magnitudes:—

$$A\frac{v^2}{2g} = xc\left(t_i - t_a\right) \qquad (1)$$

$$\frac{t_i}{t_a} = \left(\frac{p_i}{p_a}\right)^{\frac{x-1}{x}} \qquad (2)$$

Further, let a_1 be the mean height of the barometer in metres of mercury,
- ρ the density of the gas under consideration at the temperature of melting ice, and under the pressure a_1 on the earth's surface,
- σ the density of the gas contained in the inner space under the pressure p_i, and at the absolute temperature t_i,
- a the coefficient of expansion of the gas for 1° C.

Conformably to the law of Mariotte and Gay-Lussac, we then have also the following relation:—

$$\sigma = \frac{\rho}{a_1 a} \frac{p_i}{t_i} \qquad (3)$$

The pressure p_a in the plane of the discharge opening may, under the suppositions made, be considered as identical with the pressure which the atmosphere of the sun exercises at the *niveau* of the above-mentioned separating layer, *i.e.*, at its base.

Let, in this case,
- p_a be the pressure at the base of the atmosphere,
- h a certain height above the base,
- p_h the pressure at this height,
- t the absolute temperature in the atmosphere, which, in consequence of insufficient knowledge of the law of temperature is assumed to be everywhere constant,
- g the gravity of the sun at the base of the atmosphere,
- r the radius of the separating layer,
- ρ_1 the specific gravity of mercury at the temperature of melting ice,
- g_1 the intensity of gravity on the earth's surface,
- a_1 the mean height of the barometer,
- ρ the density of the gas composing the atmosphere at the temperature of melting ice, and under the influence of the quantities g_1 and a_1;

we then obtain, by a known method of deduction, the following relation,

$$\text{log. nat. } \frac{p_a}{p_h} = \frac{\rho g r h}{\rho_1 g_1 a_1 a t (r + h)} \qquad (4)$$

In order to combine this with the three previous equations, a double assumption must be made:

First, that the essential constituent of the sun's atmosphere, which produces the pressure p_a, consists of the same gas as escapes from the interior of the sun during eruptive protuberances.

Secondly, that the absolute temperature t of the atmosphere, may be considered as essentially agreeing with the absolute temperature at the *niveau* of the opening during the discharge.

Having regard to the object of the present memoir, I consider the admissibility of the first assumption as sufficiently established by observations, since the discovery of the so-called chromosphere has given the proof that the whole surface of the sun is surrounded by an atmosphere of hydrogen of very considerable extent.

The correctness of the second assumption I infer *from the luminosity of the base of all eruptive protuberances not differing to any extent from that of the chromosphere.* When it is considered that the constant mean temperature t in Formula (4), which, in consequence of the want of knowledge of the law governing the decrease of temperature, is substituted for the temperatures falling with the height h, evidently must correspond to a layer near the base,* this temperature becomes at the same time approximated to that belonging to the outer surface of the separating layer.

By virtue of the first assumption, the value ρ in Formula (4)

* *T. Zöllner. Ueber die Temperatur und physische Beschaffenheit der Sonne.* Berichte Kön. Sächs. Gesellschaft der Wissenschaften. Sitzung am 2 Juni, 1870.

† The forms of the protuberances may be divided into two characteristic groups—into the vapour- or cloud-like and into the eruptive formations. The preponderance of the one or the other type appears partly to be dependent on local conditions on the surface of the sun, partly on the time, so that at particular periods the one, at others the other, type preponderates. The striking resemblance of the cloud-like formations to terrestrial clouds is readily explained, when it is considered that the forms of our clouds are due, not to the particles of water suspended in them, but essentially to the nature and manner in which the differently heated and agitated masses of air are spread out. *The particles of aqueous vapour are, in terrestrial clouds, simply the material by means of which the above-mentioned differences between the masses of air are rendered evident to us. The glow of the incandescent masses of hydrogen is the cause of the visibility of the clouds of the protuberances.*

‡ Zeuner, Grundzüge der mechanischen Wärmetheorie. 2 Aufl. 1866, p. 165.

* With regard to the increasing density of the layers of air towards the base, the temperature introduced into Formula (4) must, apart from the special law for the decrease of temperature, always agree with the temperature of a layer which lies deeper than $\frac{h}{2}$. This difference, which, as a simple calculation shows, is in general a very considerable one, seems to me to be entirely disregarded in the barometrical estimation of heights, in which, as is known, the mean temperature of the two stations is made use of, and to give a simple explanation of certain periodical phenomena which have lately been urged.

becomes identical with the analogous one in (3), and, in consequence, of the second

(2.)

$$t = t_a$$

The theoretical foundations and essential assumptions necessary for the treatment of the phenomena in question on the sun's surface having been explained, a reconstruction and simplification of the above equations, more suitable to the object in hand, may well follow.

If H denote the height to which a body with the initial velocity v on the sun's surface is hurled up in a vertical direction, then, taking the diminution of gravity into account, we have:

$$v^2 = 2gH \frac{r}{r+H}$$

or,

$$\frac{v^2}{2g} = \frac{rH}{r+H}$$

This value substituted for $\frac{v^2}{2g}$ in Equation (1) gives:

$$t_i = \frac{rHA}{xc\,(r+H)} + t_a;$$

or taking $\frac{rHA}{xc\,(r+A)} = a$, and, according to our assumption, $t_a = t$, we obtain the following for Equation (1):

$$t_i = a + t \qquad \text{(I.)}$$

Further, let

$$\frac{x-1}{x} = \frac{1}{q}$$

$$\frac{\rho}{a_1 a} = b$$

$$\frac{g}{g_1 \rho_1} = m$$

The Equations (2) (3) (4) become then converted into the following:

$$\frac{t_i}{t} = \left(\frac{p_i}{p_a}\right)^{\frac{1}{q}} \qquad \text{(II.)}$$

$$\sigma = b\,\frac{p_i}{t_i} \qquad \text{(III.)}$$

$$p = p_h e^{bm\frac{rh}{(r+h)t}} \qquad \text{(IV.)}$$

In addition there is obtained from these four equations by elimination the following:

$$\sigma = \frac{b\,p_h}{a+t}\left(\frac{a+t}{t}\right)^q e^{bm\frac{rh}{(r+h)t}} \qquad \text{(V.)}$$

This equation, of course, expresses the density, σ, of the compressed mass of gas only as a function of the three magnitudes p_h, h, and t; if, therefore, under the assumptions made, three out of the four values considered can be determined by observation, either positively or within certain degrees, the fourth can then be determined. And in fact, partly by spectroscopic, partly by other, observations, fixed extreme values can be obtained for the magnitudes σ, p_h, and h, so that thus a limit for t, that is to say, for the outer hydrogen atmosphere in the neighbourhood of the incandescent liquid separating layer, is also obtained. This value substituted in Equation (1) the value of H being known, gives then at once a value for the inner temperature t_i, and from (III.) and (IV.) fixed values for p_i and p_a can be obtained with equal ease.

(3.)

Now to proceed, however, to the discussion of numerical values, I will commence with Formula (I.)

The lowest value which can be attached to t is evidently 0. We then obtain for the inner temperature t_i the minimum value:

$$t_i = a = \frac{rHA}{xc\,(r+H)} \qquad (5)$$

Having regard to the extreme tenuity, and therefore slight resistance, of the atmosphere even at a very moderate distance from the sun's surface, the value of H may, for the sake of simplicity, be put as equal to the mean height of the eruptive protuberances. A more detailed discussion of the conditions under which this is allowable will be given later.

Protuberances three minutes high are not of very rare occurrence; to keep, however, as close as possible within the limit of an estimation of mean value, I will assume H to be only 1 minutes.

Adopting the metre and centigrade degree as units, I take the heat equivalent A as $\frac{1}{424}$. The product xc is, according to the latest researches of Regnault, for hydrogen 3·409. According to Dulong, the value of x for hydrogen is 1·411.

The numerical value of r requires a somewhat more detailed discussion. It is, according to the preceding, the radius of the separating layer from which the protuberances break forth. There then arises the question, whether this value agrees with that of the sun's radius; that is, whether this separating layer coincides or not with the portion of the sun's luminous disc, which we have made use of for our measurements.

The late researches of Frankland and Lockyer, St. Claire, Deville, and Wüllner have proved that the discontinuous spectrum of hydrogen and other gases can, by increase of pressure, be converted into a bright luminous and continuous spectrum, the bright lines of the discontinuous spectrum passing through a series of very characteristic changes, on the pressure being gradually raised, which principally, as for instance by the line Hβ, consist in a widening out and increasing indefiniteness of outline.

These changes permit within certain limits an estimation of the intensity of the pressure on the spot in question, and Frankland and Lockyer have already hazarded such conclusions. They arrive at the result "that at the lower surface of the chromosphere the pressure is very far below the pressure of the earth's atmosphere."

The researches of Wüllner, I believe, allow even the conclusion *that the pressure at the base of the chromosphere, or at the outer edge of the sun's luminous disc, must lie between 50mm. and 500mm. of a mercury barometer on the earth's surface.*

According to this, the presence of dark lines on a continuous ground in the sun's spectrum no longer compels the conclusion that this continuous spectrum is caused by the incandescence of a solid or liquid body. The continuous spectrum can equally well be considered as produced by the incandescence of a strongly compressed gas.

Wüllner has, in fact, proved this for the sodium line; for in his account of the above-mentioned researches he remarks:—

"At a pressure of 1230mm. the maximum at H_a recedes still further; the whole spectrum is truly dazzling; the sodium lines appear as beautiful dark bands;* consequently, the light of hydrogen gas is sufficiently intense to produce a Fraunhofer's line in a sodium atmosphere—a proof that the light of an incandescent solid is not necessary."

From this it follows that the radius of the visible portion of the sun's disc need not be considered as identical with that of the supposed separating layer, but that the latter probably must be looked upon as situated beneath the layer where, through increased pressure, the spectrum of the hydrogen atmosphere becomes continuous. This view is strongly supported by a consideration of the phenomena of the sun's spots.

However different the views as to the nature of the sun's spots may be, almost all observers agree that the nuclei of the spots must lie deeper than the surrounding portion.† Partly from direct (De La Rue, Stewart, Loewy), partly from indirect (Faye) observations the depth is assumed to be about 8″.‡

If, then, the nuclei of the sun's spots are considered as scoriaceous products of a local cooling down on an incandescent liquid surface and the penumbra as clouds of condensation, which at a certain height crown the coasts of these slag islands, the simplest assumption is, that the (according to this theory) necessarily liquid surface is identical with the surface of the separating layer in question from which the protuberances break forth. The radius r of this surface therefore, the observed semi-diameter of the sun being expressed in seconds, would be approximately—

$$r = R - 8''$$
$$r = 15'52''$$

* In consequence of the high temperature in the tubes, sodium volatilises out of the glass. At a pressure of 1000mm. the sodium lines are still luminous.

† Spoerer says, however, "We consider the spots to be cloudlike formations far above the luminous surface of the sun's body. The penumbra is simply a collection of smaller spots, through the spaces between which the luminous surface is visible above which the spot is situated." (Comp. Pogg. Ann. lxxviii. 270.)

‡ From calculation of Carrington's observations Faye finds this depth t be ·005 — ·009 of the sun's radius. (Comp. Rend. lxi. 270.)

Accepting Hansen's determination of the mean parallax of the sun, 8″·915 we obtain

$$r = 680{,}930{,}000 \text{ metres};$$

consequently,

$$8'' = 5{,}720{,}500 \text{ metres.}$$

We have accordingly, in order to get at a numerical estimation of the absolute minimum temperature in the space from which an eruption 1·5 minutes high breaks forth, to introduce the following values into Formula (5):—

$$r = 680{,}930{,}000$$
$$H = 64{,}370{,}000$$
$$A = \tfrac{1}{424}$$
$$xc = 3{\cdot}409$$

It is then found,

$$t_i = 49{,}690^\circ$$

If for H a double so high a value be taken, viz., the by no means rarely observed height of eruption of three minutes, a minimum value

$$t_i = 74{,}910^\circ$$

is obtained.

The question arises here, however, are we at all authorised to introduce the extreme observed heights of protuberances at once into our formulæ as values of H, in which H denotes the height to which a body hurled up from the surface of the sun would rise if there were no resistance. If in fact, and it is conclusively proved by observation, we are dealing with ascending masses of nascent hydrogen, the ascent can also take place according to the Archimedean principle, similarly to the heated masses of air, which are thereby lighter than the surrounding portions, issuing from a chimney. It is however at once manifest that both causes of motion with regard to the time in which the masses reach a certain height are essentially different. Without entering more specially into this circumstance, it is clear that the time which, in virtue of the Archimedean principle, a protuberance requires to reach a certain height H, must under all circumstances be greater than the time expended by a body thrown up with a certain initial velocity, and without resistance to the same height H.

Consequently, a possibly correct observation of the time which an ascending protuberance requires to attain a certain height may serve as a criterion, whether we have to regard this height as the result of the first cause or not, and only in the former case can this height be made use of as an integrating constituent in the above formulæ.

According to the assumptions made, the exit opening (Ausströmungsöffnung) of the protuberances is situated in the incandescent liquid separating layer at a depth $h = 8''$ below the visible border of the sun's disc. The height of a protuberance from the plane of the exit-opening was expressed above by H.

Let now:

τ = the time occupied by the protuberance in passing from the opening to the height H,

τ_1 the time occupied by the protuberance in passing from the height h, i.e., from the outer border of the photosphere, to the height H,

v, the velocity at the exit opening,

v_1, the velocity at the height h.

Then assuming the first cause, and disregarding the decrease in the intensity of gravity (g) we obtain the following equations:—

$$\tau = \sqrt{\frac{2H}{g}} \qquad \tau_1 = \sqrt{\frac{2(H-h)}{g}}$$

$$v = \sqrt{2gH} \qquad v_1 = \sqrt{2g(H-h)}$$

Then making

$$H = 64{,}370{,}000 \text{ m.}$$
$$h = 5{,}722{,}600 \text{ m.}$$
$$g = 274{\cdot}3 \text{ m.}$$

we have

$$\tau = 11 \text{ min. } 25 \text{ sec.} \qquad \tau_1 = 10 \text{ min. } 54 \text{ sec.}$$
$$v = 187{,}900 \text{ mm.} = 25{\cdot}32 \text{ geogr. miles.}$$
$$v_1 = 179{,}400 \text{ mm.} = 34{\cdot}17 \quad ,, \quad ,,$$

If, therefore, we observe a velocity of ascent of the quoted magnitude, we are entitled to make use of the height obtained by the protuberance in the above time in our equations. I have often observed such a rapidity of evolution, and annex a sketch of a protuberance, the observed velocity of ascent of which agreed well with the value above found.

With respect to the enormous initial velocities of motion, Lockyer has by his magnificent observations of the change in refrangibility of the light arrived directly at results of exactly the same order.

Lockyer,* during the short period of observations of this nature, found 40 and 120 English miles per second as maximum values for the velocities of vertical and horizontal gas currents in the chromosphere. The above values expressed in English miles gave,

$$v = 123{\cdot}1 \text{ English miles,} \quad v_1 = 117{\cdot}7 \text{ English miles,}$$

and agree, therefore, with Lockyer's values.

But movements of such magnitude pre-suppose, necessarily, according to the mechanical theory of heat, differences of temperature of 40,690° C. for hydrogen.

We shall, accordingly, be able to ascertain the actual temperature if we can succeed in determining the temperature, t, of the outer hydrogen atmosphere at a certain spot. Why this temperature is taken as agreeing approximately with the temperature in the vicinity of the exit opening has already been discussed.

(4.)

An extreme value for t is obtained by discussion of Eq. V. This equation is:—

$$\sigma = \frac{b\,p_h}{a+t}\left(\frac{a+t}{t}\right)^q e^{\,b m \frac{r h}{(r+h)t}}$$

The density σ of the included mass of gas is in this expressed as function of the three magnitudes p_h, h and t. I shall now show that σ must not exceed a certain value, by which the value of t is also indirectly fixed within a certain limit, since the magnitude $p_h + h$ are determined within certain limits by the observations already quoted.

Stress has already been laid upon the fact that the explanation of the eruptive protuberances necessarily requires the assumption of a separating layer which separates the space from which the eruptions break forth from that into which they discharge. Only by such a separating layer are the requisite differences of pressure made possible.

With regard to the physical constitution of the separating layer the further assumption must necessarily be made, that it consist of a substance other than in a gaseous condition. It can therefore only be liquid or solid. If, having regard to the high temperature, we exclude the solid condition, there then only remains the assumption, that the separating layer consists of *an incandescent liquid.*

With respect to the inner masses of hydrogen bounded by this layer, two assumptions seem on superficial considerations possible, viz.:

1. The whole interior of the sun is filled with incandescent hydrogen: the sun therefore resembles a vast hydrogen bubble surrounded by an incandescent liquid envelope.

2. The hydrogen masses which burst forth during the eruptions are local accumulations in vesicular spaces, which form in the surface layers of an incandescent liquid mass, and which break through their envelope in consequence of the increasing tension of the included gas.

Under the first assumption a stable equilibrium could only exist when the sp. gr. of the liquid boundary layer is lower than that of the layer of gas directly beneath. The density of a ball of gas, the particles of which obey the laws of Newton and Mariotte, increases, however, from the exterior to the interior, consequently the sp. gr. of the separating layer must necessarily be lower than the mean sp. gr. of the sun; if, on the other hand, the mean sp. gr. of the sun be taken as the extreme sp. gr. of the liquid separating layer, this value would at the same time involve the assumption that all the deeper layers, therefore the layer of gas immediately below, possess the same sp. gr.

The interior of the sun would then no more consist of a gas, but of an incompressible liquid. All these properties are evidently a necessary consequence of the assumption, that the sp. gr. σ of the compressed mass of gas which breaks forth during eruptions attains its maximum value, viz., that of the sun's mean sp. gr.

Then in this case the first assumption is changed into the second, viz., that the sun consists of an incompressible liquid, in which local accumulations of incandescent hydrogen masses form near the surface, which on the necessary differences of pressure burst forth from the hollows containing them as eruptive protuberances.

However small the hollows may be assumed to be in special

* Proceedings R.S. No. 115 (1869). Comp. Rend. lxix. 123.

cases, the sp. gr. of the enclosed gas masses must not be taken as higher than that of the enclosing liquid, since otherwise the compressed gas masses would, in virtue of the Archimedean principle, sink down into the interior of the sun.

The sp. gr. of the sun is, according to the latest determinations,

$$1{\cdot}46.$$

Substituting this value for σ and for a (in Formula V.), the above found value 40,690, also for h the value 8″ in metres, we obtain for the extreme values $p_h = 0{\cdot}050$ m. above given, the following values of t:

$$\text{for } p_h = 0.500 \text{ m.} \quad t = 29{,}500^\circ$$
$$\text{for } p_h = 0{\cdot}050 \text{ m.} \quad t = 26{,}000^\circ,$$

therefore in mean, $t = 27{,}700^\circ$.

On differentiating Equation (5) by t, the differential quotient $\frac{d\sigma}{dt}$ is negative. From this follows that the values found above for t are also minimum values.

From the mean value of t for the temperature of the sun's atmosphere the value of p_h is found $= 0{\cdot}180$ m. These values will be those made use of in the following calculations.

It may be noticed in connection with the high numbers obtained for the temperature values, that they are about eight times higher than the temperatures of combustion of a mixture of detonating gas as found by Bunsen, and that iron must permanently exist in a gaseous condition in the sun's atmosphere.

With the above value for $t = 27{,}700^\circ$ we obtain from Formula (I.) for the inner temperature

$$t_i = 68{,}400$$

substituting these two values of t and t_i in Formula (II.) we have

$$\frac{p_i}{p_a} = 22{\cdot}1$$

i.e., the pressure in the interior of the space from which the protuberances break forth is 22·1 times greater than the pressure on the surface of the liquid separating layer. Further substituting the value for t in Formula (IV.) and assuming as before the value of h to be 8″, we have

$$\frac{p_a}{p_h} = 766{,}000$$

as the relation of the pressure on the fluid surface of the sun to the pressure at the height h, where the hydrogen spectrum, in consequence of the pressure, begins to become continuous.

Substituting for p_h the above value of 0·180 m. mercury, we have

$$p_a = 184{,}000 \text{ atmospheres,}$$

and consequently for $p_i = 4{,}070{,}000$,,

If the depth be calculated at which in the interior of the liquid mass of the sun which has a sp. gr. of 1·46, and simply as the result of the hydrostatic pressure, this maximum pressure of p_i would be attained, it is found that this would occur at a depth of 139 geographical miles below the surface, *i.e.*, at a depth of about 1·46 arc seconds, or $\frac{1}{655}$ of the sun's semidiameter.

Even if the liquid condition be put quite out of question, and, under assumption of a much larger atmospheric envelope of hydrogen, the depth in it be calculated, at which the atmospheric pressure becomes equal to the inner pressure p_i, it is found that even assuming a temperature of 68,400°, that depth is only 27″ below the visible edge of the sun's disc, or about $\frac{1}{38}$ of the sun's apparent semidiameter.

This circumstance shows how rapidly the pressure must increase towards the interior of the sun's body, and thus justifies the assumption that in the interior of the sun, even at such high temperatures, the permanent gases, for example, hydrogen, can only exist in an incandescent liquid condition.

(5)

A surprising result is obtained if, under the assumption of a nitrogen or oxygen atmosphere of equal weight and temperature to the hydrogen atmosphere above considered, the pressure be calculated which is reached in those atmospheres at heights at which the hydrogen spectrum commences to become continuous. If at a depth of 8″ below the visible edge of the sun's disc, *i.e.*, a the riwean of the supposed separating layer, the pressure of the three atmospheres of hydrogen, oxygen, and nitrogen be assumed as equal, and that $p_a = 184{,}000$ atmospheres, a value which from the above, corresponds to the assumed value of p_h. The following values are obtained for the pressures at the temperature above found $t = 27{,}700^\circ$ on the surface of the sun's *visible* disc in the three atmospheres:—

$$\text{Hydrogen } p_h = 180 \quad \text{millimetres.}$$
$$\text{Nitrogen } p_h = 323\tfrac{1}{1078} \quad ,,$$
$$\text{Oxygen } p_h = 124\tfrac{1}{1088} \quad ,,$$

It follows from these that, the assumptions made, the quantities of the two latter gases are, in proportion to the quantity of hydrogen in that layer in which the spectrum of the latter commences to be continuous, infinitely small. This would, as is evident, also be the case if the weights of the two atmospheres were assumed to be many million times greater, although having regard to the specific gravity, a 14-times smaller weight of nitrogen and a 16-times smaller weight of oxygen would suffice, in order that under the assumed conditions the density of these two gases should coincide at the base with that of hydrogen.

According to our former considerations, the sun's mean specific gravity would also in this case have to be assumed as the maximum value of the density at the base of these atmospheres, and it is easy to calculate, with the help of Formula 3, and the known specific gravities of oxygen and nitrogen, how high the weights of these two atmospheres would have to be assumed in order to attain this maximum value.

As result is obtained, that the weight of the oxygen atmosphere could only amount to ·56, that of the nitrogen atmosphere to ·64 of the weight of the existing hydrogen atmosphere.

If therefore the simultaneous existence of these three gases on the sun's surface be assumed, and the influence of atmospheric motion be disregarded, the rays emitted by the continuous spectrum of the hydrogen layers would, on their path to our eyes, pass through so small a number of incandescent nitrogen and oxygen particles, that the absorption caused thereby is a vanishing one, and therefore, as is in fact the case, the presence of oxygen and nitrogen in the sun's spectrum could not be demonstrable by dark lines.

Although the motion of the gases is active in lessening the differences just considered, the existence of the chromosphere proves clearly the slight influence of this action in consequence of the great intensity of gravity, and the considerable height of the layer considered (compare Formula 4).

In order, however to explain through the circumstance indicated the absence of lines in the sun's spectrum of two bodies of such universal distribution on the earth as nitrogen and oxygen, the very slight emissive power of the permanent gases in proportion to that of volatilised bodies must also be taken into consideration. If the emissive power of different gases at the same temperature for rays of the same refrangibility be referred to equal very minute weights of these gases,* the before-quoted experiment of Wüllner's, in which the small amount of sodium volatilised in the Geissler's tube emitted more light than the hydrogen gas under a pressure of 1,000mm., gives a beautiful proof of the extraordinary difference of emissive—and consequently according to the theorem of Kirchhoff of absorptive—power of different gases at the same temperature. Only by consid ration of this circumstance is the contradiction removed, which could be deduced against the above explanation of the absence of nitrogen and oxygen lines from the fact that in the sun's spectrum the lines of bodies are present whose vapour densities, as a consequence of their simple relation to the atomic weights, must be much higher than the density of oxygen and nitrogen.

From these considererations, partly directly and partly indirectly through a longer series of conclusions, a detailed exposition of which I reserve for another occasion, the following result:—

1. From the absence of lines in the spectrum of a star shining in its own light, the absence of the corresponding element must not be inferred.

2. The layer in which the reversal of the spectrum occurs is different for each element—the higher the vapour density, and the lower the emissive power of the element, the nearer it is situated to the centre of the star.

3. For different stars, under otherwise similar conditions, this layer lies the nearer to the centre the greater the intensity of gravity.

4. The distances of the reversing layers of the separate elements, both from the centre of the star and from each other, increase with an increase of temperature.

5. The spectra of different stars are under otherwise similar conditions the more rich in lines, the lower their temperature and the greater their mass.

6. The great difference of intensity of the dark lines in the sun's spectrum and other fixed stars does not depend only on the differences of absorptive power, but also on the depths at which the reversal of the respective spectra takes place.

In conclusion, I would offer a few remarks on the application of the observations carried out on rarefied gases to the heavenly bodies. Lecoq de Boisbandrau* has recently pointed out, with

* Compt. Rend. lxx. p. 1091.

reference to Wüllner's investigation on the variability of spectra at different pressures and temperatures, that the results obtained must only be applied with the greatest care to the conditions of pressure of the sun's atmosphere, as the changes in the spectra are due far more to temperature than to pressure. But even under the assumption that this conjecture should become verified by special experiments, this circumstance would influence the results brought forward in this communication but in a slight degree. For the nature of the function (Formula 5) which served us in determining the temperature of the atmosphere is such that the pressure p_h under which the hydrogen spectrum becomes continuous may be varied within very wide limits without thereby causing any considerable alterations of the requisite temperature. Thus it was shown above that, by introducing the extremes of the pressure assumed which were in the proportion of 1 : 10, the temperature values resulting were only in the proportion of 1 : 1·5.

Nevertheless, the separation of the influences which pressure and temperature exercise on the nature of the spectrum of luminous gases must be regarded as a problem the solution of which is of the highest importance for astrophysics.

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

Section A.—Mathematical and Physical Science

Rainfall: its Variation with Elevations of the Gauge.—Mr. Charles Chambers, F.R.S. The fact is well known to meteorologists that the quantities of rain received in gauges placed at different heights above the ground diminish as the elevation of the gauge increases. Several attempts have been made to explain this phenomenon, but none of them are so satisfactory as to discourage the search for other causes that may contribute substantially or mainly to its production. Hence the submission for the consideration of the British Association of this further attempt. One of the principal causes of rain is undoubtedly the transfer, effected by winds, of air charged with moisture in a warm damp district to a colder region, where the vapour it contains is partially condensed. The temperature of the lower as well as of the higher horizontal strata of the atmosphere being reduced by this transfer, it may fairly be inferred that condensation of vapour may also occur in the lower as well as in the higher horizontal strata. The rain caught by a gauge at any given elevation will therefore be the sum of the condensations in all the strata above it, and thus the lower a gauge be placed the greater will be the quantity of rain received by it. Again, it is known by observation, that there is at all times a greater or less difference of electrical tension between the atmosphere and the surface of the ground. If then—in accordance with the views of Prof. Andrews as to the continuity of the liquid and gaseous states of matter, from which it follows that the change of other physical properties must also be continuous—we regard the particles of vapour suspended in the electric bodies in relation to the dielectric principal constituents of the atmosphere, they will be polarised by induction from the ground. This polarisation will give rise to an attraction between every particle and the neighbouring particles above and below it; and being stronger in the particles near the ground than in those more remote, the tendency of the particles to coalesce—which will increase, by their mutual induction, as two neighbours approach each other—will be greatest near the ground. Thus it may be, each particle gathering to itself its neighbours in succession till their united density exceeds that of the atmosphere generally, some rain drops are formed, and that in greatest abundance near the ground. If this be the true cause of any substantial part of the phenomena in question, then, as the variation in intensity of electrical polarisation of the particles will vary with the height most rapidly near the ground, so the variation in the rainfall near the ground should be more rapid than at a greater elevation, and such is indeed the fact. Also, if the idea be correct, it will probably serve to explain other phenomena which it was not specially conceived to meet; and so it does. For, first, it requires that the rainfall over even ground, where the electrical tension is relatively weak, should be less than over similarly situated forest land, where at the tops of the trees, ends of branches, and edges of leaves, the tension is high, and this is in accordance with observation. And, secondly, the tension being relatively high at the tops of the elevations of a mountainous district, the rainfall should be greater there than in the neighbouring plains; this, again, is borne out by observation. Further, at the commencement of a passing thunderstorm, a sudden heavy shower of rain will often fall for a few moments and then suddenly cease. May not this arise from the approach, by the agency of opposite wind currents, of detached masses of differently charged clouds, the process just described of formation of rain drops going on rapidly in each mass as the two come near each other, and stopping when, by a flash of lightning between them, the two masses are brought into the same electrical condition? An experimental test of this idea would be to repeat Dalton's measures of the pressure of vapour in the vacuum space of a mercurial barometer tube—filling that space with air and a little water, and compare the values found when the mercury was charged with electricity and when not so charged. If in the former case a less pressure was found, we might conclude that the particles of vapour are really susceptible of electric induction, and the amount of difference existing would enable us to estimate whether the attractions of the particles upon each other were strong enough to cause the formation of rain-drops hypothetically attributed to them above.

* A perfect transparency of the gas mass to all rays emitted by itself is here assumed, a supposition which is the nearer the truth the smaller the weights compared.

Section C.—Geology

On the Mountain Limestone of Flintshire and part of Denbighshire.—Mr. G. H. Morton. Minute details of the physical structure of the region, and lists of the fossils, showed that these beds have been erroneously referred to the Millstone Grit, and that they were really Mountain Limestone, the shales and sandstones being intercalated among the typical rocks. The white limestone was an ancient coral reef, with the organisms exquisitely preserved. Mr. Hughes protested against co-relating with the Yorkshire beds, while Mr. Bailey supported the opinions of the author.

On the formation of Swallow-holes, or Pits with vertical Sides, in Mountain Limestone.—Mr. L. C. Miall. The author distinguished between cavities formed by direct excavation and those produced by subsidence of part of the roof of a cavern. The curious pits near the Buttertubs Pass at the head of Swaledale, were regarded as typical of the first kind, and their appearance and mode of formation were described, especially the vertical fluted sides and the isolated fluted pillars, which were ascribed to the action of dropping water, aided by pebbles. A basin is first formed upon a ledge of rock, and as the excavation proceeds it produces a semi-cylindrical scar, with sharp ridges upon the face of the limestone wall, as if cut by a gauge. The presence of a thick surface-covering of alluvium or drift was necessary to absorb and retain the rainfall, and to distribute it slowly and regularly. The limestone of a bare plateau furnishes fissures in great variety, but they are not true swallow-holes. Regular and well-marked joints were also necessary to the production of fissures, as they permitted the ready escape of the waters of erosion. The texture of mountain limestone, and its power of receiving and retaining sharp impressions, gave the peculiar features to the swallow-holes excavated in it. Some swallow-holes were due to the subsidence of an undermined crust. These frequently lie in a line, sometimes in a ring round a hill-side. A particular description of some near Ripon was given, and the testimony of eye-witnesses as to their sudden appearance was quoted. Swallow-holes are often disguised by surface accumulations. Many conical hollows in drift are probably due to concealed cavities of subsidence.

On the Stratigraphical Distribution of the British Fossil Gasteropoda.—Mr. J. L. Lobley. This was the third of a series of reports by the author on British fossil mollusca. By the help of diagrams were shown the distribution of the species, and the range, increment, decrement, and maximum development of the genera, families, and orders of the *Gasteropoda*. The cainozoic deposits contain the greatest number of genera and sub-genera, though they are numerous also in both the mesozoic and palæozoic rocks. A large number of genera and sub-genera are characteristic of single formations, and these are especially numerous in the carboniferous limestone, the lower lias, the middle Eocene, and the older and newer Pliocene. Details of the range and of the distribution of species of each of the families of *Gasteropoda* were given, and the large groups or orders were similarly passed in review. The remarkable contrast between the distribution of the species of *Holostomata* and *Siphonostomata* was pointed out, the former being very largely developed in each of the three great divisions of the stratified rocks, while the other and more highly organised order is absent from the palæozoic, has only a few species in the Mesozoic, but is largely represented in the cainozoic formations. The distribution of the species without reference to generic family or ordinal divisions showed that the maximum number occurs in middle Eocene strata, from which beds 420 species have been described. The total number recorded in the paper exceeds 3000, but a great number of these are recurrent. The author insisted, in concluding, that as the recognised formations were of different values, as they had been unequally explored, as many formations were wanting in Britain, as the organic remains in the different formations had not been subjected to a uniformly rigid scrutiny, and as the British area, compared with the whole world, was so small, only the most general conclusions could be drawn from this investigation as to the progress of life on the globe.

On the Glacial and Post-Glacial Beds in the Neighbourhood of Llandudno.—Mr. H. F. Hall. The necessity for a more exact definition of boulder clay, and for discarding a name which is made to include a series of beds formed under very different conditions, was insisted upon. The section at Llandudno exhibited a base bed formed by the action of an ice-cap covering the whole land down to the sea level, which ground together the different materials of the bed. The overlying beds lie unconformably on this base bed, and show land and water conditions connected with a much more genial climate. From the section, the author concluded that colour is no criterion for deciding as to the base bed, as it varies in each district with the underlying rock; that the materials of the base bed are obtained from the rocks of the neighbourhood; that this bed was the result of the pressure and passage of land-ice disintegrating the surface of the land which it capped; that to this bed, which is invariably denuded and has the superposed beds lying unconformably upon it, the name "Boulder-clay" should be restricted; and that the red clay, over the sands and gravels which overlie the base bed, is variable in colour and constituents, showing a change which produced extensive denudation in more northern regions, the materials being spread over the sea bottom mixed with pebbles and boulders, which fell from melting or stranded icebergs and ice-flows. The author said there was a hope of being able to co-relate the beds of the eastern districts with those he had described.

Remarks on the Fossils from the Railway Cutting at Huyton.—Mr. W. Carruthers. The great value of this collection, made by the Rev. H. Higgins, depended as much upon the comparatively limited number of species met with as on the fine state of preservation in which they occurred. It was possible to arrive at considerable—in some cases absolute—certainty as to the different parts of the same species. Of the four species of *Calamites*, the materials existed in the specimens from Huyton for reconstructing the entire plant of at least one. The roots, long considered to be a distinct plant under the name *Pinnularia*, were present in great abundance. It had a delicate fistular stem of the type described by Professor Williamson at a previous meeting of the section, but of great size. The scars of the fallen branches were shown in several specimens as well as the foliage, which was preserved in the early bud condition, as well as in its fully developed state. Several fruits showing the structure of the cone, described by the author under the name *Volkmannia binneyi*, but with differences that were at least of specific value. A cone having the structure of that described by Professor Williamson probably belonged to *Calamites longifolius*, with the foliage of which it was associated in these beds. Specimens of *Sphenophyllum* were exhibited and referred to *Calamites*. The light thrown on the structure of *Lepidodendron* by the specimens was then dwelt on, and especially two undescribed cones—one long and slender, with a single sporangium on each scale, the other short and having two sporangia on each scale. The stem and foliage of *Flabellaria*—a palm-like lycopodiaceous genus—occurred among the fossils, as well as several species of beautifully preserved ferns. Two specimens of insect remains had also been found—the one by Messrs. Clementshaw and Smith, young gentlemen whose interest in natural science was due to the revival of those studies in our great schools, and whose personal efforts had greatly contributed to its advancement at Rugby. Professor Williamson contended that the interpretation he had given on a former occasion of the structure of the stems of *Calamites* was more in accordance with the hundreds of specimens he had examined than those just expressed; but, in reply, Mr. Carruthers maintained, on structural grounds, the correctness of the views he had expounded.

SECTION D.—BIOLOGY

Department of Zoology and Botany

The Secretary read a paper by Dr. J. E. Gray, F.R.S., *On the Whalebone Whales of the Southern Hemisphere.* The author remarked that formerly the number of Cetacea was believed to be very limited, and that each species was supposed to have a very extensive geographical distribution. At one time, even, the hunchback of the Cape of Good Hope was supposed to be the same species as the whale of the North Sea. The author gave a list of the true whales, or Balænidæ, the hump-backed whales, and the Physalidæ. Five species of the first group were described, three of the second, and one of the last group. Reference was also made to three apparently different forms of Finne whales, known only from having been seen swimming.

Dr. Cunningham read a paper *On the Terrestrial and Marine Fauna of the Strait of Magellan and Western Patagonia.*

Professor Van Beneden read some notes "*Sur les Parasites*"—One frequently finds described under the title of "Parasites" animals which do not demand more than a place to live on, and do not live at the expense of their neighbour, such, for example, as the Adamsia by the side of the Pagurus. Some of these do not completely enjoy their liberty, as the Coronula on the whale. This type I would designate under the name of Oikasitæ, whereas those which are perfectly free I would designate as Coinositæ. The true Parasites may also be divided into groups: those that have no communication with the exterior are the Xenositæ, these, like the Cysticercus, are possibly only transitory forms: others, having arrived at the end of their journey, live in the open passages of organs, occupying themselves with reproduction, and these I would designate Nostocitæ; and lastly, those which appear to stray by the way, without a hope of arriving at the end of their journey, and indeed only by chance returning to the good road, such as the vesicular and agamic worms which frequent the flesh of carnivores, I would call Planositæ.

Professor Van Beneden exhibited a specimen of a species of Echinorhynchus, apparently new, lent to him for exhibition by Dr. John Barker of Dublin.

On Brackish-water Foraminifera.—Mr. H. B. Brady. The author described a form of Foraminifera from a fresh-water pond, some five or six miles from the sea, and while describing in addition a large number of new species from brackish water, he also alluded to the fact that he had met with some Foraminifera whose tests had withstood the action of acids. Without wishing positively to assert the absolute presence of chlorophyll granules, as occurring in some species, he might yet mention that he had found traces of it in the test of some of the forms he had examined.

On a stock-form of the parasitic Flat-worms.—Mr. E. Ray Lankester. This worm was found parasitic in *Tubifex rivulorum* from the Thames. It had the form of a fluke with very mobile head, no alimentary tube, a very elaborate vascular system, and simple generative organs. A small mobile tail was attached to one end of the worm at the opening of the vascular system. This tail was only paralleled by that of the *Cercariæ* or larvæ of Flukes. A worm known as Caryophyllœus, which lives in carp and tench, was stated to be exactly like the new worm in respect of its mobile head, wrongly held to be the tail by Emile Blanchard. The tailed form *Uroscolex*, Mr. Lankester considered to be the larva of *Caryophyllœus*, and hence we have in this simple worm a representative of the common ancestors of all the Trematods and Cestoids. Mr. Lankester said he was informed by Professor Van Beneden, that last year Caryophyllœus had been shown to have a six-hooked embryo.

On Worms from Thames mud.—Mr. E. Ray Lankester. The author showed that the tons of red worms which are the only non-microscopic tenants of the foul parts of the Thames at London, consist of three distinct species, and a natural hybrid between two also occurs, as he demonstrated from minute study of their characters. The species are *Tubifex rivulorum*, *T. umbellatus* and *Limnodrilus*, sp. *incert.*; the last very abundant. Mr. Lankester then mentioned the gregarinæ of these worms, and the discovery of their pseudo-naviculæ having long stiff processes, so that they run into the worms like pins, and in this way penetrate into previously uninfested worms. The formation of the spermatophors of this group of Annelids (the Oligochæta) discovered by Mr. Lankester—Professor Claparède having mistaken them for Opalinoid parasites—was also detailed.

Department of Anatomy and Physiology

On the Embryonal Development of the Hæmatozoön (*Bilharzia*).—Dr. Cobbold. After commencing with a general description of this remarkable parasite, Dr. Cobbold proceeded to notice the manner in which the larvæ escaped from the eggs; and also their subsequent activity and remarkable alterations of form and structure. He had obtained ample evidence of the existence of a complicated water-vascular system, similar to that described by Dr. Guido Wagener, as occurring in the larva of *Diplodiscus*. The prevalence of the Bilharzia disorder in Egypt and at the Cape was well known; and it had recently been suggested by Dr. Aitkin, that these parasites had some connection with the so-called Delhi boils. He refrained from entering into professional details in this matter: but stated that he had performed a large number of feeding experiments on small fishes, crustaceæ, and molluscs, with the view of putting the question of injection beyond the region of mere conjecture. Dr. Cobbold added that he had obtained for a month past about 10,000 eggs of Bilharzia daily, from a case under his care.

Dr. Cobbold exhibited the heart of a dog filled with Hæmatozoa causing the animal's death. He had received the specimen from Mr. Robert Swinhoe, H.B.M. Consul at Amoy, China, accompanied by a note from the donor, stating that the dog "died on the 18th of April, 1869, at Shanghai, after three days of great suffering." Hitherto, following the authority of M. Bohe-Moorea Diesing and other systematists, he had been accustomed to regard this form of entozoon as the species called *Spiroptera sanguinolenta*; but, in the author's opinion, this view would have to be changed. He hoped, before long, to be able, by further investigation, to set this point at rest. The presence of entozoa in the heart and blood-vessels of animals and man is much more common than is supposed. Thus, MM. Grube and Delafond, who examined 480 dogs, found Filariæ present in nearly 5 per cent. Most of these parasites, however, were of microscopic size; being probably the brood of the species marked *Filaria sanguinis* in Dr. Cobbold's list. They estimated that these verminiferous dogs severally harboured from 11,000 to 224,000 of these larval hæmatozoa.

Note on Methæmoglobin.—Mr. E. Ray Lankester. It was shown that carbonic acid, when passed through a solution of oxyhæmoglobin, gave rise to two new bands in addition to those of the oxyhæmoglobin itself. This was the nitrite-hæmoglobin of Dr. Gamgee, and the brown cruorine of Mr. Sorby, also identical with methæmoglobin as described by Preyer. Addition of a minute quantity of acetic acid to this solution caused the disappearance of the oxyhæmoglobin bands and intensification of the two new bands, which are those of what really was originally called methæmoglobin by Hoppe Seyler. It can be formed by the passage of CO_2 alone if a weak solution of hæmoglobin is used, as was done by Heynsius, who mistook this product for hæmatin. Its band in red is not identical with that of hæmatin as supposed by Hoppe Seyler and Heynsius, and all previous observers, including Hoppe Seyler, Preyer, Gamgee, and Sorby have missed the second band in blue (the fourth of the mixture of oxyhæmoglobin and methæmoglobin) now figured and described. It was shown that no separation of an albumen accompanies the change of hæmoglobin into methæmoglobin, whilst hæmatin results solely from a splitting up of the hæmoglobin into it and an albumen.

The action of certain Vapours and Gases on the red Blood Corpuscles.—Mr. E. Ray Lankester. These experiments were made with Stricker's gas chamber, which enables the observer to study gradual changes, caused by gaseous reagents, as to the change of form caused by atmospheric air in the red corpuscle of the frog, which had been acted on first by CO_2 as observed by Stricker, was shown to be equally produced by hydrogen, or by carbonic oxide, or by diminution of pressure, hence it was simply to be ascribed to the diffusion of the carbonic acid. The action of cyanogen gas, carbonic oxide, alcohol vapour, chloroform vapour, and especially of ammonia vapour, was described. A distinction was insisted on between mere definition of the nucleus—as caused by some agents—and granulation of the nucleus. The normal living frog's red corpuscles was inferred to be *usually* free from any appearance of definition of the nucleus, and to be devoid of an envelope or œcoid, though owing its form to a remarkable condition of tension, which was readily destroyed by physical agents.

On the Relations of Fins of Fishes to one another.—Professor Humphry.

Department of Ethnology and Anthropology

The Pre-Turkish Frontagers of Persia.—Mr. H. Howorth. In continuation of the previous paper the author showed with the assistance of Vivien St. Martin, Thomas, Prinsep, &c., that after the first century, the Indo-Scyths were called Kouschauk by the Armenians, Koneichang by the Chinese, that their great king Kanichka who was a convert to Buddhism, and introduced that religion into China and Thibet, was, with his people, previously a fire-worshipper, and that the form of Mithraism, which was introduced at Rome by Pompey and derived by him, in the first instance, from the Parthians, was the original religion of the Massagetæ and the Indo-Scyths.

On the decay of the power of the Indo-Scyths, the remains of the nation were conquered by the Avares or White Huns, and are called by Procopius, Priscu, and Cosmas, White Huns, and Ephtalitæ, and by the Persians Hainthelah. The etymology of these names shows they were the Yuetchi or Massagetæ, led and governed by a caste of Huns.

In latter days these White Huns are to be identified with the Khazars, the ancestors of the Circassians. Thus the Circassians are proved to be lineal descendants of the Massagetæ. That the Circassians are allied to the Thibetans was long ago showed by Mr. Hodgson in the Journal of the Asiatic Society. This is the first time their genealogy as a race has been clearly traced out, and it opens up a new light on Asiatic Ethnography.

On the Manx of the Isle of Man.—Dr. King.

SECTION G.—MECHANICAL SCIENCE

On Ashton and Storey's Steam-Power Meter.—Mr. Ashton. The apparatus described in this paper, as its name implies, shows at all times the measure of the power developed by the steam engine to which it is applied, and registers the aggregate of that power during any required period of time. The mechanisim is very like that of a well-balanced chronometer. The whole of the indicating mechanism is very light, and mounted so as to move with great freedom; and the power required to work it is exceedingly small. Its indications would be especially valuable in the case of steamships. The apparatus has been in practical use about a year.

In the discussion which followed this paper the invention was very highly praised.
